PREFACE TO THE FIRST EDITION

https://archive.org/details/namdhari

Clinical immunology is a discipline with a distinguished history, rooted in the prevention and treatment of infectious diseases in the late nineteenth and early twentieth centuries. The conquest of historical scourges such as smallpox and (substantially) polio and relegation of several other diseases to the category of medical curiosities is often regarded as the most important achievement of medical science of the past fifty years. Nevertheless, the challenges facing immunologists in the efforts to control infectious diseases remain formidable; HIV infection, malaria and tuberculosis are but three examples of diseases of global import that elude control despite major commitments of monetary and intellectual resources.

Although firmly grounded in the study and application of defenses to microbial infection, since the 1960s clinical immunology has emerged as a far broader discipline. Dysfunction of the immune system has been increasingly recognized as a pathogenic mechanism that can lead to an array of specific diseases and failure of virtually every organ system. Pardoxically, although the importance of the immune system in disease pathogenesis is generally appreciated, the place of clinical immunology as a practice discipline has been less clear. As most of the noninfectious diseases if the human immune system lead eventually to failure of other organs, it has been organ-specific subspecialists who have usually dealt with their consequences. Recently, however, the outlook has begun to change as new diagnostic tools increasingly allow the theoretical possibility of intervention much earlier in disease processes, often before irreversible target organ destruction occurs. More importantly, this theoretical possibility is increasingly realized as clinical immunologists find themselves in the vanguard of translating molecular medicine from laboratory bench to patient bedside.

In many settings, clinical immunologists today function as primary care physicians in the management of patients with inmune-deficiency, allergic, and autoimmune diseases. Indeed many influential voices in the clinical disciplines of allergy and rheumatology support increasing coalescence of these traditional subspecialities around their intellectual core of immunology. In addition to his or her role as a primary care physician, the clinical immunologist is increasingly being looked to as a consultant, as scientific and clinical advances enhance his or her expertise. The immunologist with a ‘generalist’ perspective can be particularly helpful in the application of unifying principles of diagnosis and treatment across the broad spectrum of immunologic diseases.

Clinical Immunology: Principles and Practice has emerged from this concept of the clinical immunologist as both primary care physician and expert consultant in the management of patients with immunologic diseases. It opens in full appreciation of the critical role of fundamental immunology in this rapidly evolving clinical discipline. Authors of basic science chapters were asked, however, to cast their subjects in a context of clinical relevance. We believe the result is a well-balanced exposition of basic immunology for the clinician.

The initial two sections on basic principles of immunology are followed by two sections that focus in detail on the role of the immune system in defenses against infectious organisms. The approach is two-pronged. It begins first with a systematic survey of immune responses to pathogenic agents followed by a detailed treatment of immunologic deficiency syndromes. Pathogenic mechanisms of both congenital and acquired immune deficiency diseases are discussed, as are the infectious complications that characterize these diseases. Befitting its importance, the subject of HIV infection and AIDS receives particular attention, with separate chapters on the problem of infection in the immunocompromised host, HIV infection in children, anti-retroviral therapy and current progress in the development of HIV vaccines.

The classic allergic diseases are the most common immunologic diseases in the population, ranging from atopic disease to drug allergy to organ-specific allergic disease (e.g., of the lungs, eye and skin). They constitute a foundation for the practice of clinical immunology, particularly for those physicians with a practice orientation defined by formal subspecialty training in allergy and immunology. A major section is consequently devoted to these diseases, with an emphasis on pathophysiology as the basis for rational management.

The next two sections deal separately with systemic and organ-specific immunologic diseases. The diseases considered in the first of these sections are generally regarded as the core practice of the clinical immunologist with subdisciplinary emphasis in rheumatology. The second section considers diseases of specific organ failure as consequences of immunologically mediated processes that may involve virtually any organ system. These diseases include as typical examples the demyelinating diseases, insulin-dependent diabetes mellitus, the glomerulonephritides and inflammatory bowel diseases. It is in management of such diseases that the discipline of clinical immunology will have an increasing role as efforts focus on intervention early in the pathogenic process and involve diagnostic and therapeutic tools of ever-increasing sophistication.

One of the major clinical areas in which the expertise of a clinical immunologist is most frequently sought is that of allogeneic organ transplantation. A full section is devoted to the issue of transplantation of solid organs, with an introductory chapter on general principles of transplantation and management of transplantation rejection followed by separate chapters dealing with the special problems of transplantation of specific organs or organ systems.

Appreciation of both the molecular and clinical features of lymphoid malignancies is important to the clinical immunologist regardless of subspecialty background, notwithstanding the fact that primary responsibility for management of such patients will generally fall to the haematologist/oncologist. A separate section is consequently devoted to the lymphocytic leukemias and lymphomas that constitute the majority of malignancies seen in the context of a clinical immunology practice. The separate issues of immune responses to tumors and immunological strategies to treatment of malignant diseases are subjects of additional chapters.

Another important feature is the attention to therapy of immunologic diseases. This theme is constant throughout the chapters on the allergic and immunologic diseases, and because of the importance the editors attach to clinical immunology as a therapeutic discipline, an extensive section is also devoted specifically to this subject. Subsections are devoted to issues of immunologic reconstitution, with three chapters on treatment of immunodeficiences, malignancies and metabolic diseases by bonemarrow transplantation. Also included is a series of chapters on pharmaceutical agents currently available to clinical immunologists, both as anti-allergic and anti-inflammatory drugs, as well as newer agents with greater specificity for T cell-mediated immune responses. The section concludes with a series of chapters that address established and potential applications of therapeutic agents and approaches that are largely based on the new techniques of molecular medicine. In addition to pharmaceutical agents the section deals in detail with such subjects as apheresis, cytokines, monoclonal antibodies and immunotoxins, gene therapy and new experimental approaches to the treatment of autoimmunity. The book concludes with a section devoted to approaches and specific techniques involved in the diagnosis of immunologic diseases. Use of the diagnostic laboratory in evaluation of complex problems of immunopathogenesis has been a hallmark of the clinical immunologist since inception of the discipline and many clinical immunologists serve as directors of diagnostic immunology laboratories. Critical assessment of the utilization of techniques ranging from lymphocyte cloning to flow cytomeric phenotyping to molecular diagnostics are certain to continue as an important function of the clinical immunologist, particularly in his or her role as expert consultant.

In summary, we have intended to provide the reader with a comprehensive and authoritative treatise on the broad subject of clinical immunology, with particular emphasis on the diagnosis and treatment of immunological diseases. It is anticipated that the book will be used most frequently by the physician specialist practicing clinical immunology, both in his or her role as a primary physician and as a subsequent consultant. It is hoped, however, that the book will also be of considerable utility to the non-immunologist. Many of the diseases discussed authoritatively in the book are diseases commonly encountered by the generalist physician. Indeed, as noted, because clinical immunology involves diseases of virtually all organ systems, competence in the diagnosis and management of immunological diseases is important to virtually all clinicians. The editors would be particularly pleased to see the book among the references readily available to the practicing internist, pediatrician and family physician.

PREFACE TO THE FIFTH EDITION

Each edition of *Clinical Immunology: Principles and Practice* has documented important changes in the discipline from the preceding one. This fifth edition is emphatically not an exception to that pattern. Indeed, advances in both the *Principles* and *Practice* of clinical immunology have been remarkable. The constant theme of every edition has been to emphasize that our discipline touches virtually all organ systems. The diseases that are covered range from too little to too much immunity; and from dysregulated, malignant or replaced immunological systems and functions. Fundamental concepts that are essential to a precise understanding of normal and disordered immune function and disease pathogenesis are again balanced by clinical descriptions, diagnostic approaches and therapeutic options.

Several examples of particularly notable advances are worth highlighting: Our increasing appreciation of the importance of the microbiota to normal immune system development and to the pathogenesis of immunologic and inflammatory diseases; dissection of relationships between the innate and adaptive immune systems that has served to further clarify the expression of inflammatory processes and their interaction in defenses against infectious agents; progress in rapid and cost-effective genomics that has led to the definition of numerous new primary immune deficiencies and provided new insights into the genetic aspects of many other immunologic diseases; understanding of immune deficiencies that reflect development of anti-cytokine auto-antibodies; detailed definition of cell signaling pathways and the structure of cell-surface molecules that have contributed enormously to the treatment of cancer and autoimmunity with a virtual explosion in novel therapeutics including check-point inhibitors and other recently developed immunomodulators; availability of many new humanized and human monoclonal antibodies and development of novel therapeutic approaches such as chimeric-antigen-receptor T cells; wide use of T cell excision circle receptor (TREC) assay to diagnose serious immune deficiencies of the newborn; and exploration of *in vivo* therapeutic editing of pathological mutations. With these new tools the practice of clinical immunology has become more interesting yet more complex, while offering important improvements in patient care.

Our goal with this edition is to enhance the interest of practitioners in the many specialties and subspecialties that the discipline impacts and to assist them in understanding this increasing complexity. With the increasing availability of powerful new therapeutic agents, the expert clinical immunologist today may function as a primary care physician or consultant in the management of patients with immune deficiencies, allergic, and autoimmune diseases involving multiple organ systems – a role reminiscent of that served by infectious disease physicians, particularly during the era of antibiotic proliferation in the last quarter of the previous century. It is consequently our hope that the book will find a place near the desk of most persons whose practice relies on the science or practice of clinical immunology as we have broadly defined it. We further trust that it will be especially useful to trainees and practitioners preparing for certification or recertification in an immunology-related subspecialty. In an effort to assist the latter group and as an aid to continuing education of all readers, we have added to the online version of the text, which all purchasers of the book can readily access, multiple choice questions relevant to every chapter. Additionally, we continue to believe that a comprehensive text on clinical immunology can be a valuable asset for generalists in any specialty, particularly internists, pediatricians and family physicians, who regularly care for patients across the broad spectrum of immunological disorders, offering an opportunity for physicians in all disciplines to upgrade their skills and education, and to benefit from the onward rush of science and practice improvement in modern clinical immunology.

The book continues features that have been well received in previous editions. Chapters are generously illustrated and all chapters contain summary Boxes (commonly in bulleted form) that provide Key Concepts and a Box labeled as *On the Horizon*, in which authors look to research opportunities for important advances over the next 5-10 years. Furthermore, due to the extraordinarily cross-disciplinary nature of clinical immunology, it is our hope that investigators working in one area might find new ideas and opportunities in the *On the Horizon* Boxes outside their primary area of focus. Other Boxes similarly summarize content with *Clinical Relevance*, *Clinical Pearls*, and *Therapeutic Principles*.

As always, we are immensely grateful to the hundreds of physicians and scientists whose contributions are the essence of the book. Finally, we recognize the diligence and commitment of our colleagues at Elsevier who have supported all aspects of the book's development and production, particularly Ms. Joanne Scott who has worked with both authors and editors from concept to birth to completion of every chapter.

The Human Immune Response

Robert R. Rich, David D. Chaplin

Clinical immunology is a medical subspecialty largely focused on a specific physiological process, inflammation, which is essential to good health, particularly in defense against pathogenic organisms, recovery from injury, and containment of neoplasms. But inflammation, mediated by the cells and soluble products of the immune system, is also a powerful contributor to the pathogenesis of diseases that affect virtually every organ system. A consequent challenge for clinical immunologists, both clinicians and basic scientists, is to reduce a dizzying array of disease descriptions to systematic understanding of pathogenic mechanisms, facilitating translation of fundamental concepts and new discoveries into more effective disease prevention or treatment.

This introductory chapter is directed to nonimmunologist clinicians and researchers. It is structured as an introduction to the interacting elements of the human immune system and their disordered functions in diseases. The subtleties, including immunological or molecular genetic jargon unavoidably used, are described in detail in the chapters that follow.

THE HOST–MICROBE INTERACTION

The vertebrate immune system is a product of eons of evolutionary relationships between rapidly evolving microbial organisms and their much less rapidly reproducing, and hence less adaptable, hosts.[1] In general, the relationship is mutually beneficial, each providing nutrients and other materials essential to the well-being of their partner—the host and its microbiome (Chapter 14). Occasionally, however, a normally beneficial relationship becomes pathological, as pathogenic microbes overwhelm the microbiome, invading host tissues and resulting in host morbidity or even death. Because the vertebrate host cannot win a battle with microbial invaders by rapid mutation and selection, the immune system employs a strategy of complexity and redundancy, which involves both the individual organism and its collective population. Reflecting plasticity of the response, specific defenses differ, depending on the nature of the infectious agent and its point of entry and distribution within the body. Regardless of the defense mechanism, an intended outcome is destruction or neutralization of the invading organism. A secondary consequence, however, can be collateral damage to host cells. These cells can be targeted for damage because they are sites of microbial residence and replication, or they can be damaged as "innocent bystanders." Depending on the site and severity of the host's defensive response, it may be accompanied by local and/or systemic symptoms and signs of inflammation, which may lead to long-lasting tissue dysfunction as a result of tissue remodeling and partial repair.

Adaptive and Innate Immunity

Immune responses are traditionally classified as *adaptive* (also termed *acquired* or *specific*) and *innate* (or *nonspecific*) (Table 1.1). The adaptive immune system, present uniquely in species of the phylum *Chordata*, is specialized for development of an inflammatory response based on recognition of specific "foreign" macromolecules that are predominantly, but not exclusively, proteins, peptides, and carbohydrates. The vast majority of chordate species are vertebrates, and this book addresses adaptive immunity of that subphylum. Its primary effectors are antibodies, B lymphocytes, T lymphocytes, and antigen-presenting cells (APCs). T and B lymphocytes express surface antigen receptors that are clonally specific as a consequence of receptor–gene rearrangements. Expansion of clones of lymphocytes specific for any particular antigen is induced by antigen encounter and consequent activation and proliferation, thereby constituting the basis of immunological memory.

Innate immune responses are phylogenetically far more ancient, being widely represented in multicellular phyla.[2] Rather than being based on exquisitely specific recognition of a diverse array of macromolecules (*i.e.*, antigens), they are focused on recognition of common molecular signatures of microbial organisms that are not present in vertebrates.[3] Among these structures, which are termed *pathogen-associated molecular patterns* (PAMPs) or *danger-associated molecular patterns* (DAMPs), are bacterial cell wall constituents, such as mannose-rich oligosaccharides, lipopolysaccharides, peptidoglycans, and several nucleic acid variants, including double-stranded RNA and unmethylated CpG DNA. For both innate and adaptive immunity responses, defense effector mechanisms can require either direct cell-to-cell contact or the activity of cytokines and chemokines, which are hormone-like soluble molecules that act in the cellular microenvironment (cell-mediated immunity). Most immune responses include participation of both modes of response.[2-4]

The elements of innate immunity are diverse (Chapter 3). They include physical barriers to pathogen invasion (*e.g.*, skin, mucous membranes, cilia, and mucus), as well as an array of cellular and soluble factors that can be activated by secreted or cell surface products of the pathogen, including PAMPs. Recognition of PAMPs by cells in innate immunity, which also commonly function as APCs to the lymphocytes of adaptive immunity, is via cell membrane or cytoplasmic receptors known as pattern recognition receptors (PRRs). PRRs can be either membrane bound or cytoplasmic. Membrane-bound PRRs include Toll-like receptors (TLRs) and C-type lectin receptors (CLRs). Humans express 10 distinct TLRs, which recognize (among others) specific bacterial glycolipids, lipopolysaccharide; viral single-stranded

TABLE 1.1 Features of Innate and Adaptive Immune Systems

Distinguishing Features

Innate Immunity	Adaptive Immunity
Germ line-encoded receptors targeting pathogen molecular patterns	Clonally variable receptors generated somatically by rearrangement of gene elements
Does not require immunization	Consequence of B- and/or T-cell activation
Limited memory	Immunological memory well developed
Includes physical barriers to pathogen	Antibody and cytotoxic T cells

Common Features

Cytokines and chemokines
Complement cascade
Phagocytic cells
Natural killer (NK) cells
"Natural" antibodies

RNA; and bacterial and viral unmethylated CpG DNA. CLR are particularly important in antifungal innate immunity but also have important roles in defenses against bacteria, viruses, and parasites. They comprise a large family that commonly recognizes microbe-specific carbohydrate ligands or structurally similar lectin-like domains. Cytoplasmic PRRs include RIG-1–like receptors (RLRs) and nucleotide oligomerization domain (NOD)-like receptors (NLRs). RLRs are involved in recognition of viruses through interaction with intracytoplasmic viral double-stranded RNA (dsRNA), and NLRs recognize bacterial peptidoglycan motifs.[4]

Cells of the innate immune system are commonly triggered through activation of the NF-κB transcription factor via the MyD88 signaling pathway, thereby inducing an inflammatory response using mechanisms that are broadly shared with those of the adaptive immune system. These include activation of various types of innate lymphoid cells (*e.g.,* natural killer [NK] cells), which are characterized by absence of clonally expressed receptors for specific antigen (see below), activation of granulocytes and other phagocytes, the secretion of inflammatory cytokines and chemokines, and interactions of the many participants in the complement cascade. Additionally, activation of cells of innate immunity that also act as APCs for the adaptive immune system results in upregulation of membrane molecules (*e.g.*, CD80, CD86) that provide the second signal, along with the T-cell receptor (TCR) for antigen, necessary for induction of antigen-specific T cells.[5]

Finally, because recognition of pathogens by the innate immune system relies on germline encoded, nonrearranged receptors held in common by the specific cell type, innate immunity is more rapidly responsive. It can initiate in minutes to hours and generally precedes development of a primary adaptive immune response by at least several days.

CELLS OF THE IMMUNE SYSTEM

The major cellular constituents of both innate and adaptive immunity originate in bone marrow, where they differentiate from multipotent hematopoietic stem cells (HSCs) along several pathways to become granulocytes, lymphocytes, and APCs (Chapter 2).

Granulocytes

Polymorphonuclear leukocytes (granulocytes) are classified by light microscopy into four types. By far the most abundant in the peripheral circulation are neutrophils, which are principal effector cells linking the innate and adaptive responses by virtue of their expression of surface receptors for antibody and complement (Chapter 21). They are phagocytic cells that ingest, kill, and degrade microbes and other targets of an immune attack within specialized cytoplasmic vacuoles that contain potent antimicrobial enzymes and oxidative pathways. The phagocytic activity of neutrophils is promoted by their surface display of receptors for antibody molecules (specifically the Fc portion of immunoglobulin G [IgG] molecules) (Chapter 15) and activated complement proteins (particularly the C3b component) (Chapter 21). Neutrophils are the predominant cell type in acute inflammatory infiltrates and are the primary effector cells in immune responses to pyogenic bacteria (Chapter 27).

Eosinophils (Chapter 24) and basophils (Chapter 23) are the other circulating forms of granulocytes. A close relative of the basophil, but derived from distinct bone marrow precursors, is the tissue mast cell, which does not circulate in blood. Eosinophils, basophils, and mast cells are important in defenses against multicellular pathogens, particularly helminths (Chapter 31). Their defensive functions are not based on phagocytic capabilities but, rather, on their ability to discharge potent biological mediators from their storage granules into the cellular microenvironment. This process, termed *degranulation*, can be triggered by antigen-specific IgE molecules that bind to basophils and mast cells via high-affinity receptors for the Fc portion of IgE (FcεR) on their surfaces. In addition to providing a mechanism for anthelmintic host defenses and certain antibacterial responses, this is also the principal mechanism involved in acute (IgE-mediated) allergic reactions (Chapters 41–49).

Lymphocytes

Three broad categories of lymphocytes are identified on the basis of display of particular surface molecules: B cells, T cells, and innate lymphoid cells; each of these categories can be further subdivided according to specific function and display of distinguishing cell surface molecules (Chapter 2). All lymphocytes differentiate from common lymphoid stem cells in bone marrow. B cells create their immunoglobulin receptors in bone marrow and differentiate into antibody-producing cells in the periphery (Chapter 7). T-cell precursors move from bone marrow to the thymus (or, in some cases, to extrathymic tissue compartments), where they complete their differentiation and selection (Chapter 8).

T cells and B cells are the heart of immune recognition, a property reflecting their clonally specific cell surface receptors for antigen (Chapter 4). The TCR is a heterodimeric integral membrane molecule expressed exclusively by T lymphocytes. B-cell receptors for antigen (BCRs) are membrane immunoglobulin (mIg) molecules of the same antigenic specificity that the cell and its terminally differentiated progeny, plasma cells, will secrete as soluble antibodies. Memory B cells and nondividing, long-lived plasma cells may account substantially for persistence of antibody responses (including production of autoantibodies) over many years.[6]

Receptors for "antigen" on the third class of lymphocytes, innate lymphoid cells (ILCs), are not clonally expressed. ILCs are subdivided into three major groups according to the cytokines that they produce (*e.g.,* group 1 ILCs, including NK cells, produce interferon-γ [IFN-γ] and tumor necrosis factor [TNF]).[7] ILCs express receptors for PAMPs and, as such, serve as major effectors of innate immunity. They also recognize target cells that might otherwise elude the immune system (Chapters 2, 17). Thus recognition of NK cell targets is based substantially on what their targets lack rather than on what they express. NK cells express receptors of several types for major histocompatibility complex (MHC) class I molecules via killer immunoglobulin-like receptors (KIRs).[8] KIRs are expressed on the plasma membrane of NK cells (and some T cells), which interact with class I molecules to alter NK-cell cytotoxic function. Most KIRs express in their intracellular domain a tyrosine-based inhibitory-motif (ITIM) that suppresses NK activity, thereby preventing NK cell activity directed against normal self-cells. In contrast, some KIRs express a tyrosine-based activation motif (ITAM), which amplifies their activity. NK cells will kill target cells unless they receive an inhibitory signal transmitted by an ITIM receptor. Virus-infected cells and tumor cells that attempt to escape T-cell recognition by downregulating their expression of class I molecules become susceptible to NK cell–mediated killing because the NK cells receive an activation signal and/or fail to receive an inhibitory signal through the ITAM- and ITIM-containing MHC class I receptors. The balance between ITIM and ITAM is regulated by the microenvironmental milieu, increasing expression of ITAM in the presence of viral-infected or cancer cells and of ITIM as necessary to maintain self-tolerance and prevent autoimmunity. A high frequency of ITAM-expressing cells has been reported in some patients with autoimmune diseases.[9]

Although NK cell–mediated innate immunity has been long considered to lack immunological memory, recent studies suggest that NK cells can exhibit memory of previous encounters with microbes or other antigens, the molecular basis of which remains to be fully elucidated.[10] NK cells can also participate in antigen-specific immune responses by virtue of their surface display of the activating ITAM receptor CD16, which binds the constant (Fc) region of IgG molecules. This enables them to function as effectors of a cytolytic process termed *antibody-dependent cellular cytotoxicity* (ADCC), a mechanism exploited clinically with monoclonal antibody (mAb) therapeutic agents.[11]

In general, pathways leading to differentiation of T cells, B cells, and ILCs are mutually exclusive, representing a permanent lineage commitment. No lymphocytes express both mIg and TCRs. However, a subset of T cells, termed *NKT cells*, exhibit both NK-like cytotoxicity and αβTCR with limited receptor diversity.

Antigen-Presenting Cells

KEY CONCEPTS

Features of Antigen-Presenting Cells

- Capacity for uptake and partial degradation of protein antigens
- Expression of major histocompatibility complex (MHC) molecules for binding antigenic peptides
- Chemokine receptors to allow colocalization with T cells
- Expression of accessory molecules for interaction with T cells
- Receptors for pathogen- or danger-associated molecular patterns
- Secretion of cytokines that program T helper (Th) cell responses

A morphologically and functionally diverse group of cells, all of which are derived from bone marrow precursors, is specialized for presentation of antigen to lymphocytes, particularly T cells (Chapter 6). Included among such cells are dendritic cells, monocytes (present in the peripheral circulation), macrophages (solid tissue derivatives of monocytes), cutaneous Langerhans cells (Chapter 19), and constituents of the reticular endothelial system within solid organs. B lymphocytes that specifically capture antigen via their clonally expressed mIg can also function efficiently in antigen presentation to T cells.

Cardinal features of APCs include their expression of both class I and class II Major Histocompatibility Complex (MHC; Chapter 5) molecules as well as requisite accessory molecules for T-cell activation (*e.g.*, B7-1, B7-2/CD80, CD86).[12] Upon activation, APC elaborate cytokines that induce specific responses in cells to which they are presenting antigen. In addition to processing and presenting antigen, APCs can regulate activation of the immune system via innate cell surface receptors, which contribute to determination of whether the antigen is pathogen associated.

APCs differ substantially among themselves with respect to mechanisms of antigen uptake and effector functions. Immature dendritic cells show high phagocytic and pathogen-killing activity but low ability to present antigen and activate T cells.[12] Dendritic cells (DCs) that have ingested a pathogen or foreign antigen can be induced to mature by inflammatory stimuli, especially via cells of the innate immune system and by direct activation through receptors for PAMPs or DAMPs.[12,13] Monocytes and macrophages are actively phagocytic, particularly for antibody and/or complement-coated (opsonized) antigens that bind to their surface receptors for IgG and C3b. These cells are also important effectors of immune responses, especially in sites of chronic inflammation. Upon further activation by T-cell cytokines, they can kill ingested microorganisms by oxidative pathways similar to those employed by polymorphonuclear leukocytes.

The interaction between B cells acting as APCs and T lymphocytes is notable as the cells are involved in a mutually amplifying circuitry of antigen presentation and response.[12] The process is initiated by antigen capture through B cell mIg and ingestion by receptor-mediated endocytosis. This is followed by proteolytic antigen degradation and then display to T cells as oligopeptides bound to MHC molecules. Like other APCs, B cells display CD80, which provides a requisite second signal to the antigen-responsive T cell via CD28, its accessory molecule for activation (Fig. 1.1). As a result of T-cell activation, T-cell cytokines that regulate B-cell differentiation and antibody production are produced, and T cells are stimulated to display the surface ligand CD40L (CD154), which can serve as the second signal for B-cell activation through its inducible surface receptor

BASIS OF ADAPTIVE IMMUNITY

The essence of adaptive immunity is molecular distinction between self constituents and potential pathogens (for simplicity, self/nonself discrimination, but perhaps more precisely discrimination between molecular species perceived as signaling potential "danger" and those that do not). This discrimination is a major responsibility of both T lymphocytes and cells of the innate immune system. It reflects the selection of thymocytes that have generated specific antigen receptors, which, upon later encounter, can bind nonself antigenic peptides bound to self-MHC molecules. The consequence of this selection process is that foreign proteins are recognized as antigens, whereas self-proteins are tolerated (*i.e.*, are not perceived as antigens). Additionally, the cells of innate immunity contribute importantly, through PAMPs/DAMPs and several mechanisms still being defined, to the essential

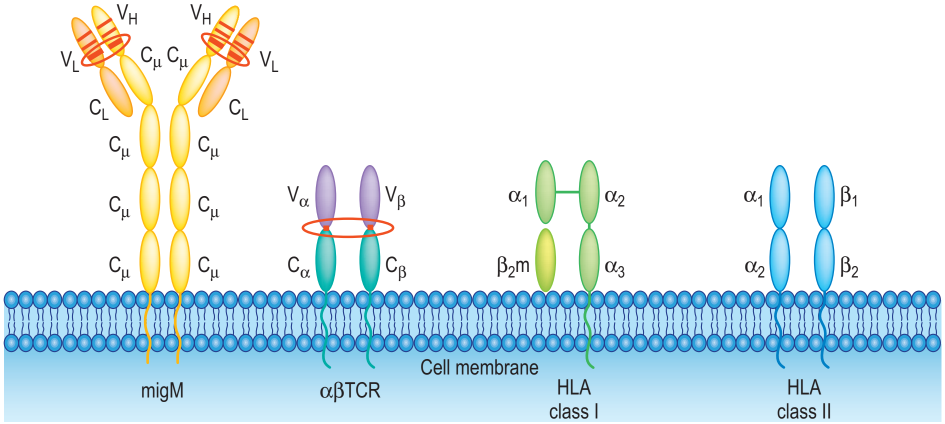

FIG 1.1 Antigen-Binding Molecules. Antigen-binding pockets of immunoglobulin (Ig) and T-cell receptor (TCR) comprise variable (V) segments of two chains translated from transcripts that represent rearranged V(D)J or VJ gene elements. Thin red bars designate two of the complementarity determining regions (CDRs) that form portions of the Ig antigen-binding site. The red ovals with thick red bars designate the regions of very high sequence variability in both Igs and TCRs that are generated by recombination of the 3′-end of the V gene element with the D and J gene elements or with the J gene element. In the Ig molecule this is designated CDR3. Antigen-binding pockets of Ig molecules are formed by the three-dimensional folding of the heavy and light chains that juxtapose the CDRs of one heavy chain and one light chain. Antigen-binding grooves of MHC molecules are formed with contributions from α_1 and β_1 domains of class II molecules and from α_1 and α_2 domains of class I molecules. All of these molecules are members of the immunoglobulin superfamily. C, constant-region domain; β_2, beta-2 microglobulin; mIgM, membrane immunoglobulin M; HLA, human leukocyte antigen; MHC, major histocompatibility complex.

distinction between commensal (not dangerous) and potentially pathogenic (dangerous) microbes.

T lymphocytes generally recognize antigens as a complex of short linear peptides bound to self-MHC molecules on the surfaces of APCs (Chapter 6). The source of these peptides can be either extracellular or intracellular proteins and derived from either self or foreign (*e.g.,* microbial) molecules. With the exception of superantigens (see below), T cells neither bind antigen in native conformation nor recognize free antigen in solution. The vast majority of antigens for T cells are oligopeptides. However, the antigen receptors of NKT cells can recognize lipid and glycolipid antigens that are presented to them by MHC-like CD1 molecules.[14]

Antigen recognition by T cells differs fundamentally from that by antibodies, which are produced by B lymphocytes and their derivatives. Antibodies are oriented toward recognition of extracellular threats and, unlike T cells, can bind complex macromolecules and can bind them in their native conformation either at cell surfaces or in solution. Moreover, antibodies show less preference for recognition of proteins; antibodies against carbohydrates, nucleic acids, lipids, and simple chemical moieties can be readily produced. Although B cells can also be rendered unresponsive by exposure to self-antigens, particularly during differentiation in bone marrow, this process does not define foreignness within the context of self-MHC recognition.

Clonal Basis of Immunological Memory

An essential element of self/nonself discrimination is the clonal nature of antigen recognition. Although the immune system can recognize a vast array of distinct antigens, all of the receptors of a single T cell or B cell (and their clonal progeny) have identical antigen-binding sites and hence a particular specificity (Chapter 4). A direct consequence is the capacity for antigen-driven immunological memory. This phenomenon derives from the fact that after an initial encounter with antigen clones of lymphocytes that can recognize the antigen proliferate and differentiate into effector cells, most of which ultimately are consumed or undergo apoptosis, and a smaller population of long-lived memory cells. These memory cells constitute a pool of cells larger than the initial naïve responders. They can elicit a greater and more rapid response upon subsequent antigen encounter. These two hallmarks of adaptive immunity, clonal specificity, and immunological memory provide a conceptual foundation for the use of vaccines in prevention of infectious diseases (Chapter 90). Immunological memory involves not only the T cells charged with antigen recognition but also the T cells and B cells that mediate the efferent limb of an inflammatory response. In its attack on foreign targets, the immune system can exhibit exquisite specificity for the inducing antigen, as is seen in the epitope-specific lysis of virus-infected target cells by cytolytic T cells.

ANTIGEN-BINDING MOLECULES

KEY CONCEPTS

Features of the Immunoglobulin (Ig) Superfamily

- Large family of ancestrally related genes (more than 100 members)
- Most products involved in immune system function or other cell–cell interactions
- Ig superfamily members have one or more domains of ~100 amino acids, each usually translated from a single exon
- Each Ig domain consists of a pair of β-pleated sheets usually held together by an intrachain disulfide bond

Three sets of molecules are responsible for the specificity of adaptive immune responses by virtue of their capacity to bind foreign antigen. These molecules are Igs, TCRs, and MHC molecules (see Fig. 1.1) (Chapters 4, 5). All are products of a very large family of ancestrally related genes, the immunoglobulin superfamily, which includes many other molecules essential to induction and regulation of immune responses.[15,16] Members of the Ig superfamily exhibit characteristic structural features. The most notable of these is organization into homologous domains of approximately 110 amino acids that are usually encoded by a single exon with an intradomain disulfide bond, characteristically configured as antiparallel strands, forming two opposing β-pleated sheets.

Immunoglobulins and T-Cell Receptors

The remarkable specificity of Ig and TCR molecules for antigen is achieved by a mechanism of genetic recombination that is unique to Ig and TCR genes (Chapter 4). The antigen-binding site of both types of molecules comprises a groove formed by contributions from each of two constituent polypeptides. In the case of immunoglobulins, these are a heavy (H) chain and one of two alternative types of light (L) chains, κ or λ. In the case of TCRs, either of two alternative heterodimers can constitute the antigen-binding molecule, one comprised of α and β chains, and the other of γ and δ chains. The polypeptides contributing to both Igs and TCRs can be divided into an antigen-binding amino-terminal variable (V) domain and one or more carboxy-terminal constant (*i.e.,* nonvariable) domains. Ig constant region domains generally include specific sites responsible for the biological effector functions of the antibody molecule (Chapter 15).

KEY CONCEPTS

Comparison of T-Cell and B-Cell Receptors for Antigen

Similarities

- Members of the immunoglobulin (Ig) superfamily
- Two polypeptide chains contribute to antigen-binding site
- Each chain divided into variable and constant regions
- Variable regions constructed by V(D)J rearrangements
- Nongenomic N-nucleotide additions at V(D)J junctions
- Exhibit allelic exclusion
- Negative selection against receptors with self-antigen specificity
- Transmembrane signaling involving coreceptor molecules

Differences

- Ig can be secreted; T-cell receptor (TCR) is not
- Ig recognizes conformational antigen (Ag) determinants; TCR recognizes linear determinants
- Ig can bind antigen in solution; TCR binds antigen when presented by major histocompatibility complex (MHC) molecule on antigen-presenting cell (APC)
- Somatic hypermutation of Ig genes can enhance antigen-binding affinity
- Ig genes can undergo isotype switching
- Inflammatory effector functions by the Ig constant domains
- Positive selection of TCR for self-MHC recognition

The most noteworthy feature of the vertebrate immune system is the process of genetic recombination that generates a virtually limitless array of specific antigen receptors from a rather limited genomic investment. This phenomenon is accomplished by the recombination of genomic segments that encode the variable domains of Ig and TCR polypeptides[17] (Chapter 4). The products of these rearranged gene elements provide a specific B or T cell with its unique antigen receptor. The variable domain of the mature receptor is created by the rearrangement of two or three separate gene segments. These are designated V (variable) and J (joining), for IgL chains and TCR α and γ chains, and V, D (diversity) and J, for IgH and TCR β and δ chains. In addition to rearrangement, N-nucleotide addition also contributes substantially to receptor diversity. N-nucleotide addition results in the insertion, at the time of rearrangement, of one or more nongenomic nucleotides at the junctions between V, D, and J segments through the action of terminal deoxynucleotidyl transferase (TdT).[17] This permits receptor diversity to extend beyond germline constraints. Analysis of the linear sequences of many Ig V regions domains has shown that they contain three sites of high sequence variability that have been designated *complementarity determining regions 1–3 (CDR1–3)* to indicate that they are the sites that contact antigen (see Fig. 1.1).

DNA rearrangement involved in generating T- and B-cell receptors is controlled by recombinases that are active in early thymocytes and in B precursor cells in bone marrow. The process is sequential and carefully regulated, generally leading to translation of one receptor of unique specificity for any given T or B lymphocyte. This result is achieved through a process termed *allelic exclusion*, wherein only one member of a pair of allelic genes potentially contributing to an Ig or TCR molecule is rearranged at a time.[18]

The process of allelic exclusion is not absolute, and a small number of lymphocytes will express dual functional Ig or TCR transcripts and, in some cases, two distinct surface receptors.[19] But B cells exclusively rearrange Ig genes, not TCR genes, and vice-versa for T cells. Moreover, after producing a functional heavy chain, B cells sequentially rearrange L chain genes, typically κ before λ. Thus B cells express either κ or λ chains, but not both. Similarly, thymocytes express α and β genes or γ and δ genes, and only rarely T cells with αδ or γβ receptors.

There is one feature of V region construction that is essentially reserved to B cells. This is somatic hypermutation (SHM), a process that can continue at discrete times throughout the life of a mature B cell at both the $V_HD_HJ_H$ and V_LJ_L gene exons.[20] Because these rearranged gene exons encode the binding groove that contains the specific points of contact with antigen, on occasion the random process of SHM will result in cells expressing mIg with increased affinity for the antigen they recognize. Typically, cells with increased affinity for antigen are activated preferentially, particularly at limiting doses of antigen. Thus the average affinity of antibodies produced during the course of an immune response tends to increase, a process termed *affinity maturation*.

TCRs do not show evidence of SHM. This absence may be related to the focus on selection in the thymus involving corecognition of a self-MHC molecule and self-peptides,[21] (Chapter 8) rather than the continuous process of antigen-driven selection in the periphery by B cells after SHM. Thymic selection results in deletion by apoptosis of the vast majority of differentiating thymocytes by mechanisms that place stringent boundaries around the viability of a thymocyte with a newly expressed TCR specificity. Once a T cell is fully mature and ready for emigration from the thymus, its TCR is essentially fixed, reducing the likelihood of emergent autoimmune T-cell clones in the periphery.

Receptor Selection

The receptor expressed by a developing thymocyte must be capable of binding with low-level affinity to some particular MHC self-molecule, either class I or class II, expressed by a resident thymic epithelial cell or APC. Because their receptors are generated by a process of semirandom joining of rearranging exon segments coupled with N-nucleotide additions, most thymocytes fail this test. They are consequently deleted as not being useful to an immune system that requires T cells to recognize antigen that is bound to self-MHC molecules. Thymocytes surviving this hurdle are said to have been "positively selected"[21] (Fig. 1.2A). Conversely, a small number of thymocytes bind with an unallowably high affinity for a combination of MHC molecule plus antigenic peptide expressed by a thymic APC. Because the peptides available for MHC binding at this site are derived almost entirely from self-proteins, differentiating thymocytes with such receptors are intrinsically dangerous as potentially autoimmune. This deletion of thymocytes with high-affinity receptors for self-MHC plus (presumptively) self-peptide is termed "negative selection"[21] (Fig. 1.2B), a process that may also involve activity of regulatory T cells (Tregs).[22,23]

Another feature that distinguishes B cells from T cells is that the cell surface antigen receptors of the former can be secreted in large quantities as antibody molecules, the effector functions of which are carried out in solution or at the surfaces of other cells. Secretion is accomplished by alternative splicing of Ig messenger RNAs (mRNAs) to include or exclude a transmembrane segment that is encoded by the Ig heavy-chain genes.

Immunoglobulin Class Switching

In addition to synthesizing both membrane and secreted forms of Igs, B cells also undergo class switching. Antibody molecules are comprised of five major classes (isotypes). In order of abundance in serum, these are IgG, IgM, IgA, IgD, and IgE (Chapters 4 and 15). In humans the IgG class is further subdivided into four subclasses and the IgA class into two subclasses. The class of Ig is determined by the sequence of the constant region of its heavy chain (C_H). The H chain constant region gene locus is organized with exons that encode each of the Ig isotypes and subclasses located downstream (3') of the variable (V_H) genes. Thus an antibody-producing cell with a successfully rearranged $V_HD_HJ_H$ exon can change the class of antibody molecule that it synthesizes by utilization of different C_H genes without changing its unique antibody specificity. This process, termed *class switch recombination*, is regulated by cytokines and is accomplished through the action of activation-induced cytidine deaminase.[24]

There is no process comparable with class switch recombination in T cells. The two types of TCRs are products of four

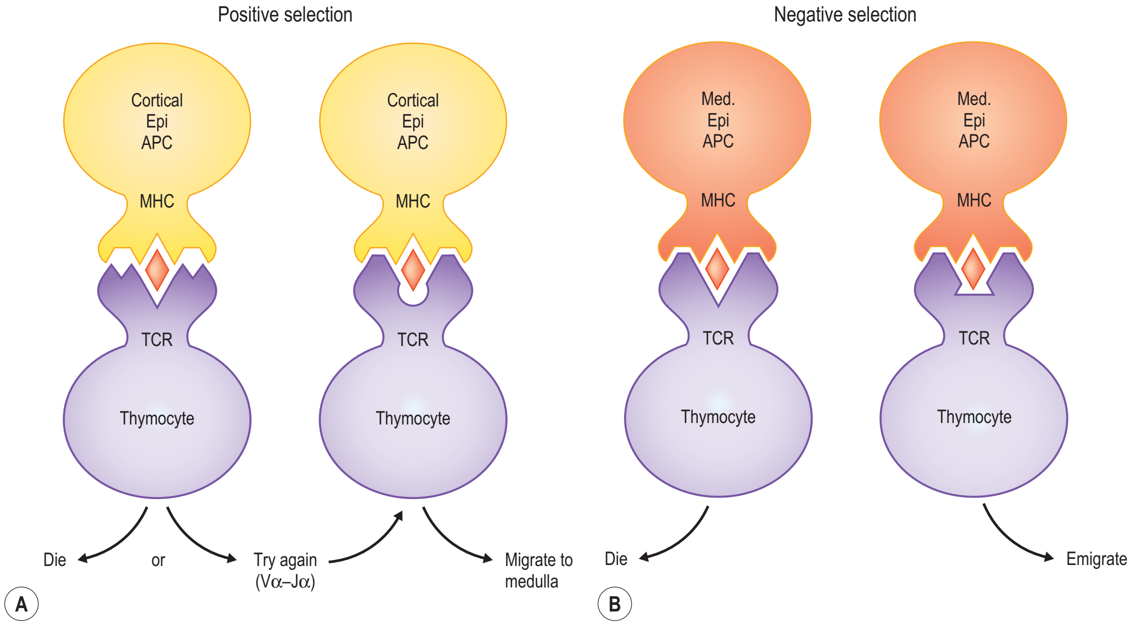

FIG 1.2 Two-Stage Selection of Thymocytes Based on Binding Characteristics of Randomly Generated T-Cell Receptors (TCRs). (A) *Positive selection.* "Double-positive" ($CD4^+$, $CD8^+$) thymocytes with TCRs capable of *low* avidity binding to some specific self-MHC molecule (either class I or class II) expressed by thymic cortical epithelial cells are positively selected. This process may involve sequential attempts at α gene rearrangement in order to express an αβ TCR of appropriate self-MHC specificity. If binding is to a class I molecule, the positively selected thymocyte becomes CD8 single-positive, and if to a class II molecule, a CD4 single-positive. Thymocytes that are unsuccessful in achieving a receptor with avidity for either a class I or a class II self-MHC molecule die by apoptosis. The solid diamond represents a self-peptide derived from hydrolysis of an autologous protein present in the thymic microenvironment or synthesized within the thymic epithelium itself. (B) *Negative selection.* "Single-positive" ($CD4^+$ *or* $CD8^+$) thymocytes, positively selected in the thymic cortex, that display TCRs with *high* avidity for the combination of self-MHC plus some self (autologous) peptide present in the thymus are negatively selected (*i.e.,* die) as potentially "autoimmune." Those few thymocytes that have survived both positive and negative selection emigrate to the periphery as mature T cells.

independent sets of V-region and C-region genes. A large majority of peripheral blood T cells express αβ TCRs, with a small fraction expressing γδ TCRs (usually ≤5% in peripheral blood). There is a higher representation of γδ T cells in certain tissues, particularly those lining mucous membranes, where they may be specialized for recognition of heavily glycosylated peptides or nonpeptide antigens that are commonly encountered in these tissue compartments. Thymocytes are committed to the expression of either αβ or γδ TCR, and their differentiated progeny (T cells) never change their TCR type in the periphery.

Major Histocompatibility Complex

MHC molecules constitute a third class of antigen-binding molecules. When an MHC class I molecule was initially crystallized, an unknown peptide was found in a binding groove formed by the first two (α_1 and α_2) domains of the molecule. This binding groove has since been established as a general feature of MHC molecules.[25] It is now known that the function of MHC molecules is to present antigen to T cells in the form of oligopeptides that reside within this antigen-binding groove (Chapter 6). The most important difference between the nature of the binding groove of MHC molecules and those of Ig and TCR is that the former does not represent a consequence of gene rearrangement. Rather, all the available MHC molecules in an individual are encoded in a linked array, which in humans is located on chromosome 6 and designated the human leukocyte antigen (HLA) complex.

MHC molecules are of two basic types, class I and class II. Class I molecules are found on the surface of almost all somatic cells, whereas cell surface expression of class II genes is restricted primarily to cells specialized for APC function. Class I molecules have a single heavy chain that is an integral membrane protein comprised of three external domains (see Fig. 1.1). The heavy chain is noncovalently associated with β_2 microglobulin, a nonpolymorphic, non–membrane-bound, single-domain Ig superfamily molecule that is encoded in humans on chromosome 15, not linked to the MHC. Class II MHC molecules, in contrast, comprise two polypeptide chains, α and β (or A and B), of approximately equal size, each of which consists of two external domains connected to a transmembrane region and cytoplasmic tail. Both chains of class II molecules are anchored on the cell by a transmembrane domain, and both are encoded within the MHC. Class I and class II molecules have a high degree of structural homology, and both fold to form a peptide-binding groove on their exterior face, with contribution from the α_1 and α_2 domains for class I molecules and from α_1 and β_1 domains for class II.[25]

There are three class I loci (HLA-A, -B, and -C) and three class II subregions (HLA-DR, -DQ, and -DP) that are principally involved in antigen presentation to T cells (Chapter 5). The functions of other class I and class II genes within this complex are less clear. Some, at least, appear to be specialized for binding (presentation) of peptide antigens of restricted type, source, or function (*e.g.*, HLA-E),[26] and others (*e.g.*, HLA-DM and HLA-DO) are clearly involved in antigen processing and loading of antigenic peptides into the binding cleft of the HLA-DR, -DQ, and -DP molecules [27] (Chapter 6). Additionally, members of a family of "nonclassic" class Ib molecules, $CD1_{a-d}$, which are encoded on chromosome 1, outside the MHC, are specialized for binding and presentation of lipid and lipid-conjugate antigens to T cells.[14,28]

The HLA complex represents an exceedingly polymorphic set of genes (Chapter 5). Consequently, most individuals are heterozygous at each major locus. In contrast to TCRs and Igs, the genes of the MHC are codominantly expressed. Thus, at a minimum, an APC can express six class I molecules and six class II molecules (the products of the two alternative alleles of three class I and three class II loci). This number is, in fact, usually an underestimate, as a consequence of additional complexity in the organization of the class II region (Chapter 5).

ANTIGEN PRESENTATION

Because MHC genes do not undergo recombination, the number of distinct antigen-binding grooves that they can form is many orders of magnitude less than that for either TCRs or Igs. Oligopeptides that bind to MHC molecules are the products of self or foreign proteins. They are derived by hydrolytic cleavage within APCs and are loaded into MHC molecules before expression at the cell surface (Chapter 6). Indeed, stability of MHC molecules at the cell surface requires the presence of a peptide in the antigen-binding groove; cells mutant for the loading of peptide fragments into MHC molecules fail to express MHC molecules on their cell surfaces.[29] Since in the absence of infection most hydrolyzed proteins are of self-origin, the binding groove of most MHC molecules contains a self-peptide. Class I and class II molecules differ from one another in the length of peptides that they bind, usually 8–9 amino acids for class I and 14–22 amino acids for class II.[25] Although important exceptions are clearly demonstrable, they also generally differ with respect to the source of peptide. Those peptides binding to class I molecules usually derive from proteins synthesized intracellularly (*e.g.*, autologous proteins, tumor antigens, virus proteins, and proteins from other intracellular microbes), whereas class II molecules commonly bind peptides derived from proteins synthesized extracellularly (*e.g.*, extracellular bacteria, nonreplicating vaccines, toxins/allergens). Endogenous peptides are generated by the immunoproteasome and then are loaded into newly synthesized class I molecules in the endoplasmic reticulum following active transport from the cytosol. Proteolytic breakdown and loading of exogenous peptides into class II molecules, in contrast, occurs in acidic endosomal vacuoles. As a consequence of proteolytic processing and binding into an MHC molecule, T cells see linear peptide epitopes. In contrast, because B-cell antigen recognition requires neither proteolytic processing nor binding into an MHC molecule, B cells recognize native, three-dimensional epitopes.

In addition to the recognition of lipids and lipid-conjugates presented by CD1 molecules, there are other exceptions to the generalization that MHC molecules only present (and T cells only recognize) oligopeptides. It has been known for many years that T cells can recognize haptens, presumably covalently or noncovalently complexed with peptides residing in the antigen-binding groove. This phenomenon is familiar to physicians as contact dermatitis to nonpeptide antigens, such as urushiol (from poison ivy) and nickel ion. Additionally, a newly recognized subset of T cells designated mucosal-associated (semi-)invariant T (MAIT) cells recognize vitamin B_2 (riboflavin) and vitamin B_9 (folate) derivatives bound to MR1, a nonpolymorphic MHC class I–like molecule; these vitamin derivatives are expressed by many strains of bacteria and yeast.[30] As MAIT cells constitute ~5% of human T cells and up to 25% of CD8 cells, their binding specificity suggests a role for these cells in host defenses. Additionally, certain human γδ T cells can recognize a variety of nonpeptide phosphoantigens, such as phosphorylated nucleotides, other phosphorylated small molecules, and alkylamines. The role of

APCs and MHC-like molecules in presentation of phosphoantigens to γδ T cells remains a subject of investigation.[31]

Another exception to the generalization of T-cell recognition of oligopeptides is represented by a group of proteins termed *superantigens* (SAgs).[31] SAgs, of which the staphylococcal enterotoxin A represents a prototype, are produced by a broad spectrum of microbes, ranging from retroviruses to bacteria. They differ from conventional peptide antigens in their mode of contact both with MHC class II molecules and TCRs (Chapter 6). They do not undergo processing to oligopeptide fragments but, rather, bind as intact proteins to class II molecules and TCRs outside the antigen-binding grooves. Their interaction with TCRs is predominantly determined by variable residues of the TCR Vβ region. Because SAgs bind more or less independently of the TCRs α chain and the other variable segments of the β chain, they are capable of activating much larger numbers of T cells compared with conventional peptide antigens, and hence their name. SAgs cause a wave of T-cell activation, proliferation, and production of proinflammatory molecules that can have profound clinical consequences, leading to development of such diseases as toxic shock syndrome.[31]

LYMPHOCYTE ADHESION AND TRAFFICKING

The capacity to survey continuously the antigenic environment is an essential element of immune function. APCs and lymphocytes must be able to find antigen wherever it occurs. Surveillance is accomplished through an elaborate interdigitated circulatory system of blood and lymphatic vessels that establish connections between the solid organs of the peripheral immune system (*e.g.*, spleen, lymph nodes, and lymphoid structures in mucosal tissues) in which the interactions between immune cells predominantly occur (Chapter 2).

The trafficking and distribution of circulating cells of the immune system is largely regulated by interactions between molecules on leukocyte surfaces and ligands on vascular endothelial cells[32] (Chapter 11). Leukocyte-specific cellular adhesion molecules can be expressed constitutively or can be induced by cytokines (*e.g.*, as a consequence of an inflammatory process). Several families of molecules are involved in the regulation of lymphocyte trafficking. Particularly important are selectins and integrins, which ensure that mobile cells home to appropriate locations within lymphoid organs and other tissues. Selectins are proteins characterized by a distal carbohydrate-binding (lectin) domain. They bind to a family of mucin-like molecules, the endothelial vascular addressins. Integrins are heterodimers essential for the emigration of leukocytes from blood vessels into tissues. Members of the selectin and integrin families not only are involved in lymphocyte circulation and homing but are also important in interactions between APCs, T cells, and B cells in induction and expression of immune responses. Certain endothelial adhesion molecules, mostly members of the Ig superfamily, are similarly involved in promoting interactions between T cells and APCs, as well as in leukocyte transmigration from the vasculature. Additionally, receptors for chemokines are important determinants of lymphocyte migration, particularly in guiding tissue-selective cell trafficking.[33]

LYMPHOCYTE ACTIVATION

For both B cells and T cells, initial activation is a two-signal event[34] (Chapter 12). This generalization is particularly true for immunologically naïve cells that have not been previously exposed to antigen. The first signal is provided by antigen. Most commonly, antigens for B cells are proteins with distinct sites, termed *epitopes*, which are bound by membrane Ig. Such epitopes can be linear, defined by a contiguous amino acid sequence or (more frequently) can be conformationally defined by the three-dimensional structure of the antigen. Epitopes can also be simple chemical moieties (haptens) that have been attached, usually covalently, to amino acid side chains (Chapter 6). In addition to proteins, some B cells have receptors with specificity for carbohydrates, and less commonly lipids or nucleic acids. Antigens that stimulate B cells can be either in solution or fixed to a solid matrix (*e.g.*, a cell membrane). As previously noted, the nature of antigens that stimulate T cells is more limited. TCRs do not bind antigen in solution but are usually stimulated only by small molecules, primarily oligopeptides, which reside within the antigen-binding cleft of a self-MHC molecule.

The second signal requisite for lymphocyte activation is provided by an accessory molecule expressed on the surface of the APC (*e.g.*, B7/CD80) for stimulation of T cells or on the surface of a helper T cell (*e.g.*, CD40L/CD154) for activation of B lymphocytes. The cell surface receptors for this particular second signal on T cells is CD28 and on B cells is CD40 (Fig. 1.3). Other cell surface ligand-receptor pairs may similarly provide the second signal (Chapters 8, 12). The growth and differentiation of both T cells and B cells additionally requires stimulation with one or more cytokines, which are peptide hormones secreted in small quantities by activated leukocytes and APCs for function in the cellular microenvironment.[35] In the absence of a second signal, cells stimulated only by antigen become unresponsive to subsequent antigen stimulation (anergic)[36] (Chapter 12).

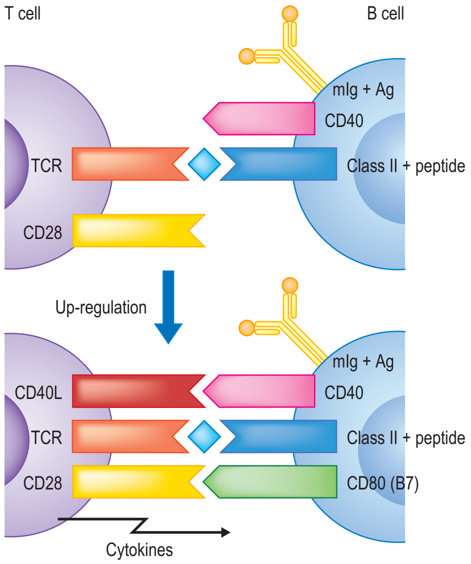

FIG 1.3 Reciprocal Activation Events Involved in Mutual Simulation of T Cells and B Cells. T cells constitutively express T-cell receptors (TCRs) and CD28. B cells constitutively express mIg and major histocompatibility complex (MHC) class II. Antigen bound to mIg is endocytosed and processed to peptide fragments that bind to MHC class II molecules for presentation to TCRs. Activation of B cells by antigen (Ag) upregulates their expression of CD80 that interacts with CD28 to activate T cells. This upregulates CD40L (CD154) on the T cell and induces cytokine synthesis. Costimulation of B cells by antigen, CD40L, and cytokines leads to Ig production.

Signal transduction through the antigen receptor is a complex process involving interactions between the specific receptor and molecules coexpressed in the cell membrane.[37] For B cells, this is a heterodimer, Igα/Igβ; and for T cells it is a macromolecular complex, CD3, usually comprising γ, δ, εε and ς chains.

Within the cell membrane, antigen receptor stimulation induces phosphorylation of Igα/Igβ or CD3 and hydrolysis of phosphatidylinositol 4,5-bisphosphate by phospholipase C, leading to generation of diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). As a consequence of signal transduction and secondarily of DAG and IP_3 generation, tyrosine and serine/threonine protein kinases are activated. In turn, these kinases catalyze phosphorylation of a number of signal transducing proteins, leading to activation of cytoplasmic transcription factors NF-AT in T cells and NF-κB in both T cells and B cells. These transcription factors then translocate to the nucleus, where they bind to 5' regulatory regions of genes that are critical to generalized lymphocyte activation[37,38] (Chapter 12).

CELL-MEDIATED IMMUNE RESPONSES

T-Cell Subsets

T lymphocytes expressing an αβ TCR can be divided into two major subpopulations based on the class of MHC molecule that their TCR recognizes and the consequent expression of one of a pair of TCR accessory molecules, CD4 or CD8 (Chapters 4, 8). Binding of CD4 to class II MHC molecules or CD8 to class I MHC molecules on APCs contributes to the overall strength of intercellular molecular interactions. The ratio of CD4 to CD8 cells in peripheral blood is usually about 2 : 1.

CD4 T Cells, Cytokines, and Chemokines

The activities of CD4 T lymphocytes, commonly referred to as *T helper (Th) cells*, are mediated predominantly through the secretion of cytokines (Chapter 9). Cytokine activity can include autostimulation (autocrine function) if the cell producing the cytokine also expresses a surface receptor for it, or stimulation of other cells in the microenvironment of the cytokine-secreting cell (paracrine function) including B cells, APCs, and other T cells. Although it is now recognized that their biological effects are broader than implied by their name, many of the principal cytokines active in the immune system are known as *interleukins* (ILs), implying that they are produced by a leukocyte to act on other leukocytes.

The specific profile of cytokines produced by CD4 T cells allows further functional subdivision (Chapters 16, 18).[35,39] CD4 T cells elaborating the "inflammatory" cytokines involved in effector functions of cell-mediated immunity, such as IL-2 and IFN-γ, are designated Th1 cells. Th2 CD4 T cells synthesize cytokines, such as IL-4 and IL-13, which control and regulate antibody responses and activate cells that are involved in host defense against parasites. Differentiation of Th1 versus Th2 subsets is a process substantially controlled by positive feedback loops, being promoted particularly by IL-12 in the case of Th1 cells and IL-4 in the case of Th2 cells. It is important to note that generalizations regarding cytokine activity are usually oversimplifications, reflecting a substantial overlap and multiplicity of functions (Chapter 9). For example, although IL-2 was initially identified as a T-cell growth factor, it also significantly affects B-cell differentiation. The prototypic inflammatory cytokine, IFN-γ, which promotes differentiation of effector function of cytotoxic lymphocytes (CTLs) and macrophages, is also involved in regulation of Ig isotype switching. And IL-4, although known primarily as a B-cell growth and differentiation factor, can also stimulate proliferation of T cells.

A distinct subset of cytokines is a large group of highly conserved cytokine-like molecules, smaller than typical cytokines (~7–12 kilodaltons [kDa]), termed *chemo*tactic cyto*kines*, or *chemokines*[33] (Chapter 10). Chemokines are classified on the basis of the number and spacing of specific cysteine residues. They regulate and coordinate trafficking and activation of leukocytes, functioning importantly in host defenses, and also broadly in a variety of nonimmunological processes, including organ development and angiogenesis. They are characterized by binding to seven-transmembrane-domain G protein–coupled receptors. Of particular interest to clinical immunologists, the chemokine receptors CCR5 and CXCR4 together with CD4 are utilized by human immunodeficiency virus (HIV) as coreceptors to gain entry into target cells.[40]

Cytokines produced by activated T cells can downregulate as well as initiate or amplify immune responses.[41] Downregulating cytokines include IL-10 (produced by both T cells and B cells) and transforming growth factor-β (TGF-β). The functions of IL-10 *in vivo* are thought to include both suppression of proinflammatory cytokine production and enhancement of IgM and IgA synthesis. TGF-β, produced by virtually all cells, expresses a broad array of biological activities, including promotion of wound healing and suppression of both humoral and cell-mediated immune responses.

In addition to their central role in initiation and regulation of immune responses, CD4 T cells are important effectors of cell-mediated immunity (Chapter 16). Through the elaboration of inflammatory cytokines, particularly IFN-γ, they are essential contributors to the generation of chronic inflammation, characterized histologically by mononuclear cell infiltrates, where their principal role is thought to be the activation of macrophages. Additionally, in some circumstances CD4 T cells can function as cytotoxic effectors, either directly as CTLs (in which case the killing is "restricted" for recognition of antigen-bound self-MHC class II) or through the elaboration of cytotoxic cytokines, such as lymphotoxin and TNF-α.

A third subset of Th cells, designated Th17, has been recognized more recently. With differentiation driven particularly by TGF-β and IL-23 and characterized by the production of the proinflammatory cytokine IL-17, Th17 cells are important in the induction and exacerbation of autoimmunity in a variety of disease models, as well as in host defenses against a broad spectrum of extracellular bacteria, fungi and other pathogens.[42] Research continues to identify additional examples of CD4 T cells, which may become recognized as distinct subsets, whose function is governed by other predominantly expressed cytokines to achieve specialized effector responses.

One final category of CD4 cells, Tregs, plays a crucial role suppressing the functions of other lymphocytes. Tregs can differentiate either in the thymus (tTregs) or in the periphery (pTregs). A third category of Tregs are induced *in vitro* (iTregs)[43] (Chapter 18). These are commonly characterized by surface expression of CD4 and CD25 and by nuclear expression of the transcription factor Foxp3. Peripheral activation of $CD25^+$ Tregs is via the TCRs; the cells are IL-2 dependent and apparently require cell-to-cell contact for suppressive function. They can suppress functions of both CD4 and CD8 T cells, as well as B cells, NK cells, and NKT cells. In contrast to activation, suppressor effects are independent of the antigen specificity of the target cells. Other Tregs are noted for production of inhibitory cytokines, including IL-10- and TGF-β–secreting Th3 cells, and IL-10–producing Tr1 cells.[44,45]

CD8 T Cells

The best understood function of CD8 T cells is that of CTL effectors.[46] CTLs are particularly important in host defenses against virus-infected cells, where they can kill target cells expressing viral peptides bound to self-MHC class I molecules (Chapter 17). This process is highly specific and requires direct apposition of CTLs and target cell membranes. Bystander cells, expressing MHC molecules that have bound peptides that the CD8 T cell does not recognize, are not affected. The killing is unidirectional; the CTL itself is not harmed, and after transmission of a "lethal hit," it can detach from one target to seek another. Killing occurs via two mechanisms: a death-receptor-induced apoptotic mechanism and a mechanism involving insertion of perforins into the target cell membrane to create a pore through which granzymes and other cytotoxic enzymes can be transferred from the CTL into the target cell. CTL activity is enhanced by IFN-γ. As CTL function is dependent on target cell surface display of MHC class I molecules, a principle mechanism of immune evasion by viruses and tumors is elaboration of factors that downregulate class I expression (Chapter 25). However, this increases susceptibility of such cells to cytolysis by NK cells that are activated to attack cells expressing low levels of class I MHC molecules.

ANTIBODY-MEDIATED IMMUNE RESPONSES

The structure of antibodies permits a virtually limitless binding specificity of its antigen-binding groove. Antigen binding can then be translated into biological effector functions based on properties of the larger nonvariable (constant) region of its heavy chains (Fc fragment) (Chapter 15). Moreover, in response to cytokines in the cellular microenvironment, through the mechanism of isotype switching an antibody-producing cell can alter the exons that are used to encode its heavy-chain constant region and thereby the biological effects of its secreted product without affecting its antigen-binding specificity. With functional heterogeneity determined by isotype, the antibody molecules provide a broad-based and efficient defense system against extracellular microbes or foreign macromolecules (*e.g.,* toxins and venoms) (Chapters 15, 27, 90).

Each antibody class contributes differently to an integrated defense system.[47] IgM is the predominant class formed on initial contact with antigen (primary immune response). As a monomeric structure comprises two light (κ or λ) and two heavy (μ) chains, it is initially expressed as a membrane bound antigen receptor on the surface of B lymphocytes. The avidity of serum IgM for antigen binding is increased by its organization into a pentamer of five of the monomeric subunits held together by a joining (J) chain. IgM is essentially confined to the intravascular compartment. As a multivalent antigen binder that can efficiently activate ("fix") complement, it is an important contributor to immune responses early after the initial encounter with antigen. The synthesis of IgM, compared with other isotypes, is much less dependent on the activity of T lymphocytes.

IgG is the most abundant immunoglobulin in serum and the principal antibody class of a secondary (anamnestic or memory) immune response. IgG molecules are heterodimeric monomers with two light (κ or λ) and two heavy (γ) chains joined by interchain disulfide bridges. Because of its abundance, its capacity to fix complement, and the expression on phagocytes of Fcγ receptors, IgG is the most important antibody for systemic secondary immune responses. IgG is the only isotype that is actively transported across the placenta. These transported maternal IgG antibodies provide the neonate with an important level of antibody protection during the early months, when its own antigen-driven antibody responses are first developing (Chapter 38).

IgA is the principal antibody in the body's secretions (Chapter 20). It is found in serum in monomeric form of two light and two heavy (α) chains or as a dimer joined by J chain. In secretions, it is usually present in dimeric form and is actively secreted across mucous membranes by attachment of a specialized secretory component (SC) that is recognized by the polyIg receptor on mucosal epithelial cells. Dimeric IgA is found in high concentration in tears, saliva, and secretions of the respiratory, gastrointestinal, and genitourinary systems; it is relatively resistant to enzymatic digestion. It is particularly abundant in colostrum, where its concentration may be >50 times that in serum, providing passive immunity to the gastrointestinal system of a nursing neonate. IgA does not fix complement by the antibody-dependent pathway and hence does not promote phagocytosis. Its role in host defenses lies in preventing a breach of the mucous membrane surface by microbes or their toxic products.

IgD and IgE are present in serum at concentrations much lower than that of IgG. The biological role of IgD remains controversial. B cells can express both membrane IgM and IgD by alternative splicing of the Ig heavy chain gene, or can secrete only IgD via an apparently atypical form of class switch recombination.[48] These mechanisms do not require T-cell help.

Although IgE is the least abundant isotype in serum, it has dramatic biological effects because it is responsible for immediate-type hypersensitivity reactions, including systemic anaphylaxis (Chapter 42). Such reactions reflect expression of high-affinity receptors for Fcε on the surfaces of mast cells and basophils. Cross-linking of IgE molecules on such cells by antigen induces their degranulation, with the immediate release of preformed potent biological mediators and *de novo* synthesis and secretion

KEY CONCEPTS

Biological Properties of Immunoglobulin (Ig) Classes

- IgM
  - Principal Ig of the primary immune response
  - Generally restricted to the vascular compartment
  - Antigen receptor (monomer) for most naïve B cells
  - Fixes complement potently
- IgG
  - Principal Ig of secondary immune responses
  - Binds to Fcγ receptors on neutrophils, monocytes/macrophages, natural killer (NK) cells
  - Four subclasses with different effector functions
  - Fixes complement (except IgG_4 subclass)
- IgA
  - Principal Ig of mucosal immunity
  - Two subclasses
- IgD
  - Antigen receptor for mature B cells
  - Typically coexpressed with membrane IgM
- IgE
  - Binds to Fcε receptors on mast cells and basophils
  - Antibody of immediate hypersensitivity
  - Important in defenses against helminths

of additional proinflammatory molecules. The protective role of IgE is in host defenses against parasitical infestation, particularly with helminths (Chapter 31).

Complement and Immune Complexes

As noted, the biological functions of IgG and IgM are importantly reflections of their capacities to activate the complement system. Through a cascade of sequential substrate–enzyme interactions, the 11 principal components of the antibody-dependent complement cascade (C1q, C1r, C1s, and C2–C9) cause many of the principal consequences of an antigen-antibody interaction (Chapter 21). These include the establishment of pores in a target cell membrane by the terminal components (C5–C9) leading to osmotic lysis; the production of factors (principally C5a) with chemotactic activity for phagocytic myeloid cells; opsonization by C3b, promoting phagocytosis; and the ability to induce degranulation of mast cells (C3a, C4a, and C5a). There are three distinct pathways to complement activation.[49] The pathway mediated by the binding of the first component (specifically C1q) to IgG or IgM has been termed the "classical" pathway (CP). The lectin pathway is similar to the CP but is activated by selected carbohydrate-binding proteins, the mannose (or mannan)-binding lectin (MBL), and ficolins, which recognize certain carbohydrate repeating structures on microorganisms. MBL and ficolins are plasma proteins that are homologous to C1q and contribute to innate immunity through their capacity to induce antibody- and C1q-independent activation of the CP. Finally, a large number of substances, including certain bacterial, fungal, and viral products, can directly activate the cascade through a distinct series of proteins also leading to activation of the central C3 component. Although bypassing C1, C4, and C2, this distinct pathway can achieve all the biological consequences of C3–C9 activation. Non–antibody-induced activation of C3 is referred to as the "alternative" pathway (AP) or "properdin" pathway. Additionally, the central components of the cascade (*e.g.,* C5a) can be directly produced by the action of serine proteases of the coagulation system.[49] Reflecting these separate pathways to activation and the fact that many types of leukocytes express receptors for activated complement components, the complement system is a major contributor to the efferent limbs of both innate and acquired immune systems.

In addition to their roles in pathogen/antigen elimination, constituents of the complement system, together with antigen–antibody (immune) complexes, act at leukocyte surfaces to regulate immune functions. For example, interaction of immune complexes via FcγR on B cells decreases their responsiveness to stimulation. In contrast, complement activation on B-cell surfaces coligates their receptors with B-cell receptors for antigen, rendering the cells more readily activated and resistant to apoptosis.

Essential for the proper function of the complement system is a series of downregulatory mechanisms that prevent unwanted activation of the system and that extinguish its activity when no longer needed. The regulatory pathways are mediated by a combination of both soluble complement-binding and digesting molecules and cell surface binding proteins.

APOPTOSIS AND IMMUNE HOMEOSTASIS

An immune response is commonly first viewed in a "positive" sense—that is, lymphocytes are activated, proliferate, differentiate, and carry out effector functions. It is equally important, however, that this positive response be tightly regulated by mechanisms that operate to turn off the response and to eliminate cells no longer required.[50,51] Under physiological circumstances, once an immune response fades, commonly as a consequence of antigen depletion, two pathways to terminal lymphocyte differentiation become available: apoptosis or differentiation into memory cells. Memory cells are, of course, a key to the effectiveness of the adaptive immune system, since a second activating encounter with antigen (*e.g.,* pathogen) is both more rapid and more productive. Isotype-switched high-affinity antibodies are rapidly produced, and/or clones of CTL effector cells proliferate. But the majority of lymphocytes in an active response are not required for maintenance of immunological memory, and the necessity for homeostasis leads to apoptosis of cells no longer required.

Apoptosis (or Regulated Cell Death; RCD) is a unique process of cellular death, widely conserved phylogenetically, and distinguished from death by necrosis by cellular shrinking, DNA fragmentation, and breakdown of cells into "apoptotic bodies" containing nuclear fragments and intact organelles that can be eliminated by phagocytosis without release into the extracellular space of the majority of intracellular, especially nuclear, components. Necrosis can be genetically determined (Regulated Necrosis; RN) or unregulated, reflecting some accidental or otherwise inevitable process (Chapter 13). Apoptosis depends on the activation of cysteinyl proteases, termed *caspases*, which cleave proteins that regulate DNA repair and the establishment/maintenance of cellular architecture. In the absence of these apoptotic mechanisms, massive proliferation of cells in lymphoid tissues results and is seen clinically as autoimmune lymphoproliferative syndrome (ALPS), which is characterized by lymphocytosis with lymphadenopathy and splenomegaly as well as autoimmunity and hypergammaglobulinemia.[52]

MECHANISMS OF IMMUNOLOGICAL DISEASES

Immunological diseases can be classified on the basis of our understanding of normal immune physiology and its perturbations in disease states (Table 1.2). One type of immunological disease results from failure or deficiency of a component of the immune system leading to failure of normal immune function (Chapters 32–40). Such disorders are usually identified by increased susceptibility to infection (Chapter 37). Failure of host defense can be congenital (*e.g.,* X-linked agammaglobulinemia; Chapter 34) or acquired (*e.g.,* acquired immunodeficiency syndrome [AIDS]; Chapter 39). It can be global (*e.g.,* severe combined immunodeficiency [SCID]; Chapter 35) or, quite specific, involving only a single component of the immune system (*e.g.,* selective IgA deficiency; Chapter 34).

A second type of immunological disease is malignant transformation of immunological cells (Chapters 77–80). Manifestations of leukocyte malignancies are protean, most commonly

TABLE 1.2 Mechanisms of Immunological Diseases

1. Functional deficiency of key immune system components
    a. Congenital
    b. Acquired
2. Malignant transformation of immune system cells
3. Immunological dysregulation
4. Autoimmunity
5. Untoward consequences of physiological immune function

reflecting the secondary consequences of solid organ or bone marrow infiltration or replacement of normal cells by tumor cells, with resulting anemia and immunological deficiency.

The remaining types of immunopathogenesis are more specific to the immune system. Dysregulation of an essentially intact immune system constitutes a third general type of immune disorder. Features of an optimal immune response include antigen recognition and elimination, with little adverse effect on the host. Both initiation and termination of the response, however, involve regulatory interactions that can go awry when the host is challenged by antigens of a particular structure or presented in a particular fashion. Diseases of immune dysregulation can result from genetic and environmental factors that act together to produce a pathological immune response, such as acute allergic diseases (Chapters 41–49). Some forms of allergic disease are thought to be a consequence of insufficient exposure to nonpathogenic microbes and other potential allergens in early childhood, resulting in an increased susceptibility to allergy, atopy, and asthma once the immune system has matured. The so-called "hygiene hypothesis" suggests that mucosal tissue-colonizing organisms play key roles in the initial establishment of immune homeostasis.[53] The importance of establishing immune homeostasis early in life is also supported by studies demonstrating reduction in the likelihood of food allergy associated with feeding of the allergenic foods to infants at high risk for allergy[54-56] (Chapter 45).

A fourth type of immunological disorder is the result of failure of a key feature of normal immune recognition, the molecular discrimination between self and nonself. Ambiguity in this discrimination can lead to autoimmune tissue damage (Chapters 50–76). Although such damage can be mediated by either antibodies or T cells, the common association of specific autoimmune diseases with inheritance of particular HLA alleles (Chapter 5) suggests that the pathogenesis of autoimmune diseases usually represents a failure of regulation of the anti-self inflammatory response by T cells. The immunologic attack on self-tissues can be general, leading to systemic autoimmunity, such as systemic lupus erythematosus; or it can be localized, as in organ-specific autoimmune diseases. In the latter instances, the immune system attacks specific types of cells and usually particular cell surface molecules. In most cases, pathology is a consequence of target tissue destruction (*e.g.*, multiple sclerosis, rheumatoid arthritis, or insulin-dependent diabetes mellitus). However, depending on the antigenic specificity of the abnormal immune response, autoimmunity can lead to receptor blockade (*e.g.*, myasthenia gravis or insulin-resistant diabetes) or hormone receptor stimulation (*e.g.*, Graves disease). It is thought by many immunologists that ambiguity in self/nonself discrimination is commonly triggered by an unresolved encounter with an infectious organism or other environmental agent that shares some structural features with self-tissue structures, although this remains a subject of controversy[57,58] (Chapter 50). Insight into mechanisms whereby specific HLA alleles predispose to development of autoimmunity and others may be protective are suggested by studies in HLA-transgenic mice, which suggest that alleles that predispose animals to a particular autoimmune disease may reflect a T cell phenotype associated with secretion of pro-inflammatory cytokines. In contrast protective alleles were associated with elaboration of trolerogenic cytokines by regulatory T cells.[59]

A fifth form of immunological disease occurs as a result of physiological, rather than pathological, immune functions. Inflammatory lesions in such diseases are the result of the normal function of the immune system. A typical example is contact dermatitis to such potent skin sensitizers as urushiol, the causative agent of poison ivy dermatitis (Chapter 44). These diseases can also have an iatrogenic etiology that can range from mild and self-limited (*e.g.*, delayed hypersensitivity skin test reactions) to life-threatening (*e.g.*, graft-versus-host disease, organ graft rejection).

HOST IMMUNE DEFENSES SUMMARIZED

The first response upon initial contact with an invading pathogen depends on components of the innate immune system (Chapter 3). This response begins with recognition of PAMPs expressed by cells of the pathogen. These include lipoproteins, lipopolysaccharide, unmethylated CpG-DNA, and bacterial flagellin, among others. PAMPs bind to PRRs on or within effector cells of the host's innate immune system, including DCs, granulocytes, and ILCs.[3] The best characterized PRRs are the TLRs, first recognized as determinants of embryonic patterning in *Drosophila* and subsequently appreciated as components of host defenses in both insects and vertebrates. TLR subfamilies can be distinguished by expression either on the cell surface or in intracellular compartments. A second major family of PRRs comprises NLRs, which detect intracellular microbial products. Binding of TLRs or NLRs by PAMP ligands triggers intracellular signaling pathways via multiple "adapters," leading to a vigorous inflammatory response.

The innate immune response also includes the capacity of NK lymphocytes to identify and destroy, by direct cytotoxic mechanisms, cells lacking surface expression of MHC class I molecules, which marks them as potentially pathogenic.[4] Additionally, an innate immune response involves elements of the humoral immune system that function independently of antibody, especially the activation of the complement cascade through the lectin pathway and the AP, with consequent opsonization of particles and microbes to promote their phagocytosis and destruction.

The nature of the adaptive immune response to any particular pathogenic agent is determined largely by the context in which the pathogen is encountered. Regardless, effectiveness depends on the four principal properties of adaptive immunity: *(i)* a virtually unlimited capacity to bind macromolecules, particularly proteins, with exquisite specificity, reflecting generation of antigen-binding receptors by genetic recombination and, in the case of B cells, somatic hypermutation; *(ii)* the capacity for self/nonself discrimination, consequences of a rigorous process involving positive and negative selection during thymocyte differentiation, as well as negative selection during B-cell differentiation; *(iii)* the property of immunological memory, reflecting antigen-driven clonal proliferation of T cells and B cells, which results in increasingly rapid and effective responses on second and subsequent encounters with a particular antigen or pathogen; and *(iv)* mechanisms for pathogen destruction, including direct cellular cytotoxicity, release of inflammatory cytokines, opsonization with antibody and complement, and neutralization in solution by antigen precipitation or conformational alteration plus phagocytosis and intracellular digestion.

Although most acquired immune responses include multiple defense mechanisms, several generalizations may be conceptually useful. T cell–mediated (and NK cell–mediated) effector functions are particularly important in defenses against pathogens encountered intracellularly or at cell surfaces, such as intracellular viruses, intracellular bacteria, and tumor cells. These responses involve the production of inflammatory cytokines by CD4 Th1 cells, as well as the direct cytolytic activity of CD8 CTLs. In contrast, host defenses to most antigens encountered primarily in the extracellular milieu are largely dependent on humoral mechanisms (antibody and complement) for antigen neutralization, precipitation, or opsonization and subsequent destruction by phagocytes. Targets of antibody-mediated immunity include extracellular virus particles, bacteria, and toxins (or other foreign proteins). It is worth reiterating, however, that induction of an effective antibody response (including isotype switching) and development of immunological memory (resulting from B-cell clonal expansion and B memory cell differentiation) require antigen activation not only of specific B cells but also CD4 T cells, particularly of the Th2 type. Additionally, antibacterial and antifungal responses that involve prominent responses by neutrophils require CD4 T cells of the Th17 type.

KEY CONCEPTS

Characteristic Infections Associated With Immune Deficiency Syndromes

Deficiencies of T Cell–Mediated Immunity

- Mucocutaneous fungal infections, especially *Candida albicans*
- Systemic (deep) fungal infections
- Systemic infection with attenuated viruses (*e.g.*, live viral vaccines)
- Infection with viruses of usually low pathogenicity (*e.g.*, cytomegalovirus)
- *Pneumocystis jiroveci* pneumonia

Antibody Deficiencies

- Infections by encapsulated bacteria (*e.g.*, *Streptococcus* spp., *Haemophilus influenza*)
- Recurrent pneumonia, bronchitis, sinusitis, otitis media
- *Giardia lamblia* enteritis

Phagocyte Deficiencies

- Infection by gram-positive bacteria (*e.g.*, staphylococci, streptococci)
- Gram-negative sepsis
- Systemic fungal infections (*e.g.*, *Candida* spp., *Aspergillus* spp.)

Adhesion Molecule Deficiencies

- Infections with pyogenic bacteria (especially staphylococci)
- Cutaneous and subcutaneous abscesses

Complement Component Deficiencies

- C3 deficiency: Infections with encapsulated bacteria
- Deficiency of terminal components: infections with gram-negative bacteria, especially *Neisseria* spp.

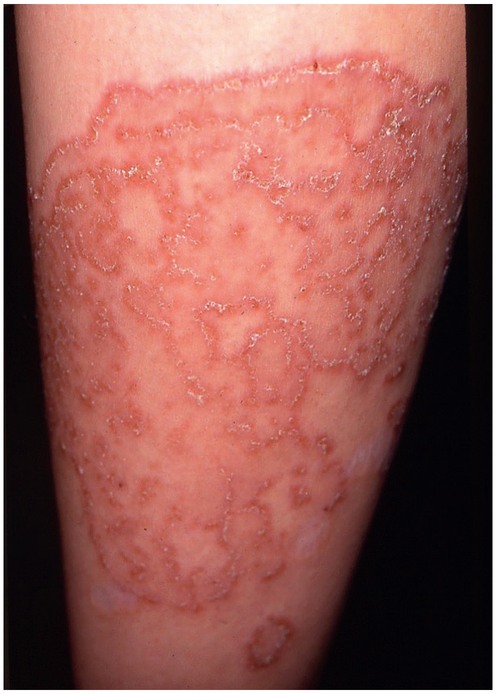

FIG 1.4 Leg of a 16-year-old patient with chronic mucocutaneous candidiasis as a consequence of a congenital T-cell deficiency associated with hypoparathyroidism and adrenal insufficiency.

Finally, clinical "experiments of nature" have proven particularly instructive in our efforts to understand the role of specific components of the immune system in overall host defenses[60] (Chapter 37). The importance of T cell–mediated immunity in host defenses to intracellular parasites, fungi (Fig. 1.4), and viruses is emphasized by the remarkable susceptibility of patients with T cell–deficiency to pathogenic organisms, such as *Pneumocystis jiroveci* and *Candida albicans*, and by the fact that utilizing attenuated live virus vaccines in such patients can lead to devastating disseminated infections. Indeed, the relationship between susceptibility to particular potential pathogens and specific immunological deficiencies is nicely illustrated by recent demonstrations that the pathogenesis of various familial forms of chronic mucocutaneous candidiasis reflects deficiency of IL-17–mediated immunity.[61]

However, patients with defects in antibody synthesis or phagocytic cell function are characteristically afflicted with recurrent infections with pyogenic bacteria, particularly gram-positive organisms. And patients with inherited defects in synthesis of terminal complement components have increased susceptibility to infection with species of *Neisseria*.

In recent years, immunology has entered the lay lexicon, largely as a result of the HIV pandemic. People throughout the world are now aware of the tragic consequences of immune deficiency. The remarkable progress in understanding this disease, however, depended substantially on earlier studies of relatively rare patients with primary immunodeficiency syndromes, more recent acceleration due to progress in genomic definition of their molecular basis. Similarly, cure of patients with primary immunodeficiencies by cellular reconstitution, particularly bone marrow or stem cell transplantation[62] (Chapter 82), presaged recent progress in correction of such diseases by gene replacement therapy[63] (Chapter 85). The "present" of clinical immunology is, indeed, bright. But its future potential to impact prevention and treatment of many challenging diseases, including cancer (Chapter 77), through specific analysis of genetic mutations and enhancement or suppression of global or antigen-specific immune responses and check-point inhibition is even more exciting to contemplate.[64] A few approaches are broadly hinted at here, and it is hoped that readers will enjoy considering such "perspectives" throughout the book and, given the nature of the immune system, it is also hoped will challenge themselves to transform a particular author's views to new and different clinical settings.

Studies in experimental animals, especially murine studies, have been critical to our understanding of molecular aspects of

ON THE HORIZON

Enhancement of Immune Responses

- Use of CRISPR/Cas9 technology in correction of gene defect in monogenic immunodeficiency diseases
- Enhancement of molecular-pathway-specific cancer immunotherapy
- Prediction of molecular targets and improvements in adjuvants for vaccines

Suppression of Immune Responses

- Further development of protocols for prevention of childhood allergic diseases by appropriate environmental exposures in infancy
- Improved allergen-specific immunotherapy of allergic diseases
- Prevention of graft-versus-host disease in allogeneic bone marrow transplantation cases
- Induction of antigen-specific immune tolerance in humans
- Pharmacological development of specific inhibitors of cytokines, chemokines, and their receptors

Immunodiagnostics and Immunopathogenesis

- Routine use of genomic analysis for development of personalized medicine applicable to immunological diseases
- Development of novel diagnostic tools based on nanotechnology arrays
- Application of gastrointestinal microbiome analysis in understanding the pathogenesis of inflammatory bowel diseases, leading to novel therapeutic options
- Understanding the role of inflammation in the pathogenesis of leading causes of morbidity and mortality, including myocardial infarction, stroke, and Alzheimer disease

immune system function and have contributed importantly to our appreciation of how aberrations of such functions are involved in the pathogenesis of disease. Insights gained from use of transgenic mice (including murine expression of human genes) and constitutive or conditional gene-knockout mice are essential to a comprehensive view of the immune system at the advancing edge of its clinical application, implying that future progress in clinical immunology will equally depend on detailed analysis in such systems. It has become apparent, however, that there are important differences in aspects of the human and rodent immune systems. Consequently, the carefully studied patient, particularly when coupled with the power of increasingly feasible genome and transcriptome sequencing, will remain the ultimate crucible for understanding human immunity and the roles of the immune system in the pathogenesis of and protection from disease.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following statements regarding B cells is correct?
   A. B cells can function as antigen-presenting cells (APCs).
   B. Activation for antibody production requires antigen presentation by APCs.
   C. Activation requires association of B-cell receptors for antigen with CD3.
   D. Expression of major histocompatibility complex (MHC) class II molecules on B cells requires cytokines produced by APCs.

2. Natural killer (NK) cells of the innate immune system:
   A. Express clonally specific antigen receptors
   B. Exhibit allelic exclusion of antigen receptors
   C. Express receptors for immunoglobulin molecules
   D. Upregulate cytotoxic activity on virus-infected target cells that express increased levels of major histocompatibility complex (MHC) class I molecules

3. Expression of human leukocyte antigen (HLA) class I molecules:
   A. Exhibits allelic exclusion
   B. Is associated with activation-induced cytidine deaminase
   C. Produces an antigen-binding site formed by folding of a single polypeptide chain
   D. Comprises two polypeptide chains that are both encoded within the HLA gene complex

4. A 2-year-old child is referred for evaluation of massive lymphadenopathy, splenomegaly, and apparent autoimmune anemia of 6 months' duration without fever or weight loss. You suspect the child's primary problem is:
   A. Acute myelogenous leukemia
   B. Excess production of IL-2 by CD4$^+$ T helper (Th) cells
   C. Dysregulated proliferation of B cells
   D. Defective lymphocyte apoptosis

5. A 6-year-old boy is referred for evaluation of a presumptive diagnosis of a genetic deficiency of intercellular adhesion molecules. The referring pediatrician's basis for this referral was:
   A. Recurrent viral infections
   B. Unusual susceptibility to infection with gram-negative bacteria
   C. Recurrent cutaneous abscesses
   D. Presence of *Pneumocystis jiroveci* pneumonia

6. A 35-year old female presents with exophthalmos, tremor, and weight loss. You suspect that the cause of her autoimmune disease is:
   A. Destruction of target gland hormone-producing cells
   B. Destruction of target gland stromal cells
   C. Blocking of target cell hormone receptors
   D. Stimulation of target cell hormone receptors

Organization of the Immune System

Dorothy E. Lewis, Sarah E. Blutt

The human immune system consists of organs and movable cells. This design provides central locations for the initial production and differentiation of committed cells from naïve precursors, such as the fetal liver, the bone marrow, and the thymus; and more dispersed sites for the selection and further differentiation of cells into mature effector cells, such as the spleen, lymph nodes, and intestinal Peyer patches. This arrangement also allows regulation of immune responses at locations peripheral to primary lymphoid organs to provide local control of infectious processes. This chapter covers the basic features and the ontogeny of cells involved in the immune response, as well as the essential structure of lymphoid organs and sites of organized immune cells, including skin, the large intestine, and adipose tissue.

IMMUNE CELL DEVELOPMENT

Ontogeny of the Cells of the Immune System

In the first month of embryogenesis, stem cells capable of producing white blood cell progenitors are found in erythropoietic islands that are in the yolk sac.[1] The aorta–gonad–mesonephros (AGM), which is adjacent to the liver, produces progenitor cells that develop into hematopoietic stem cells (HSCs). In the sixth week of gestation, or just after the embryonic liver can be identified, progenitor stem cells in the liver begin blood cell production. By the eleventh week, the liver is the major source of hematopoiesis and remains so until the sixth month of gestation.[2]

HSC-derived progenitor cells can differentiate into granulocytes, erythrocytes, monocytes, megakaryocytes, and lymphocytes.[3] Subsequent to skeleton formation, which occurs between the second and fourth months of gestation, white blood cell development starts shifting to bone marrow. This transition is completed by 6 months' gestation. Cells that differentiate from early stem cells begin to populate the primary lymphoid organs, such as the thymus, by 7 to 8 weeks' gestation.[4] B-cell precursors initiate immunoglobulin (Ig) rearrangements by 7 to 8 weeks' gestation (Chapter 7), and T-cell precursors that have initiated T-cell receptor (TCR) rearrangement (Chapter 8) can be detected in thymus by 8 weeks' gestation. In bone marrow, B-cell progenitors congregate in areas adjacent to the endosteum and differentiate in the direction of the central sinus. HSC differentiation is a continuous process and is thus associated with many phenotypic stages. In the bone marrow of aged humans, there is evidence for a myeloid predominance, with a restricted diversity of HSCs.[5]

Stem cells with different characteristics and limited self-renewal can be induced into peripheral blood via injection of granulocyte–colony-stimulating factor (G-CSF).[4] Cord blood cells are being banked, and methods to increase levels of HSC self-renewal, including three-dimensional scaffolding, are under intensive study.[6]

Tools Essential to an Understanding of Immune Cell Biology

Understanding of the categorization and development of hematopoietic cells greatly depends on the use of monoclonal antibodies and flow cytometry to identify stage-specific leukocyte cell surface antigens. Leukocyte differentiation antigen workshops have grouped monoclonal antibodies that recognize the same single molecules on leukocytes by the cluster pattern of cells with which they are identified, hence the term *cluster of differentiation* (CD) antigen (Table 2.1, Appendix 1).

HEMATOPOIESIS AND LYMPHOPOIESIS

All mature cells of the hematopoietic and lymphoid lineages are derived from pluripotent stem cells that produce progenitors for lineage specific cells.[7] Hematopoietic progenitors mature into cells of the granulocytic, erythroid, monocytic–dendritic, and megakaryocytic lineages. Likewise, lymphoid progenitors mature into B, T, and innate lymphoid cells (ILCs), including natural killer (NK) cells (Fig. 2.1).

The site of development differs by cell type. After birth, granulocytes, monocytes, dendritic cells (DCs), erythrocytes, platelets, and B cells develop in bone marrow through the mature B-cell stage (Chapter 7) (Table 2.2). T-cell progenitors leave bone marrow and differentiate into αβ and γδ T cells in the thymus (Chapter 8). Some NK cells develop in the thymus.[7] Tissue-specific NK-cell development occurs outside the thymus, including bone marrow, lymph nodes, and the uterus.[8]

Characteristics of Hematopoietic Stem Cells

HSCs are rare in human bone marrow: 1 in 10 000 cells. They occupy distinct niches. One is close to bone and contains osteoblasts (endosteal niche), and the other is associated with the sinusoidal endothelium (vascular niche). Quiescent HSCs can be found near the arterioles in the endosteum. Actively dividing HSCs are located near the sinusoid regions close to the central veins. Different lineages of progenitors have preferred niches for development, and many HSCs are closely associated with perivascular mesenchymal stem cells.[3]

Long-term human HSCs divide once or twice per year. HSCs have characteristic flow cytometric light-scattering properties (low side scatter, medium forward scatter), no lineage-specific markers (Lin$^-$; *e.g.,* lacking CD2, CD3, CD5, CD7, CD14, CD15,

TABLE 2.1 Important Cell Surface Antigens on Hematopoietic Cells

Cell Type	Surface Antigens	Predominant Location
Hematopoietic Stem Cells		
Bone marrow hematopoietic stem cells (HSCs)	CD34$^+$, Lin$^-$, 90$^+$	Bone marrow
Peripheral blood HSCs	CD34$^+$, Lin$^-$, CD38$^+$, CD71$^+$	Blood
Myeloid Cells		
Monocytes	CD14, CD35 (CR1), CD64	Blood
Macrophages	(FcRγ1)CD68, CD13 CD64,CD35	Tissue

or CD16), and expressing CD34, CD90, and CD49f.[6] As HSCs become active, they lose expression of CD90 and CD49f before diversion to lymphoid or myeloid precursors. Lymphoid precursors express CD10, CD45Ra, whereas myeloid precursors express CD135.

Transcription factors are unique for each population. For HSCs, these include SOX8, SOX18, and NFIB. Out of quiescence, HSCs express MYC and IKZF1. Key signaling pathways include Notch and Wnt/β-catenin.[3]

A long-lived stem cell has the capacity for self-renewal via asynchronous division.[9] HSCs circulate in peripheral blood with 10 to 100 times less frequency. Mobilization of “stem cells” to the periphery is induced by G-CSF. Of these induced cells, about 5–20% are true stem cells, although most are Lin$^-$.[9] Peripheral blood HSCs are more differentiated than bone marrow HSCs and have less self-renewal properties. Peripheral blood HSCs engraft 2 to 3 days faster than conventional bone marrow HSCs and are important in the reduction of bone marrow transplantation morbidities.

Regulation of Hematopoietic and Lymphopoietic Cell Growth and Differentiation

Regulation of stem cell differentiation occurs through interactions with a variety of microenvironmental factors. Cell surface receptors recognize either soluble ligands (*e.g.*, cytokines) released by other cells or surface ligands (*e.g.*, cell interaction molecules) expressed on adjacent cells. These receptors can facilitate differentiation. The differential expression of receptors on the stem cells allows control of proliferation and differentiation along one of the hematopoietic or lymphoid lineages.[6]

FIG 2.1 The differentiation of hematopoietic cells.

Cytokines (Chapter 9) affect the growth and maintenance of pluripotent stem cells, as well as the development and differentiation of specific cell lineages. The effect of the cytokine can depend on whether the cell has previously been or is concurrently being stimulated by other cytokines. The stage of differentiation, as well as the presence or absence of the cytokine's receptor on the cell surface, also affects the cellular response.

Stromal cells located within bone marrow and the thymus regulate hematopoietic and lymphoid cell growth and differentiation by releasing cytokines, such as interleukin 4 (IL-4), -6, -7, and -11; leukemia inhibitory factor (LIF); granulocyte macrophage–colony-stimulating factor (GM-CSF); G-CSF; and stem cell factor (SCF).[3] Stromal cells also participate in cell–cell interactions with progenitors that express fibroblast growth factor 1 (FGF-1) and FGF-2, which support HSC expansion. Stromal cells form the intercellular matrix (*e.g.,* fibronectin and collagen), which binds to the selectin and integrin receptors present on hematopoietic and lymphoid progenitors.[10]

Cytokines That Affect the Growth and Maintenance of Pluripotent and Multipotent Stem Cells

Pluripotent stem cells can reconstitute cells of the hematopoietic and lymphoid lineages. Maintenance of pluripotent capacity is mediated through factors that keep HSCs quiescent, including c-kit, N-cadherin, osteopontin, transforming growth factor-β (TGF-β), and Wnt. Factors that have a negative effect on quiescence include Hedgehog and the notch ligands Delta and Jagged.[3] Because the stem cell pool is depleted as the progeny differentiate, a low level of proliferation of stem cells is required to avoid exhaustion. The entry of stem cells into the cell cycle and the subsequent proliferation, as well as commitment to particular lineages, are controlled by cytokines and transcription factors. Data suggest that flt-3 ligand, c-kit ligand, and megakaryocyte growth and development factor all promote long-term stem cell expansion. The combination of c-kit ligand, IL-3, and IL-6 causes more rapid expansion but does not allow long-term extension of precursor cells.[11]

Several cytokines, alone or in combination, promote stem cell growth (Table 2.3).[4] Cytokine combinations are more effective at inducing stem cell growth compared with individual cytokines. IL-1 promotes stem cell growth by inducing bone marrow stromal cells to release additional cytokines and by synergistically stimulating these cells in the presence of other cytokines. IL-3 promotes the growth of hematopoietic progenitors. The effect is significantly enhanced by IL-6, IL-11, G-CSF, and SCF. Stromal cell–derived IL-11 enhances IL-3–induced colony formation in 5-fluorouracil–resistant stem cells. Cytokines secreted by stromal cells (*e.g.,* IL-6, G-CSF, and SCF) exert their effects by shortening the G0 period in stem cells. IL-3 acts on cells after they have left G0. IL-12 is unable to support the growth of primitive hematopoietic stem cells, either by itself or in conjunction with IL-11 or SCF. However, it acts in synergy with IL-3 and IL-11, or IL-3 and SCF, to enhance stem cell survival and growth.

In some situations, a cytokine can enhance the growth of hematopoietic and lymphoid cells, whereas in others the same cytokine can inhibit cell growth or enhance differentiation. LIF

TABLE 2.3 Cytokines Important for Hematopoietic Cell Growth and Differentiation

Cytokines	Stem Cells	Thymocytes	B Cells	Natural Killer (NK) Cells
Interleukin (IL)-1	Acts on stromal cells	Differentiation		
IL-2		Pleomorphic	Proliferation	Proliferation
IL-3	Proliferation			
IL-4		Pleomorphic	Promotes (low) Prevents (high)	Inhibits IL-2
IL-5			Proliferation/differentiation	
IL-6	Shortens G0	Enhances stimulation	Maintains potential	Enhances IL-2
IL-7		Survival/proliferation	Proliferation of pro- and pre-B cells	Activation
IL-10			Survival	
IL-11 Oncostatin M	Shortens G0		Maintains potential	
IL-12	Survival			Activation proliferation
IL-13			Activation/division of mature B cells	
IL-15			Proliferation	Development/survival
IL- 21			Proliferation	Expansion
Stem cell factor (SCF)/c-kit	Survival	Atrophy	Maintains potential	Expansion
G-CS	Shortens G0		Maintains potential	
FLt3 ligand	Growth factor		Increases proliferation	Expansion
Stromal cell–derived factor (SDF)1-α		Proliferation/regeneration	Chemoattractant	
Leukemia inhibitory factor (LIF)	Proliferation	Atrophy		
Thrombopoietin	Expansion/regulates self-renewal			
Tumor necrosis factor (TNF)-α	Proliferation: inhibits granulocytes			
Transforming growth factor (TGF)-β	Inhibits growth enhanced granulocytes			
Macrophage inflammatory protein (MIP)-1α	Inhibits			
Nerve growth factor (NGF)			Proliferation/differentiation	Expansion

can enhance the growth and development of bone marrow progenitor cells along multiple lineages in media containing IL-3, IL-6, and GM-CSF. However, in the absence of other cytokines or factors in serum, LIF has little effect on the growth and development of CD34$^+$ progenitors. TGF-β and IL-4 are potent inhibitors of hematopoietic progenitor cell growth; yet they enhance granulocyte development. Tumor necrosis factor-α (TNF-α) inhibits the development of granulocytes, but it can potentiate IL-3 effects on hematopoietic progenitor cell proliferation.

Other cytokines have effects on the proliferation and differentiation of multipotent progenitors of hematopoietic and lymphoid cells. GM-CSF and IL-3 promote development of granulocytes, macrophages, DCs, and erythrocytes. IL-6 participates in the development of neutrophils, macrophages, platelets, T cells, and B cells. Thrombopoietin signaling promotes stem cell self-renewal to increase transplantation success.[7]

Cytokines That Inhibit Hematopoietic Stem Cell Growth

Cytokines produced by mature cells can downregulate hematopoietic stem cell growth. Macrophage inflammatory protein-1α (MIP-1α) is an inhibitor of hematopoietic progenitor cell proliferation. Other factors regulate stem cell growth through a variety of mechanisms, including the promotion of terminal differentiation (*e.g.*, interferon-γ [IFN-γ] and TGF-β) or through the induction of apoptosis (*e.g.*, TNF-α). When pathologic conditions exist, these cytokines can have adverse effects on hematopoietic and lymphoid cell development.

Cytokines Affecting Development and Differentiation of Specific Cell Lineages

Differentiation begins with the commitment of pluripotent stem cells to a specific lineage. Cytokines can have lineage-specific effects that act specifically at late stages of differentiation. Erythropoietin regulates the later stages of erythrocyte differentiation, whereas G-CSF induces granulocyte differentiation and macrophage colony-stimulating factor (M-CSF) promotes macrophage maturation.[12] Cytokines that play an important role in the growth and development of specific cell lineages are described below under each cell type.

KEY CONCEPTS

Cells of the Immune System

- Pluripotent stem cells in bone marrow give rise to all lineages of the immune system, platelets, and red blood cells.
- Development and regulation of cells of the immune system is associated with programmed appearance of specific cell surface molecules called "cluster of differentiation" (CD) markers and with responsiveness to selective cytokines.
- Mature cells of the immune system include antigen-presenting cells (APCs); phagocytic cells, including neutrophils, eosinophils, and basophils; and lymphocytes, including T cells, B cells, and natural killer (NK) cells, as well as other innate lymphoid cells.
- APCs include monocytes, macrophages, dendritic cells (DCs), B cells, endothelial cells, epithelial cells, and adipocytes. They can direct the differentiation and function of both innate and acquired immune cells.
- Polymorphonuclear (PMN) granulocyte cells are important in the early response to stress, tissue damage, and pathogens. They include neutrophils, eosinophils, and basophils.
- Lymphocyte lineages have discrete subpopulations with specialized functions. These include CD4 and CD8 T cells, B-1 and conventional B-2 B cells, and NK and other innate lymphoid cells. CD4 T-helper (Th) subsets include regulatory T cells (Tregs), Th17, and Tfh cells.

Mature Cells of the Immune System

The mature cells of the immune system primarily arise from progenitor cells in bone marrow. They include both nonspecific and antigen-specific effector cells.

Antigen-Presenting Cells

The central player in both nonspecific and antigen-specific lines of defense is the antigen-presenting cell (Chapter 6). In addition to their nonspecific effector functions, these cells are crucial for the development of specific immune responses. With maturation, these cells enter the blood (Table 2.4) and circulate into the tissues and organs.

Antigen-presenting cells (APCs) are found in the solid lymphoid organs and skin (Chapter 19) at a frequency that varies from 0.1–1%. Specialized APCs in B-cell areas of lymph nodes and spleen are termed *follicular dendritic cells* (FDCs). They trap antigen–antibody complexes important in the generation and maintenance of memory B cells. FDCs do not express major histocompatibility complex (MHC) class II molecules as do other APCs. Instead, they have receptors for immunoglobulin G (IgG) (FcγRI [CD64]) and complement component C3b (CR1 [CD35]), respectively.

Monocytes–Macrophages

Monocyte–macrophage lineage cells exist in blood (~10% of leukocytes) primarily as monocytes, which are large 10- to 18-µm cells with peanut-shaped, pale purple nuclei as determined by Wright staining (see Table 2.4). The cytoplasm, which is 30–40% of the cell, is light blue and has azurophilic granules that resemble ground glass with intracytoplasmic lysosomes. The cells express MHC class II, CD14 (the receptor for lipopolysaccharide), and distinct Fc receptors (FcRs) for Ig. The latter include FcγRI (or CD64), which has a high affinity for IgG, and FcγRII (or CD32), which is of medium affinity and binds to aggregated IgG. FcγRIII (or CD16) has low affinity for IgG and is associated with

antibody-dependent cellular cytotoxicity (ADCC). It is expressed on macrophages, but not on blood monocytes. Monocytes and macrophages also express CD89, the Fc receptor for IgA.[12]

Macrophages are more differentiated monocytes that reside in various tissues, including the lungs, liver, and brain.[13] Cells of the monocyte–macrophage lineage adhere strongly to glass or plastic surfaces. This process activates them, and this can confound functional studies when they are isolated in this way. Many cells of this lineage phagocytose organisms or tumor cells *in vitro*. Cell surface receptors, including CD14, Fcγ receptors, and CR1 (CD35), are important in opsonization and phagocytosis. This lineage expresses MHC class II, and some express the low-affinity receptor for IgE (CD23). Other cell surface molecules include myeloid antigens CD13 (aminopeptidase N) and CD15 (Gal (1–4) or [Fuc (1–3)] GlcNAc) and the adhesion molecules CD68 and CD29 or CD49d (VLA-4). Classic blood monocytes in humans (85%) express high levels of CD14, but no CD16. Nonclassic monocytes express less CD14, but more CD16. This later subset produces more IL-12, TNF-α, and IL-1β. These cells have receptors for various cytokines (*e.g.*, IL-4 and IFN-γ). Activated macrophages are a major source of cytokines, including IFN, IL-1, and TNF, as well as complement proteins and prostaglandins.

Macrophages, along with dentritic cells (DCs), are much more plastic in differentiation and function than previously realized. They can be alternatively activated and thereby become suppressive, developing antiinflammatory properties relevant in immune responses to cancer as well in maintaining adipose integrity. Alternative activation is induced by the T-helper cell 2 (Th2) (Chapter 16) cytokines IL-4 and IL-13.[14]

Monocytes and macrophages arise from colony-forming unit–granulocyte monocyte (CFU-GM) progenitors that differentiate into monoblasts, promonocytes, and then monocytes.[12] Mature monocytes leave bone marrow and circulate in the bloodstream until they enter tissues, where they develop into tissue macrophages (alveolar macrophages, Kupffer cells, intestinal gut macrophages, and microglial cells). Tissue macrophages appear to originate from fetal macrophages and seed tissues early in fetal development, where they are maintained by longevity and slow self-renewal.[13]

Several cytokines participate in the development of monocytes and granulocytes. SCF, IL-3, IL-6, IL-11, and GM-CSF promote development of myeloid lineage cells from CD34$^+$ stem cells, especially at early stages. M-CSF acts at later stages of development and is lineage specific, inducing macrophage maturation.[12]

Dendritic Cells

DCs express high levels of MHC class II molecules and are potent inducers of primary T-cell responses. Except for bone marrow, they are found in virtually all primary and secondary lymphoid tissues and in skin, mucosae, and blood. DCs are abundant in the thymus medulla for selection of thymocytes.

DCs are derived from CD34$^+$ MHC class II-negative precursors present in bone marrow, which also give rise to macrophages and granulocytes. GM-CSF and TNF-α are involved in DC development.[15] DCs residing in peripheral sites, such as skin, the intestinal lamina propria, lungs, the genitourinary tract, and so on, are typically immature. These cells are more phagocytic with less MHC class I, MHC class II, and costimulatory molecules. These immature DCs take up antigens in tissues for subsequent presentation to T cells, and as they migrate, they mature into efficient APCs.

The predominant APCs of the skin are the Langerhans cells[16] found in the epidermis and characterized by rocket-shaped granules called *Birbeck granules.* Immature tissue DCs in peripheral tissues engulf and process antigen and home to T-cell areas in the draining lymph nodes or spleen.[17] Mature DCs can directly present processed antigens to resting T cells to induce proliferation and differentiation, and this is a key functional difference between mature DCs and macrophages. The effector cells produced after this presentation then home to the site of the antigenic assault.

TNF-α maintains viability of Langerhans cells in skin and stimulates their migration. In Peyer patches (Chapter 20), immature DCs occur in the dome region underneath follicle-associated epithelium (FAE), where they actively endocytose antigens taken up by M cells. Mature interdigitating DCs are found in T-cell regions, where they can induce Th2 immune responses (Chapter 16).

Three types of DC are prominent—two types of “conventional” dendritic cells (cDCs) and plasmacytoid dendritic cells (pDCs). cDC1s derive from bone marrow are found in lymphoid tissues and express CD1a and CD11c. About 50% peripheral blood DCs are cDC1. cDC2s express CD141, are similar to murine CD8 α/α DCs in function, and are rare in peripheral blood but are common in lymph nodes. pDCs are high producers of IFN-α. They express CD123 and low levels of CD11c, along with BDCA 2 and 4. DCs can be derived from either myeloid or lymphoid lineages. DCs are largely influenced by stimulation with Toll-like ligands found on a variety of stimuli, which then direct the differentiation and function of innate and acquired immune cells.

Polymorphonuclear Granulocytes

Polymorphonuclear (PMN) granulocytes arise and mature in bone marrow. After release from bone marrow, their life span varies from a few to 5 to 6 days and is regulated by environmental conditions. They constitute 65–75% of the white blood cells in peripheral blood, are 10–20 μm in diameter, and have a multilobed pyknotic nucleus characteristic of cells undergoing apoptosis (see Table 2.4).[18] PMNs use diapedesis to gain access to tissues from blood.

Granulocytes are early responders to stress, tissue damage, or pathogen invasion. Because of their function in phagocytosis and killing, they possess granules with unique staining characteristics that are used to categorize the cells as neutrophils (Chapter 22), basophils (Chapter 23), or eosinophils (Chapter 24).

Neutrophils

Most circulating granulocytes are neutrophils (90%). Their granules are azurophilic and contain acid hydrolase, myeloperoxidase, and lysozymes. These granules fuse with ingested organisms to form phagolysosomes, which kill the invading organism. In some cases, there is extracellular release of granules after activation via the Fc receptors. Neutrophils express CD13, CD15, CD16 (FcγRIII), and CD89 (FcαR). In response to bacterial infection, the number of circulating granulocytes typically increases. This often includes the release of immature granulocytes, called *band* or *stab cells,* from bone marrow. In a mild infection, both the number and the function of neutrophils are increased. This is associated with a delay in apoptosis. With more severe infection, function may be impaired due to the immaturity of cells.

A newly described function of some neutrophils is to release neutrophil extracellular traps, which can capture microbes extracellularly and then use autophagy to digest them intracellularly.[19]

Neutrophils mature from CFU-GM progenitor cells and differentiate within a 10- to 14-day period. These progenitors give rise to myeloblasts, promyelocytes, myelocytes, and finally mature neutrophils. SCF, IL-3, IL-6, IL-11, and GM-CSF promote the growth and development of neutrophil precursors. Other cytokines are important for differentiation of CFU-GM progenitors into mature neutrophils.[20] G-CSF induces maturation of neutrophil precursors into mature neutrophils. IL-4 enhances neutrophil differentiation induced by G-CSF, while inhibiting the development of macrophages induced by IL-3 and M-CSF.

Eosinophils

Eosinophils typically comprise 2–5% of the white cells in blood. They exhibit a unique form of diurnal variation. Peak production occurs at night, perhaps because glucocorticoid levels are lower. Eosinophils are capable of phagocytosis followed by killing, although this is not their main function. The granules in eosinophils are much larger than in neutrophils and are actually membrane-bound organelles. The crystalloid core of the granules contains a large amount of the major basic protein (MBP), which can neutralize heparin and is toxic. During degranulation, the granules fuse to the plasma membrane, and their contents are released into the extracellular space. Organisms that are too large to be phagocytosed, such as parasites, can be exposed to cell toxins by this mechanism. The MBP can damage schistosomes *in vivo*, although damage is minimized because the MBP is confined to a small extracellular space. Eosinophils also release products that counteract the effects of mast cell mediators. Whether eosinophils are absolutely required for helminth control is controversial.

Eosinophils mature from a progenitor (CFU-Eo) into an eosinophilic myeloblast, then an eosinophilic promyelocyte, a myelocyte, and finally a mature eosinophil.[21] Three cytokines are important in the development of eosinophils: GM-CSF, IL-3, and IL-5. GM-CSF and IL-3 promote eosinophil growth and differentiation. SCF also has an effect on eosinophil function. Eotaxin (CCL11) promotes eosinophilia. IL-5 has more lineage-specific effects on eosinophil differentiation. Although it also affects some subsets of T and B cells, it is important for eosinophil survival and maturation. Eosinophils are involved in the pathophysiology of asthma, with contribution to airways dysfunction and tissue remodeling, and IL-5 is being targeted to correct eosinophilia.

Basophils and Mast Cells

Basophils represent less than 1% of the cells in the peripheral circulation. They are characterized by large, deep-purple granules. Mast cells are found in proximity to blood vessels and are much larger than peripheral blood basophils. Their granules are less abundant, and the nucleus is more prominent. There are two different types of mast cells—designated mucosal and connective tissue—depending on their location. Mucosal mast cells require T cells for their proliferation, whereas connective tissue mast cells do not. Both types have granules that contain effector molecules. After degranulation, which is effected by cross-linkage of cell surface IgE bound to cells via the high-affinity receptor for IgE, basophils and mast cells release heparin, histamine, and other effector substances to mediate an immediate allergic attack (Chapters 23 and 42).

Basophils and mast cells share a number of phenotypic and functional features that suggest derivation from a common precursor. Both basophils and mast cells contain basophilic-staining cytoplasmic granules; both express the high-affinity IgE receptor (FcεRI); and both release a number of similar chemical mediators that participate in immune and inflammatory responses, particularly anaphylaxis. They both have been implicated in allergic inflammation and in fibrosis. However, basophils and mast cells also have some distinct morphological and functional characteristics that suggest that they may be distinct lineages of cells, rather than cells at different stages within the same lineage. In human, transcription factor analysis places basophils closer to eosinophils than mast cells.[22]

Basophils mature from a progenitor (CFU-BM) into basophilic myeloblasts and then into basophilic promyelocytes, myelocytes, and finally mature basophils. Less is known about the stages of mast cell development, although they are probably derived from the same CFU-BM progenitor as basophils.

In humans, SCF induces the most consistent effects on the growth and differentiation of both basophils and mast cells. Both IL-3 and SCF are important for intestinal mast cell differentiation. Il-6 can also increase mast cell numbers. This probably explains why T cells are needed for their development.[28] Both IL-4 and IL-9 stimulate mast cell development in mice. However, in humans, only IL-9 acts in synergy with SCF to enhance mast cell growth. Additional cytokines that affect basophil growth include nerve growth factor and GM-CSF or TGF-β, and IL-5 for basophil differentiation.

Platelets and Erythrocytes

Hematopoietic stem cells give rise to platelets and erythrocytes. Platelets are necessary for blood clot formation and mediate a number of immune functions. Mature red blood cells are necessary for oxygen delivery to tissues.[23] Platelets derive from CFU-GEMM progenitors, which differentiate into burst-forming units for megakaryocytes (BFU-MEG). BFU-MEG then differentiate into CFU-MEG, promegakaryoblasts, megakaryoblasts, megakaryocytes, and finally platelets.[24] Several cytokines, particularly thrombospondin, IL-1, IL-3, GM-CSF, IL-6, IL-11, and LIF, affect the growth and differentiation of platelets.

Erythrocytes also derive from CFU-GEMM progenitors, but their progenitors are burst-forming units for erythrocytes (BFU-E), which, in turn, differentiate into CFU-E, pronormoblasts, basophilic normoblasts, polychromatophilic normoblasts, orthochromic normoblasts, reticulocytes, and finally erythrocytes. Again, several cytokines, notably GM-CSF, SCF, IL-9, thrombospondin, and erythropoietin, regulate erythrocyte development.

Lymphocytes

Lymphocytes, the central cell type of the specific immune system, represent about 25% of the white blood cells in blood (see Table 2.4). Small lymphocytes range from 7–10 μm in diameter and contain a nucleus that stains dark purple with Wright staining, and a small cytoplasm. Large granular lymphocytes range from 10–12 μm in diameter and contain more cytoplasm and scattered granules. The three types of lymphocytes that circulate in the peripheral blood—T cells, B cells, and ILCs, including NK cells—constitute approximately 80%, 10%, and 10% of the total blood lymphocyte population, respectively (Chapters 7, 8, and 17). In the thymus, most of the lymphocytes (90%) are T cells; however, in the spleen and lymph nodes, only about 30–40%

are T cells. The preponderant lymphocytes in these locations are B cells (60–70%).[25]

T Lymphocytes

T lymphocytes arise from lymphocyte progenitors in bone marrow committed to the T-cell lineage before moving to the thymus. In the early stages of embryogenesis, T-cell precursors migrate to the thymus in waves.[26] Associated with this migration is the developing ability of thymic education elements, epithelial cells, and DCs to select appropriate T cells.[27]

In the thymus, T cells rearrange their specific antigen receptors (TCRs) (Chapter 4) and then express CD3 along with the TCRs on their surface (Chapter 8). Resting T cells in blood typically range from 7–10 μm in diameter and are agranular, except for the presence of a structure termed *Gall body,* which is not found in B cells (see Table 2.4). The Gall body is a cluster of primary lysosomes associated with a lipid droplet. A minority of T cells in blood (about 20%) are of the large granular type, that is, they are 10–12 μm in diameter and contain primarily lysosomes that are dispersed in the cytoplasm. Golgi apparati also are found.

The preponderant form of the TCR, found on about 95% of circulating T cells, expresses TCRαβ.[28] Some $CD3^+$ cells do not express either CD4 or CD8 (double-negative, or DN) and express an alternative TCRγδ. Further differentiation in the thymus occurs from $CD3^+$ cells that express both CD4 and CD8 (double-positive, or DP) to cells expressing either CD4 or CD8 but not both (Chapter 8). These mature cells then circulate in peripheral blood at a ratio of about 2 : 1 (CD4:CD8) and populate lymph nodes, the spleen, and other secondary lymphoid tissues.

T-cell progenitors, which are $CD7^+$, arise in bone marrow from a multipotential lymphoid stem cell. After migration to the thymus, the $CD7^+$ progenitors give rise to a population of $CD34^+$, $CD3^-$, $CD4^-$, and $CD8^-$ T-cell precursors, which undergo further differentiation into mature T cells. Cytokines produced by thymic epithelial cells (*e.g.,* IL-1 and soluble CD23) promote differentiation into $CD2^+$, $CD3^+$ thymocytes (see Table 2.3). IL-7 induces the proliferation of $CD3^+$ DN ($CD4^-$ $CD8^-$) thymocytes, even in the absence of comitogenic stimulation. IL-7 is an absolute requirement for human T-cell development.[29]

IL-2 and IL-4 demonstrate complex effects on thymocyte development. Both can promote development of prothymocytes, as well antagonizing their development. IL-6 acts as a costimulator of IL-1– or IL-2–induced proliferation of DN thymocytes and can stimulate the proliferation of mature, cortisone-resistant thymocytes alone.

Subpopulations of T Cells

T cells can be divided into subsets based on surface expression of CD4 and CD8 as well as by function in immune response. CD4 and CD8 T cells were originally characterized by expression of the respective antigen and association with functional ability. For example, human T cells expressing CD4 provide help for antibody synthesis, whereas cells expressing CD8 develop into cytotoxic T cells. The distinction is better described on the basis of which antigen-presenting molecule is used for TCR interaction. Thus CD4 T cells recognize antigen in the context of MHC class II molecules, and CD8 T cells recognize antigen presented by class I molecules (Chapters 5 and 6). Memory T cells are divided on the basis of expression of CD45R0, CCR7, CD28, and CD95, which categorize the functions of cells as stem cell memory, central memory, transitional memory, effector memory, and terminal effector cells. Early memory T cells have high potential for lymph node homing and proliferation, but later stage cells home to the periphery, are effector cells, and do not proliferate.[30]

Th cells mature in response to foreign antigens. Their function is dependent on the production of cytokine patterns, which characterize them as Th type 1 (Th1), Th2, or Th17.[31] The precursor Th cell first differentiates into a Th0 cell, which produces IFN-γ and IL-4. The cytokine environment subsequently determines whether Th1 or Th2 cells predominate. Th1 cells produce primarily IFN-γ, IL-2, and TNF-α and are important in cell-mediated immunity to intracellular pathogens, such as the tubercle bacillus. Th1 cells primarily use T-bet transcription factor. Th2 cells produce predominantly IL-4, -5, -6, -10, and -13, as well as IL-2; they predominate in immediate or allergic type 1 hypersensitivity and primarily use GATA-3 transcription factor. Other populations of CD4 T cells can develop and rely on IL-23 or IL-12 action upon the cells. If T cells are exposed to IFN-γ, they upregulate both IL-12R and IL-23R, which then produce either conventional Th1 cells or another subset, Th17, which produces IL-17 and is important for controlling immune cell activation in the gastrointestinal (GI) tract. Overactive function of this subset has been associated with autoimmunity. The Th17 population preferentially uses RORγt transcription factor. T follicular helper cells are those classically determined to help B cell responses in germinal centers. They are $CD4^+$, $ICOS^+$, and $PD\text{-}1^+$; and they express transcription factor BCL-6. It is likely that there are other epigenetically altered T cells that allow diversity of function during an immune response.

A minor subpopulation (<5%) of $CD3^+$ cells in peripheral blood express γδ TCR molecules. Most of these cells do not express CD4 or CD8. However, some intraepithelial lymphocytes (IELs) that express γδ TCR also express CD8 αα homodimers in place of conventional CD8 αβ heterodimers. These cells, which are thymus independent, are involved in the initial response to bacterial antigens presented in mucosal epithelium.

Another minor subpopulation of T cells, natural killer T cells (NKT cells), can be $CD4^+$ or $CD8^+$ and express a single Vα chain, Vα24, which recognizes glycolipids in the context of CD1a, rather than a classic MHC molecule.[31,32] NKT cells express MIP-1 α and β and have a Th1 bias, but lack IL-10 production. The final subset comprises regulatory T cells (Tregs), which occur naturally and can be induced *in vitro*. They are $CD4^+$ and express high levels of CD25 and the transcription factor FOXP3 and perhaps GARP.[33] These cells are important in regulatory immune responses. Tregs are reduced in autoimmunity and in adipose tissue during obesity and increased in cancer.

B Cells and Plasma Cells

B cells represent 5–10% of lymphocytes in blood (see Table 2.4). They are typically 7–10 μm in diameter and lack Gall bodies and granules. The cytoplasm is characterized by scattered ribosomes and isolated rough endoplasmic reticulum (RER). Unless the cells are activated, the Golgi apparatus is not prominent. B cells express cell membrane immunoglobulin (mIg), the majority expressing both IgM and IgD.[34] A small minority of B cells express either surface IgG or IgA. Cell surface molecules found on B cells (Chapter 7) include CD19, CD20, CD23, CD40, CD72, CD79a and b, MHC class II, FcγRII (CD32), and complement receptors C3b (CR1a; CD35) and C3d (CR2a; CD21). B-cell mIg is a part of a B-cell receptor complex that consists of CD19, CD21, and CD81 (Chapter 4). B-cell proliferation and differentiation processes take place in the germinal centers of the lymph nodes.

Upon activation and cross-linking of surface Ig by specific antigen, B cells undergo proliferation and differentiation to produce plasma cells, which lose expression of mIg and MHC class II molecules. Plasma cells (10–15 μm) are not normally found in blood. They display an eccentric nucleus and a basophilic cytoplasm with a well-developed Golgi apparatus and parallel arrays of expanded Ig-containing RER. Plasma cells are nondividing, specialized cells terminally differentiated from B cells and whose primary function is to secrete Ig.

In vitro studies of cytokines involved in the development of early B-cell progenitors show that combinations of SCF (but not IL-3) with IL-6, IL-11, or G-CSF can maintain B-lymphoid potential.[34] Stromal cell–dependent differentiation of fetal pro-B cells occurs in conjunction with FLK-2/FLT-3 ligand and IL-7 and on several transcription factors, including PU.1, IKAROS, E2A, EBF, PAX5, and IRF8. Unlike in mice, IL-7 is not an absolute requirement for B-cell development in humans.[35]

IL-4 has a variety of important effects on B-cell growth and differentiation. Low doses of IL-4 induce pre-B cells to differentiate into B cells expressing surface membrane IgM, whereas higher doses of IL-4 inhibit differentiation of B cells. In mature B cells, IL-4 increases expression of MHC class II, CD23, and CD40; promotes activation and progression to the G1 stage of the cell cycle; enhances proliferation after stimulation through the Ig receptor; and induces immunoglobulin class switch in human to IgG4 and IgE (IgG1 and IgE in mouse). IL-13, which is closely related to IL-4, has many similar effects on B cells.

IL-2, -5, -6, and -11 and nerve growth factor act on mature B cells to either enhance their proliferation or promote their differentiation into immunoglobulin-secreting cells. IL-10 enhances the viability of B cells *in vitro*, increases MHC class II expression, and augments the proliferation and differentiation of B cells after stimulation through the Ig receptor or CD40. TGF-β1 is a major switch factor for IgA. This cytokine induces human B cells triggered by mitogen to switch to both IgA1 and IgA2. Stromal cell-derived factor 1 (SDF-1) attracts early-stage B-cell precursors and is a likely mechanism whereby B cells form islands in bone marrow.

There are at least two major populations of B cells: B-1 cells, which are found in the follicular mantle and peritoneal cavity, and conventional B-2 cells, which are found in lymphoid follicles. The B-1 lineage predominates early in gestation and produces natural antibodies of the IgM isotype.[36] There is good evidence for local expression of IgA plasma cell precursors in the ileum important for bacterial containment.[37]

Innate Lymphoid Cells

Natural Killer Cells

A new nomenclature has arisen to classify lymphocytes that have cytolytic or noncytolytic functions typical of T cells, but do not express a T cell receptor. The first described were cytolytic NK cells, which comprise about 10–15% of circulating lymphocytes (see Table 2.4). These cells are usually larger than typical lymphocytes (10–12 μm), but have less nuclear material and more cytoplasm. They possess electron-dense, peroxidase-negative granules and a developed Golgi apparatus. Functional NK cells can be found in the fetal liver as early as 6 weeks' gestation. These fetal NK cells express cytoplasmic CD3 proteins but no TCR rearrangements. Evidence suggests that an Fcγ receptor–positive cell that does not express lineage-specific markers (Lin$^-$) exists in the fetal mouse thymus, where it normally gives rise to T cells. However, if removed from the thymus, the cells develop into CD3$^-$ NK cells. Such CD3$^-$ cells with variable CD16 expression exist in the human thymus and can be induced to proliferate, express NK-associated antigens, and exhibit NK cell function *in vitro*. These cells also express substantial levels of CD3δ and CD3ε in the cytoplasm.[38]

Mature NK cells in blood do not express conventional antigen receptors, such as TCR or Ig, and the genes for these receptors remain unrearranged. Some express FcγRIII (CD16) and others express CD56, an adhesion molecule. More than 90% of these cells are CD11b$^+$ but CD27$^-$. In tissues, subsets of human NK cells express variable levels of both CD11b and CD27, and this defines their function (tolerant, cytotoxic, or regulatory). NK cells, like T cells, also express the CD2 molecule. NK cells express the β chain of the IL-2 receptor, CD122, which allows resting NK cells to respond directly to IL-2.

The function of some NK cells is to provide nonspecific cytotoxic activity toward virally infected cells and tumor cells (Chapter 17). When provided with an antibody, NK cells can kill specifically. This death delivery mechanism, known as ADCC, occurs via binding of the antibody to the Fcγ receptor CD16. After activation, NK cells produce cytokines, such as IFN-γ, and this affects proliferation and differentiation of other cell types, especially DCs. Some of the recognition molecules on human NK cells activate, some inhibit, and some act as receptors for MHC class I molecules.

NK cells express a number of membrane antigens in common with T cells, and they share functional properties with some T-cell subsets, suggesting a common origin. NK cells are found in fetuses before the development of T cells or the thymus, and they develop normally in nude, athymic mice. NK cells probably develop extrathymically, and data suggest that they can develop from stem cells in lymph nodes. NK cells arise from "triple-negative" (CD3$^-$CD4$^-$CD8$^-$) precursors that are CD56$^+$, but CD34$^-$ and CD5$^-$. T cells, in contrast, develop from triple-negative precursors that are CD34$^+$CD5$^+$CD56$^+$. It is likely that T cells and NK cells arise from a common triple-negative precursor with the phenotype CD7$^+$CD34$^+$CD5$^+$CD56$^+$.

The α chain of the IL-2 receptor, CD25, is the prime determinant of T cell versus NK lineage specificity. Once CD25 is upregulated, the cell is destined to become a T cell. IL-15 and IL-7 play major roles in the early development of NK cells. FLT ligand and c-KIT also facilitate NK cell expansion. In mature NK cells, IL-2 induces proliferation and activation. This probably occurs via the IL-2 receptor β chain (CD122), as NK cells do not express CD25. IL-2 also induces the growth of NK cells from precursors in bone marrow cultures. Both IL-7 and IL-12 activate NK cells. Although IL-4 inhibits the effects of IL-2 or IL-7 on NK cells, it acts synergistically with IL-12 to induce proliferation of CD56$^+$ cells. IL-6, despite having no effect by itself, enhances NK cell activity in thymocytes cultured with IL-2. Finally, IL-15 is involved in signaling NK cells for survival.[39] Subsets of human NK cells develop on the basis of responsiveness to TGF-β and IL-10 (tolerant); IL-12 and IGF-1 (cytotoxic); and TGF-β, IL-7, and IL-15.[40]

Noncytotoxic Innate Immune Cells

These cells, which are similar in function to T-helper subsets, are divided into three main groups, ILC1, ILC2, and ILC3, defined by the cytokines they produce.[41] ILC1 cells are noncytotoxic Lin$^-$ cells that produce INF-γ and TNF. ILC2 cells produce Th2 cytokines, such as IL-4, -5, -9, and -13; and some produce amphiregulin. ILC3 cells produce IL-17A, -17F, and -22; GM-CSF;

and TNFα and are the most heterogeneous. They also express CCR6 and CD117 and can be divided on the basis of expression of the NCR Nkp44. The role of these cells in normal host function and responses to chronic inflammatory stimuli and cancer is under intensive study.

KEY CONCEPTS

Tissues of the Immune System

- Stem cells proliferate and mature into effector cells in the primary lymphoid organs, which include bone marrow and the thymus.
- Mature immune cells reside in secondary lymphoid organs, where additional maturation occurs and immune responses are generated.
- The spleen and lymph nodes comprise the systemic immune system, which functions to protect the body from antigens in the lymphatic drainage and the bloodstream.
- The mucosal immune system (respiratory, gastrointestinal, and genital) and the skin and adipose tissue have distinguishing features that differentiate the immune system at these sites from those of the systemic immune system.
    - Mucosal sites include the mucosa-associated lymphoreticular tissue (MALT).
    - Commensal organisms at mucosal surfaces are an important component of the immune response at these sites.

MAJOR LYMPHOID ORGANS

The primary lymphoid organs are sites where lymphocytes differentiate from stem cells and then proliferate and mature into effector cells. In humans, from birth to old age, these functions are carried out only in bone marrow and the thymus.

Bone Marrow

Bone marrow provides the environment necessary for the development of most of the white blood cells of the body (Fig. 2.2). At birth, most bone cavities are filled with actively dividing blood-forming elements known as "red" marrow. By 3 to 4 years, however, the tibia and femur become filled with fat cells, limiting their role in hematopoietic development. The ribs, sternum, iliac crest, and vertebrae remain 30–50% cellular and produce hematopoietic cells throughout a person's life.[1] Main components of bone marrow include blood vessels, cells, and extracellular matrix. The production of cells from HSCs occurs in areas separated by vascular sinuses. The walls of the surrounding sinus contain a layer of endothelial cells with endocytic and adhesive properties. These specialized endothelial cells of the sinuses appear to produce type IV collagen and laminin for structural support via CXCL-12 (SDF-1) interactions. These cells also elaborate CSFs and IL-6. The outer wall of the sinus is irregularly covered with reticular cells that branch into areas where cells develop and provide anchors by producing reticular fibers. Megakaryocytes lie against this wall, touching the endothelial cells.

A functional unit of marrow, called a *spheroid,* contains adipocytes, stromal cell types, and macrophages. These reticular cell networks compartmentalize the developing progenitor cells into separate microenvironments called *hematons.* Osteoblasts and osteoclasts regulate the production of progenitor cell expansion.[3]

The distribution of stem and progenitor cells across the radial axis of bone suggests that HSCs are next to the bone surface, whereas the more mature progenitor cells are nearer to the central venous sinus to facilitate release of mature cells. The production of new progenitor cells from stem cells occurs as a result of interactions between stem cells and stromal cells. Given the right stimuli, most of the progeny proliferate and differentiate further, which may result in migration from the bone marrow. In migrating, the cells become detached from stromal elements and progress toward the central sinus.

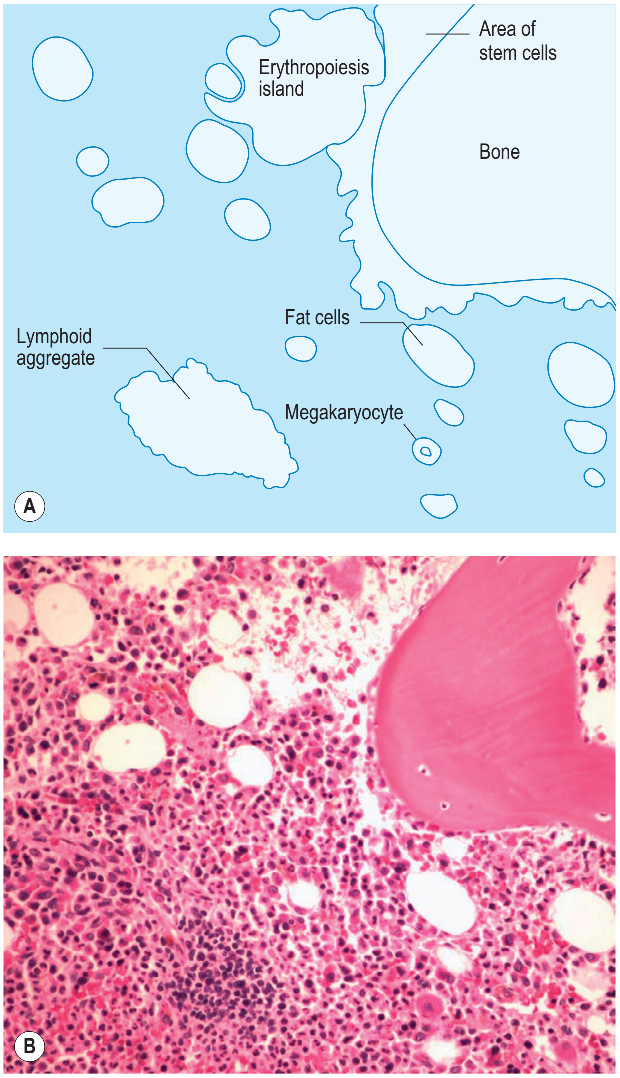

FIG 2.2 Structure of bone marrow, showing islands of erythropoiesis, granulopoiesis, and scattered lymphocytes.

Control of hematopoiesis is regulated by both positive and negative cytokines, and by upregulation and downregulation of various adhesion molecules in committed progenitor cells. The molecules involved include the fibronectin receptor, glycoproteins IIb and IIIa, ICAM-1 (CD54), LFA-1 (CD11, CD18), LFA-3 (CD58), CD2, and CD44. Adhesion molecules on stromal cell surfaces include fibronectin, laminin, ICAM-1 (CD54), types I, III and IV collagen, and N-CAM. The most clearly established role for adhesion molecules involves fibronectin, which allows erythroid precursors to bind to stromal cells and thus facilitates progression from erythroblast to reticulocyte. Molecular signals important for the HSC niche include N-cadherin, which regulates osteoblastic interactions with HSCs; WNT/B catenin signals, which are important for the self-renewal of HSCs; VEGF, which is important for coupling osteoblasts with vascular endothelial cells; and PDE2, which is an inflammatory mediator that can increase HSC numbers.

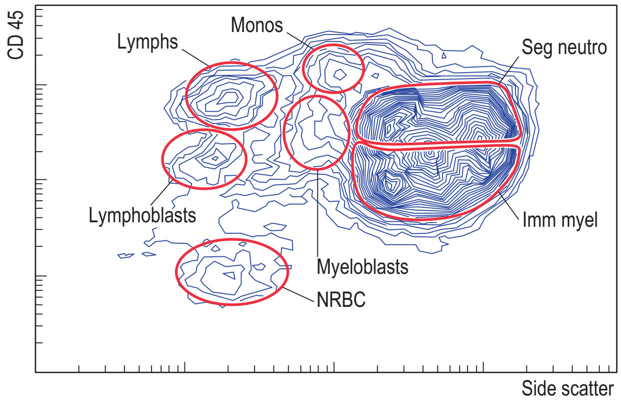

FIG 2.3 Flow cytogram of Normal Human Bone Marrow Based on CD45 Expression and Side Scatter. Most of the major hematopoietic populations can be delineated. In this example 1.5% are red blood cell precursors (NRBCs), 1.5% are lymphoblasts, 3% are mature lymphocytes (Lymphs), 3% are monocytes (Monos), 4% are myeloblasts, 45% are segmented neutrophils (Seg neutro), and 42% are immature myeloid cells (Imm myel).

Accessory cell populations in bone marrow regulate many aspects of hematopoiesis. The upregulation of growth of the earliest progenitor cells is mediated by cytokines. For example, macrophages produce IL-1, which then induces stromal cells to express growth factors, such as GM-CSF, IL-6, and IL-11. Downregulation can occur at any stage. For example, T cells regulate hematopoiesis by producing factors that act on the early erythroid progenitor cells, BFU-E. Later progenitors, CFU-E, are fully differentiated by erythropoietin. Activated T cells, however, produce factors that suppress BFU-E and CFU-E *in vitro*.

The cells in bone marrow were originally characterized by morphology. The predominant types are those of the myeloid lineage, which account for about 50–70% of the cells. Red blood cell precursors represent 15–40% of the total cells. Other lineages exist in lower proportions (<5%). With the advent of cell surface antigen markers and flow cytometry, a more precise delineation could be made (Fig. 2.3). Thus of the mature leukocytes in bone marrow, approximately 70% are $CD3^+$, $CD14^+$, $CD20^+$, or $CD11b^+$. Both memory T and B cells return to bone marrow after generation. These are designated as Lin^+. Of the Lin^- cells, about 6% are $CD33^+$ and primarily of myeloid lineage. A Lin^-CD71^+ population comprises about 18% of the total and is mostly of red blood cell lineage.

Thymus

The thymus is located in the mediastinum and below the sternum. This bilobed organ develops from the third and fourth pharyngeal pouches and is endodermal in origin. It is organized into a loose lobular structure, with areas in each lobe consisting of a cortex of rapidly dividing cells and a medulla that contains fewer, but more mature, T cells (Figs. 2.4 and 2.5). This arrangement has long suggested a scenario for differentiation, where cells progress from the cortex to the medulla. Nonlymphocyte cells play very important site-specific roles in the development of T cells. Epithelial cells are scattered throughout the thymus. Depending on their location, they are known as *nurse cells, cortical epithelial cells,* or *medullary epithelial cells.* Macrophage-type cells and interdigitating cells that are derived from bone marrow are located at the junction between the cortex and the medulla and are involved in T-cell selection.

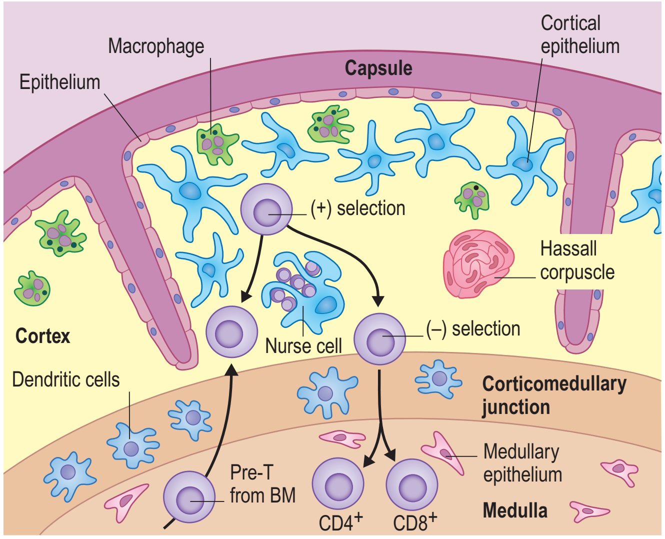

FIG 2.4 Structure of the Thymus, Showing pre–T Cells Entering from Bone Marrow (BM). Positive selection occurs on thymic epithelial cells; negative selection probably occurs during interactions with cortico-medullary dendritic cells. This may explain why single-positive CD4 or CD8 cells are found primarily in the medulla. Nurse cells appear to remove negatively selected cells. Hassall corpuscles are specialized cells producing thymic growth factors.

Enlarged, activated T-cell precursors from bone marrow begin by colonizing the subcapsular region of each lobe. These are actively proliferating and can self-renew. Selection begins when their progeny encounter MHC class II–bearing cortical epithelial cells. A further education process probably occurs by interaction with macrophage-like cells found at the cortico-medullary junction and in the medulla.

Thymus nurse cells, found in the cortex, were originally thought to contribute to the thymic education of T cells. Because large numbers of thymic cells (50–200) can be found inside each nurse cell, it was believed that these structures provided an environment where selection and expansion could occur. There is now evidence that secondary rearrangement of TCRα can occur in these structures.[42]

A structure known as *Hassall corpuscle,* which consists of concentric whorls of epithelial cells, is found in the medulla; but its function is unclear. Hassall medullary epithelial cells contain secretory granules, and this network of cells may be active in the production of thymic hormones, especially thymic stromal lymphopoietin, which has a role in production of DCs that select Tregs in the thymus.[43] In the fetus, these bundles of cells are widely scattered but become larger as the thymus matures. The center cells eventually become keratinized and die.

Thymic differentiation (Chapter 8) involves rearrangement of functional TCR (Chapter 4), surface expression of CD3, and both positive and negative selection (Chapter 8), which allow only a small percentage of T cells to survive. Pre–T cells in the thymus express CD2, CD5, and CD7, as well as activation antigens, such as CD38 and the transferrin receptor (CD71). Pre–T cells express intracytoplasmic CD3 and exhibit rearrangements in the TCRβ chain. Successful rearrangement of TCRα allows the cell to progress to the next stage of development, with functional

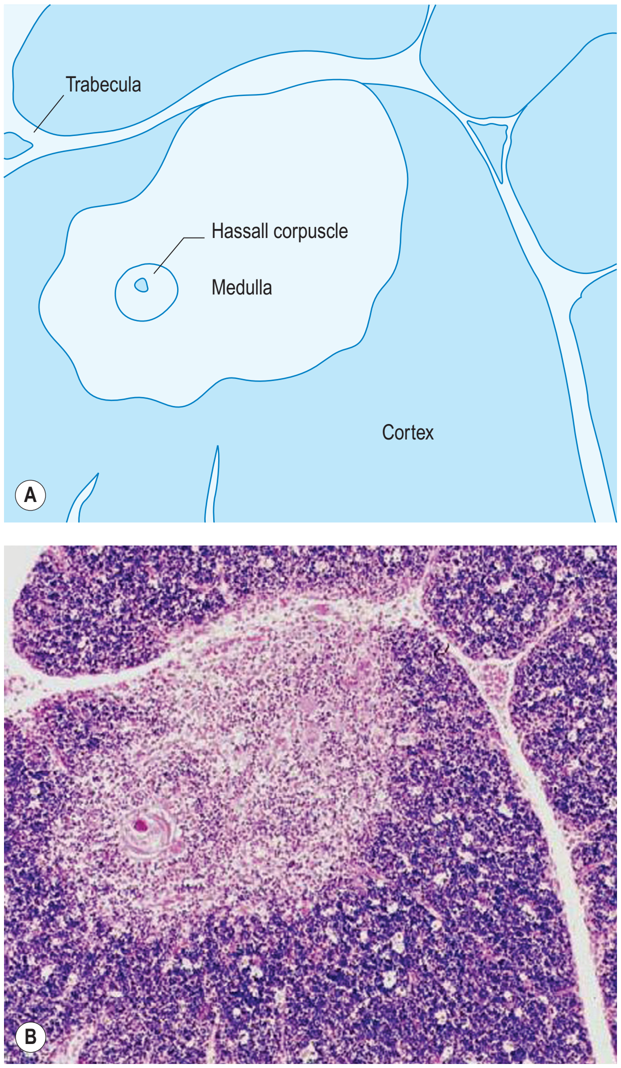

FIG 2.5 Human Thymus Showing Cortex and Medullary Areas. Cortical thymocytes are stained with an anti-CD1 antibody. Most medullary T cells do not express CD1.

TCR and CD3 on the cell surface.[27] Most of the cells in the thymus (85%) express both CD4 and CD8 on their surface and are termed DP. They also express CD1 and CD69, an activation marker. CD69 is expressed until the cell reaches the single-positive stage, where it expresses either CD4 or CD8, but not both.

T cells are CD45RO$^+$ at the DP stage into the single-positive stage. Before leaving the thymus, CD45RO is downregulated, and CD45RA appears. The most mature thymus cells lose CD1 expression and either CD4 or CD8 expression. Most of these mature cells are also negative for activation molecules (CD38 and CD71). However, they acquire an adhesion molecule called *CD44,* which is necessary for homing. Upon completion of this thymus selection and education process, mature CD4 or CD8 T cells leave the thymus and enter the peripheral circulation via the postcapillary venules at the cortico-medullary junction.

After birth and during childhood, the thymus continues to grow and select T cells. This process is probably necessary to develop a fully normal repertoire. Before puberty, however, the thymus begins to involute. The rapidly dividing cortex is the first to atrophy, leaving medullary areas intact. The sensitivity of cortical thymocytes to hormone-induced death probably accounts for the involution, although human thymocytes are less sensitive to glucocorticosteroids compared with murine thymocytes. However, an increase in steroids reduces immature thymocyte numbers and enhances thymus involution. Recent evidence suggests that active TCR rearrangements, and hence T-cell development, continue in the adult thymus, albeit at a lower level than during childhood. There is an age-associated decline in new T-cell production, such that by age 75 years, the ability to make new T cells in humans is severely reduced.

Development of Hematopoietic and Lymphoid Cells

Although most of the key steps during the growth and development of hematopoietic and lymphoid cells occur in bone marrow and the thymus, additional maturation steps occur after the cells leave those tissues. For example, monocytes and DC precursors migrate from blood vessels into tissues, where they mature into macrophages and DCs, respectively. There is recent evidence for a tissue-associated macrophage that is fetal in origin. Mast cells and eosinophils also undergo further differentiation in resident tissues. After leaving bone marrow and the thymus, B and T cells undergo further maturation and memory cell development in secondary lymphoid organs. There is strong evidence that some T cells, particularly the γδ T cells residing in mucosal epithelium, do not develop in the thymus.

SECONDARY LYMPHOID ORGANS

Secondary lymphoid organs are sites where mature lymphocytes reside and where immune responses are generated. Secondary lymphoid organs belong to either the systemic immune system or the mucosal immune system. The systemic immune system, which includes the spleen and lymph nodes, functions to protect the body from antigens in the lymphatic drainage and circulating in the bloodstream. The mucosal immune system responds to antigens that enter through mucosal epithelium and plays an important role in the inductive phase of the immune response. Unique features differentiate the mucosal immune system from the systemic immune system (Chapter 20). These include efferent, but not afferent, lymphatics, a specialized FAE involved in antigen sampling at the mucosal surface (Fig. 2.6), specialized DCs that rapidly process and present antigens to initiate antigen-specific immune responses, unique distribution and subsets, and an environment that promotes class switching to IgA.

Systemic Immune System

Spleen

The human spleen is surrounded by a capsule of fibrous tissue with many trabeculae traversing from the capsule into the tissue of the spleen. These trabeculae branch and anastomose, forming a complex framework of lobules. Splenic blood vessels enter and exit through the hilum of the spleen and branch into smaller vessels within the trabeculae. Splenic tissue is supported by a fine network of reticular cells and fibers, called the *reticulum,* which connects and supports the trabeculae, blood vessels, and the capsule. The lobules of the spleen can be functionally divided into two compartments, the red pulp and the white pulp. The largest compartment is the red pulp, which contains numerous venous sinuses situated between arteries and veins. Blood is filtered through these sinuses, which contain many macrophages that phagocytose senescent red and white blood cells, bacteria, and other particulate material. Other leukocytes, including

neutrophils, eosinophils, and lymphocytes, particularly plasma cells, are found in the red pulp.[44]

The white pulp consists of lymphoid tissue surrounding central arterioles, which are branches of trabecular arteries. The human spleen is structurally different from rodent spleens because there is no central organization of follicles and the central artery.[44] Rather, a T cell–predominant area is found immediately surrounding a central arteriole, the so-called *periarteriolar lymphoid sheath*, which contains both CD4 and CD8 T cells. It is punctuated at intervals by B cell–predominant areas, follicles, or so-called *malpighian corpuscles.* These B cell–predominant areas contain primary and secondary follicles. Primary follicles consist of only a mantle zone, without germinal centers, whereas secondary follicles contain an inner germinal center in addition to the outer mantle zone (Fig. 2.7). Within the mantle zone are predominantly resting B cells, which express surface IgM/IgD and CD23 (FcεRII). It is within the germinal centers that immunoglobulin class switching, affinity maturation through somatic mutation, and the development of memory B cells occur. Germinal centers are more prevalent at younger ages and diminish with aging. CD4

T cells play a key role in B-cell responses through CD40L and other interactions. The signaling that occurs through this interaction is central to B-cell activation and class switching. In addition to activated B cells and CD4 T cells, the germinal center contains FDCs and macrophages.

At the interface between the white pulp and the red pulp is a region known as the *marginal zone,* which receives blood from branches of central arterioles opening into this region. It contains T cells, as well as subsets of macrophages and B cells. Marginal zone (MZ) B cells are distinct from follicular B cells. They express surface IgM and low levels of IgD and lack CD23. The initial encounter of T cells and B cells with antigen occurs in the marginal zone after blood enters through branches of the central arteriole. Antigen presentation is enhanced by MZ B cells, which are important in T cell–independent responses.

Lymph Nodes and Lymphatics

Lymph nodes occur as chains or groups located along lymphatic vessels. Lymph nodes exist in two major groups: those that drain the skin and superficial tissues (*e.g.,* cervical, axillary, or inguinal lymph nodes) and those that drain the mucosal and deep tissues of the body (*e.g.,* mesenteric, mediastinal, and periaortic lymph nodes). Lymph nodes are oval structures surrounded by adipose tissue with an indentation at the region of a hilus, where blood vessels enter and leave the node (Fig. 2.8). A lymph node is surrounded by a fibrous capsule contiguous with trabeculae traversing the node. Blood vessels and nerves, which enter through the hilus, branch through these trabeculae to various parts of the node. Immediately beneath the capsule is a subcapsular (marginal) sinus. Afferent lymph vessels enter this sinus opposite the hilus. DCs process antigen encountered in skin and migrate into lymph nodes from afferent lymphatics through the subcapsular sinus and into the lymph node. Lymph nodes vary in size, from being barely visible in an unstimulated state to several centimeters in size when undergoing an active immune response.

A lymph node is divided into two major regions, the cortex and the medulla. The cortex contains numerous primary and secondary lymphoid follicles, each approximately 0.5 mm in diameter, similar to those in the spleen. Surrounding the lymphoid follicles in the cortex is the paracortical region, which contains mostly T cells, along with some macrophages and DCs. Both CD4 and CD8 T cells are present, as are macrophages and B cells. The accessory cells, such as interdigitating DCs, present peptide antigens in association with MHC molecules to the TCR on T cells to activate the T cells. Additional accessory molecules (*e.g.,* B7 [CD80] or LFA-3 [CD58]) on the accessory cell and their ligands (CD28 or CD2, respectively) on the T cell provide important costimulatory signals required for activation of the T cell. Other surface antigens, particularly adhesion molecules, such as LFA-1 (CD18) and ICAM-1 (CD54), are involved in stabilizing cellular interactions, as well as providing additional signals between cells.

In the center of the lymph node, beneath the cortex, lies the medulla, which is divided into medullary cords that contain T cells, B cells, plasma cells, and macrophages. Surrounding the medullary cords are medullary sinuses that drain into the hilus. B and T cells migrate from the follicles and paracortical region to the medulla. The Ig produced by the plasma cells drains into medullary sinuses that empty into the hilus. Efferent lymphatic vessels leave the hilus carrying lipids and antibodies, together with mature B and T cells that migrate to other tissues and act as memory B and T cells. The lymphatic vessel system serves to carry lymphocytes derived from various tissue spaces through the network of lymph nodes and to the thoracic duct. Lymphatic capillaries are lined with lymphatic epithelial cells that serve as valves to move lymph fluid, cells, and nutrients around the body. These epithelial cells express high levels of Toll-like receptor-4 (TLR4), which allows them to be activated after lipopolysaccharide delivery to increase lymphaniogenesis.[45] Lymph from the nodes is drawn into the left subclavian vein and back into circulation. Cancer cells found in lymph nodes may take advantage of this system to seed the body. This system of transport develops early in gestation with both lymphatic muscle cells for propulsion and valves that regulate unidirectional lymph flow.

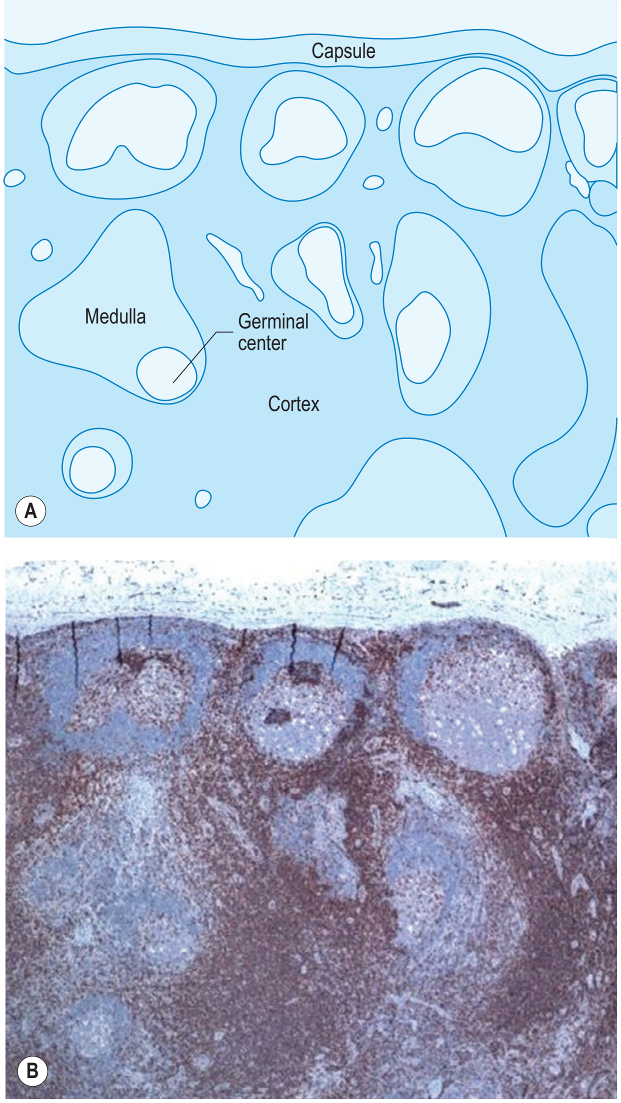

FIG 2.8 Human lymph node showing cortex, medullary areas, and germinal centers.

Adipose Tissue

Adipose tissue has been recently extensively studied in light of the recent obesity epidemic with the realization that immune cells play central roles in adipose homeostasis and in the chronic inflammation in obesity. Macrophages are a central component. They switch from the M2 to the M1 type in obesity. In lean adipose tissue, there are numerous Tregs and few CD8 T cells, which reverses during obesity when inflammation increases.[46]

Mucosal Immune System

The mucosal immune system is located along the surfaces of mucosal tissues (Chapter 20). Each mucosal immune system consists of organized secondary lymphoid structures, termed *mucosa-associated lymphoreticular tissue* (MALT), where inductive immune responses occur, and more diffuse tissues, such as the exocrine glands and lamina propria, where effector immune responses occur.[47] Some mucosal sites, such as the intestine and lungs, have well-developed MALT. Others, such as the vaginal–cervical mucosal surface, have minimally developed MALT.

MALT organization resembles lymph nodes with B cell follicles, intervening T-cell zones and numerous APCs, such as DCs and macrophages. Naïve T and B cells encounter antigen, become activated, exit the tissue via efferent lymphatics, and migrate to the local lymph nodes and then into the thoracic duct and the bloodstream. The cells home to effector sites, particularly the lamina propria of various mucosal tissues. IELs, contained within mucosal epithelium and the lamina propria located beneath the epithelium, are responsible for effector functions. They occur diffusely in mucosal tissues and lack the well-defined structure of the organized mucosal immune system.

The homing of activated lymphocytes from one inductive site to several mucosal surface effector sites has led to the concept of a common mucosal immune system, although significant compartmentalization remains in humans.[48] Trafficking from MALT to the lamina propria is well regulated. Expression of cell surface molecules, such as sphingosine 1 phosphate (S1P), MAdCAM-1, VLA-1, LFA-1, and VCAM-1; the cell surface integrin, α4β7; and chemokines, such as CCR9, CCL25, CCR10, and CCL28, are important in directing activated lymphocytes to the lamina propria surface.[49] The environment at the mucosal surface is favorable for induction of IgA. Low-affinity IgA inhibits commensal bacteria on mucosal surfaces. High-affinity IgA helps neutralize microbial pathogens.

Gastrointestinal Tract

The organized MALT of the GI system is termed *gut-associated lymphoreticular tissue* (GALT). It encompasses Peyer patches, cecal and rectal patches, and isolated lymphoid follicles. Isolated lymphoid follicles and cecal and rectal patches are found throughout the lamina propria and are similar to an individual follicle of a Peyer patch. Peyer patches consist of variably sized aggregates of closely associated lymphoid follicles located in the intestinal lamina propria, occurring predominantly in the ileum (Fig. 2.9).[50] Although these structures arise during fetal life, their full development, with follicles containing germinal centers, does not occur until several weeks after birth, presumably in response to antigenic stimulation. Their number and size increase until puberty and decline thereafter.

Peyer patches and lymphoid follicles have a structural organization that belies their function of presenting antigen from the intestinal lumen to T and B cells. The epithelium overlying lymphoid follicles and Peyer patches—that is, FAE (see Fig. 2.6)—lacks villi and contains very few goblet cells. Particulate antigen uptake via pinocytosis occurs in the FAE through specialized epithelial cells called *M cells* that do not express the polymeric immunoglobulin receptor (secretory component) required for secretion of IgA, expressed by crypt epithelial cells in villous epithelium.[51]

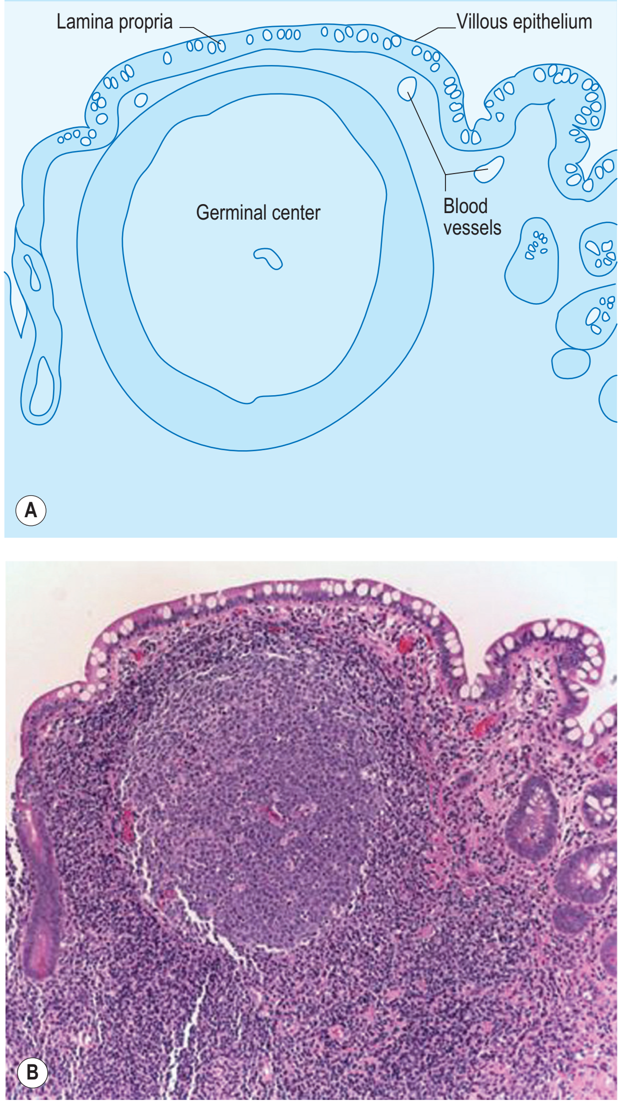

FIG 2.9 Germinal center in terminal ilium.

Beneath the epithelium that overlies individual follicles lies the dome. A substantial number of T cells, including CD4 T cells, are found in this subepithelial region. Macrophages, DCs, and naïve B cells are found here. Antigen, which is pinocytosed by M cells, is transported to the dome region, where antigen presentation to T cells occurs. Macrophages and DCs express high levels of MHC class II. Follicles lying beneath the dome contain mantle zones with predominantly resting B cells, most of which are surface IgM and IgD. Peyer patch follicles have germinal centers that contain activated B cells, FDCs, CD4 T cells, and tingible-body macrophages (so called because of their appearance after they have phagocytosed cellular debris). Many B cells within Peyer patch germinal centers express surface IgA, and it is believed that this is where IgA class switching occurs. Very few CD8 T cells are located within the follicles. An interfollicular region contains predominantly CD4 and CD8 T cells, as well as DCs, macrophages, and some B cells. CD4 T cells predominate over CD8 T cells in this region and the dome.

The diffuse tissue of the GI tract consists of two components: the lamina propria and IELs. The lamina propria is located immediately beneath the epithelium. It contains large numbers of B lymphocytes and plasma cells. A key effector function of the lamina propria is the secretion of antibodies, primarily IgA. IgM represents only 10–18% and IgG 3–5% of all Ig produced from the lamina propria. Two IgA subclasses, IgA1 and IgA2, occur. IgA1 represents greater than 90% of IgA in the respiratory tract and greater than 60% in the lamina propria of the small intestine.[51] IgA2 increases in the lower ileum and becomes predominant in the colon and the rectum. IgA is transported from the lamina propria into epithelial cells through polymeric immunoglobulin receptor-mediated uptake and subsequently secreted into the lumen. Normally, very few IgG B cells are present in the lamina propria. However, under certain inflammatory conditions, such as inflammatory bowel disease, the number of IgG-producing B cells and plasma cells increases dramatically.

The lamina propria also contains large numbers of both CD4 and CD8 T cells in a 2 : 1 ratio. Almost all lamina propria T cells (>95%) express αβ TCR.

Several specialized T cell subsets are present within the GI tract. IELs are found at the basal surface of the epithelium as well as interdigitated with epithelial cells. The vast majority of IEL (>90%) are T cells, which are either $CD8^+$ or $CD4^-CD8^-$. Although the majority of IEL T cells express TCRαβ, a substantial number express TCRγδ. The function of IELs remains incompletely understood, but they can be cytotoxic and also maintain oral tolerance. As part of their effector function, they produce several cytokines, including IL-5 and IFN-γ. Two other T-cell subsets play antagonizing roles in controlling inflammation within the intestinal lamina propria: Tregs and Th17 cells. Tregs are $FOXP3^+$ and function to repress inflammation, whereas Th17 cells mount inflammatory and autoimmune responses through production of IL-17.[52] Another T-cell subset, which comprises NKT cells, expresses the characteristics of both T cells and NK cells. NKT cells express perforin and granzymes but recognize antigens through non-MHC–mediated pathways.[53]

Other cells, including macrophages, DCs, eosinophils, mast cells, and a few neutrophils, are also found in the lamina propria and mediate effector functions. There is an elaborate network of APCs, including DCs and macrophages distributed within the lamina propria and GALT. Two major DC subsets, characterized by $CD103^+CD11b^-$ and $CD103^+CD11b^+$, develop into distinct lineages on the basis of secreted factor requirement. $CD103^+CD11b^+$ are predominately localized to the lamina propria and migrate to the mesenteric lymph nodes upon activation. In contrast, $CD103^+CD11b^-$ populations are localized to the Peyer patches. The GI tract contains the largest number of resident macrophages in the body. These macrophages are similar to macrophages in other tissues and express CD68, lysozyme, ferritin, MHC II, CD11b, CX3CR1, and CD74 but do not migrate to the mesenteric lymph nodes.

Respiratory Tract

Surrounding the entrance to the throat are three tonsillar groups: palatine tonsils, lingual tonsils, and pharyngeal tonsils or adenoids. Together, these are known as *Waldeyer ring.* Tonsils reach full development in childhood and involute by puberty. The palatine tonsils, one located on each side of the pharynx, each measures approximately 2.5 × 1.25 cm. Except at the pharyngeal surface, they are surrounded by a poorly organized capsule that is covered with stratified squamous epithelium. Trabeculae subdivide the tonsil into lobules. Blood vessels and nerves enter through the capsule and extend within trabeculae (Fig. 2.10). The surface of the tonsil is covered by pits, which are the openings of crypts. The crypts extend down into the tissue of the tonsil with branching, increasing surface area. Abundant lymphoid follicles in each lobule contain germinal centers that are predominantly B cells. The lymphoid tissue surrounding the follicles contains T cells, macrophages, DCs, and some B cells. The lingual tonsils consist of 35–100 separate crypts surrounded by lymphoid tissue and are located at the root of the tongue. The pharyngeal tonsils, or adenoids, are accumulations of lymphoid tissue, 2.5–4.0 cm long, located on the median dorsal wall of the nasopharynx. They contain a series of longitudinal folds, but not crypts. The lingual and pharyngeal tonsils also contain lymphoid nodules with germinal centers. The palatine tonsils and adenoids (nasopharyngeal tonsils) comprise the nasopharyngeal–associated lymphoreticular tissues.

Inductive immune responses to inhaled antigens within the respiratory tract occur mainly in the bronchus-associated lymphoid tissue (BALT). BALT consists of lymphoid aggregates located within the bronchial wall near bifurcations of the major bronchial branches (Fig. 2.11). These structures are analogous to the GALT present in the GI tract and function to provide T- and B-cell protection against inhaled microbes. BALT is present at birth and rapidly expands when exposed to antigenic stimulation. The specialized epithelium overlying the lymphoid aggregates consists of M cells heavily infiltrated with lymphocytes and with DCs below the epithelium. The main result of BALT immune induction is secretory IgA production.[54]

The diffuse mucosal tissue of the respiratory tract is minimal. Pools of lymphocytes are present within the lung interstitium, which is 10–20% T cells. Macrophages are present on both the air and the mucosal sides of the lungs and airways.[50] Minimal inflammation occurs in the bronchial mucosa as a result of Tregs that inhibit T-cell activation and expansion. Instead, antigen is carried by local macrophages to the regional lymph nodes, where most respiratory effector immune responses originate. Communication occurs between the GI and respiratory mucosae through cell trafficking. Antigen-reactive T and B cells from Peyer patches can populate the bronchial mucosa. This sharing feature has been exploited in the development of oral vaccines against respiratory microbes.[55]

Genital Tract

The male and female reproductive tracts are components of the common mucosal system. The genital tract immune system must maintain a delicate balance between tolerance of germinal center cells, spermatozoa, and the fetus and the recognition of microbes. The female reproductive tract has been studied the most. Its mucosal immune system is influenced by hormones that regulate all aspects of innate and adaptive immunity.[56] "Professional" APCs, including macrophages and DCs, are present in the stroma of both the uterus and the vaginal tract, where they have unique phenotypes. Reproductive tract NK cells play a role in host defense, implantation of the embryo, and pregnancy and also express a distinct phenotype. CD8 T cells predominate and, along with B cells and macrophages, form unique lymphoid aggregates. Formation of these nodules depends heavily on hormone regulation. Both secretory IgA and IgG are expressed in genital secretions, and levels vary with the stage of the menstrual cycle. The production and transport of antibody produced in the genital tract

depends on hormonal and local factors, including IL-1b, IL-6, and IL-10, all of which influence the maturation of B cells to plasma cells within the mucosa.[56]

SKIN

Skin also serves as a specialized secondary immune organ (Chapter 19). It contains two layers, the epidermis and the dermis. The epidermis is the outermost layer and contains three distinct cell types: keratinocytes, melanocytes, and Langerhans cells (Fig. 2.12). Keratinocytes are squamous epithelial cells and are the principal cell type. They secrete a number of cytokines and chemokines, including IL-1, -6, -10, -18, and -33; TGF-β; TNF-α; CXCL9; CXCL10; CXCL11; and CCL20. These can profoundly influence immune cell recruitment and responses. The second cell type is the pigment-producing melanocyte. Melanocytes derive from the neural crest and reside in the basal layer of the epidermis. The third cell type, and the one of particular importance for the immune system, is the Langerhans cell. Langerhans cells are scattered throughout the epidermis within the malpighian, or prickle cell, layer. They are important for both normal and pathologic cutaneous T-cell responses. After encountering antigen in the presence of keratinocyte cytokines, such as TNF-α and IL-6, Langerhans cells migrate from the epidermis to the dermis,

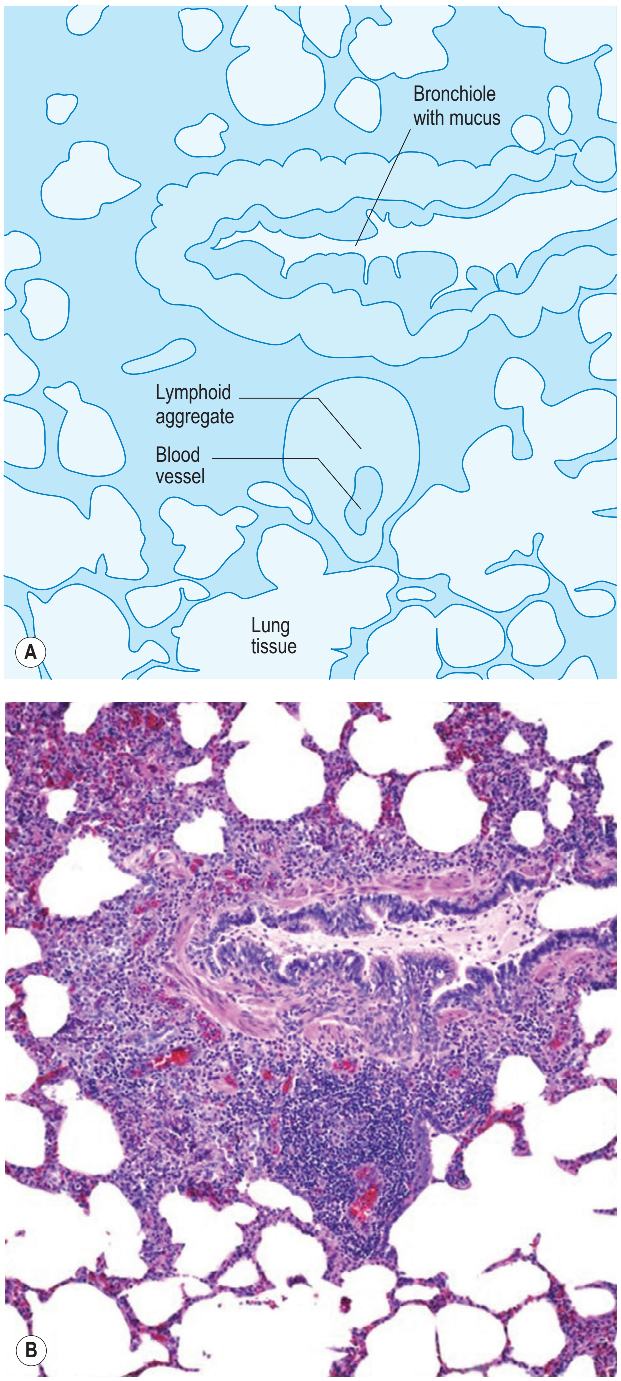

FIG 2.11 Lymphoid regions in the human lung.

enter the afferent lymphatics, and migrate to draining lymph nodes. There they present antigen to T cells to promote primary immune responses. Other types of dermal DCs, including those that are macrophage-like, expressing CD14, and those that are DC-like, expressing CD1c and CD14, have consequences for atopic dermatitis and psoriasis.[57]

The dermis lies under the epidermis. It contains abundant fibroblasts producing collagen, a principal component of skin. The dermis also contains blood vessels and various epidermal adnexal structures, such as hair follicles, sweat glands, and sebaceous glands. The dermal vasculature includes an extensive network of plexuses with arterioles, capillaries, and venules. Dermal lymphatics are associated with the vascular plexuses. In normal skin, a small number of lymphocytes can be found in perivascular areas. These lymphocytes are mostly T cells with distinctive features, including expression of a memory phenotype (CD45RO) and expression of a cutaneous lymphocyte–associated antigen that binds to the vascular addressing endothelial cell leukocyte adhesion molecule-1 (ELAM-1, or CD62E) present on the endothelium. This latter interaction plays an important role in homing of memory T cells to inflamed regions of skin. The dermis also contains mast cells important for immediate hypersensitivity reactions. Tregs are abundant in the skin. CD8 T cells are common in the epidermis. CD4 T cells are common in dermis infected with shingles.[57]

Commensal Organisms/Toll-Like Receptors

Humans live in symbiosis with over 1000 different species of viruses, bacteria, protozoa, and fungi that far outnumber human cells. Collectively termed *commensal microbiota,* these organisms are essential to the development, maturation, organization, and regulation of the mucosal immune system.[58] Many of their immune interactions involve TLR triggering. TLRs activate and prime both innate and specific immune responses. Production of IgA, induction of regulatory T cells, and stimulation of antiinflammatory cytokines are associated with commensal microbiota.[59] Thus the types and quantities of microorganisms present at a mucosal surface is an important component of the mucosal immune response.[60]

ON THE HORIZON

- Understanding how stem cells self-renew is a key to exploiting them for gene therapy.
- Exploiting innate and acquired immune cell function requires an understanding of the multiple subpopulations of cells and the manner in which they are induced.
- Increasing generation of new T cells and B cells later in life might enhance immune function, and thus prolong quality of life.
- The role of adipose tissue in hematopoietic stem cell (HSC) development in bone marrow and control of inflammation in obesity is fundamental to controlling the epidemic of obesity.
- Exploiting interactions between the mucosal immune system and commensal populations may improve health, prevent inflammation, and lead to less antibiotic use.
- Cellular migration via the lymphatics to the brain is unknown; inflammation and cancer spread might be reduced by controlling inflammation of the lymphatics.

ACKNOWLEDGMENTS

We thank Dr. Gregory R. Harriman at BioAdvance for his work on previous editions of this chapter; Dr. Edwina Popek, Pathology Department, Texas Children's Hospital, Houston, Texas, for providing histopathologic images of lymphoid tissues; Dr. Gregory Stelzer and Wendy Schober for the flow cytometric display; Eleanor Chapman, Anna Wirt, Terry Saulsberry, Yvette Wyckoff, and Pamela Love for help with the manuscript; and Dr. Jerry McGhee for critical review of the first edition.

MULTIPLE-CHOICE QUESTIONS

1. Characteristics of hematopoietic stem cells include:
   A. Deleted as progeny develop
   B. Derive all lineages of blood cells
   C. Form distinct niches in fetal liver
   D. Rely on stromal factors to regulate differentiation
2. Interactions between innate and acquired immune cells involve (more than one correct answer):
   A. Processing and presentation of antigens
   B. Stimulation of macrophages by TLR-ligands
   C. Only tissue based interactions
   D. Migration of immature dendritic cells to lymph nodes
3. Mucosal immune sites include (more than one correct answer):
   A. Vaginal and rectal tissues
   B. M cells which transport antigens across the lumen
   C. Inguinal and axial lymph nodes
   D. Mesenteric lymph nodes
4. Lymph nodes are (more than one correct answer):
   A. Located throughout the body
   B. Delivery sites for phagocytized organisms
   C. Location of T- and B-cell rearrangements
   D. Peyer patches in the gastrointestinal tract

3

Innate Immunity

Douglas R. McDonald, Ofer Levy

Innate immunity is the first line of host defense against infection. All living organisms are continually exposed to microbes. For example, the human gut is colonized by trillions of commensal bacteria. The innate immune system must accommodate commensal bacteria but be able to be activated by pathogens (*e.g., Salmonella* or *Shigella*). Potentially life-threatening infections can result from naturally occurring defects in the innate immune response (Chapter 36).

A defining characteristic of innate immunity is its existence before microbial exposure. Innate immune responses are initiated rapidly by microbes and precede the development of adaptive immune responses. The adaptive immune system is characterized by the tremendous diversity of its receptors and its antigen ligands. The innate immune system responds to a more constrained set of antigens that are typically essential and invariant structural components specific to microbes. These microbial components are known as *pathogen-associated molecular patterns* (PAMPs).[1] They include microbial cell wall components and nucleic acids. PAMPs are recognized by pattern recognition receptors (PRRs), and they are highly potent and effective in initiating inflammatory responses.

"Trained immunity" is used to describe the phenomenon of enhanced innate immune responses following microbial exposure.[2,3] This increase in host resistance to reinfection can provide "cross-protection" against other infectious agents. For example, macrophages and natural killer (NK) cells can expand and contract their cell populations, upregulate genes involved in pathogen recognition and presentation, and secrete cytokines that augment the antimicrobial activity of bystander cells. Thus there is a growing appreciation that the adaptive and innate immune systems have certain similar characteristics.

BARRIERS TO INFECTION

Skin and Mucosa

The epithelial layers of the skin and the linings of the gastrointestinal (GI), genitourinary (GU), and respiratory tracts provide a mechanical barrier to microbial entry and thus play an essential role in host defense. The stratum corneum of the skin is the first barrier encountered by microbes (Chapter 19). The skin is persistently colonized with numerous microbes. Thus an intact physical barrier is essential to prevent activation of the immune system under nonpathological conditions. Key cellular components of the skin immune barrier include keratinocytes, dendritic cells (DCs), macrophages, T lymphocytes, and mast cells. These cells express a wide variety of pathogen recognition receptors and secrete a broad range of cytokines, chemokines, and antimicrobial proteins and peptides (APPs) that mediate inflammatory responses to infection. Genetic disorders of the skin that compromise skin integrity, such as epidermolysis bullosa (Chapter 63), can result in life-threatening infections.

Skin disorders that impair barrier function, such as atopic dermatitis (AD) (Chapter 44) or eczema, are common.[4] Filaggrin (FLG) is a key a structural component of the outermost layer of the epidermis. Loss of function variants in filaggrin (R510X, 2282del4) is estimated to be present in up to 50% of patients with AD.[4] FLG mutations are a risk factor for the development of early-onset AD and thus for sensitization to food allergens (Chapter 45), allergic rhinitis, and asthma (Chapter 72) (the atopic march). Eczematous skin can lead to reduced expression of APPs and increased susceptibility to cutaneous bacterial (*e.g., Staphylococcus*, *Streptococcus*) and viral (*e.g.,* herpes) infections.[5]

The luminal surfaces of the intestines are sites of continual exposure to massive numbers of microbes. Intestinal epithelial cells (IECs) (Chapter 20) protect against infection by forming a physical barrier through tight junctions and by producing mucus (goblet cells) and APPs. IECs express apical junction complexes, including E-cadherin, ZO-1, claudin, and occludin, which function to form a tight monolayer that prevents penetration by bacteria.[6] A breakdown in epithelial gut homeostasis can lead to inflammatory bowel diseases (*e.g.,* Crohn disease, ulcerative colitis) (Chapter 75) and increased susceptibility to bacterial infection.[7]

KEY CONCEPTS

The Innate Immune System

- The innate immune system provides the initial immune response to pathogens.
- Although less specific than the adaptive immune system, the innate immune system must differentiate commensal from pathological microbes.
- The innate immune system comprises barriers to the environment (*e.g.,* skin, mucosa), antimicrobial peptides and proteins, cells (*e.g.,* neutrophils, macrophages, monocytes), and soluble factors (*i.e.,* cytokines, chemokines, complement).
- Pathogen detection is mediated by a variety of germline-encoded pathogen recognition receptors (PRRs) that can recognize invariant microbial structures known as pathogen-associated molecular patterns (PAMPs).
- Activation of the innate immune system leads to subsequent activation of the adaptive immune system.
- The innate immune system has a form of memory or "trained immunity" such that innate immune activation can modulate innate immune responses to subsequent unrelated stimulus/infection.

Influenza viruses and respiratory syncytial virus replicate in airway epithelial cells, leading to cell death and inflammation. The impaired barrier function of the airways can lead to increased susceptibility to secondary invasive bacterial infections by *Streptococcus pneumoniae* and other pyogenic bacteria. Inflammatory bowel diseases also result in impaired barrier functions of the small and large intestines, which can be associated with increased translocation of bacteria across gut mucosa, potentially leading to serious infection.

CLINICAL PEARLS

Innate Immunity Barriers

- Innate immune barriers consist of epithelial layers, including those of skin and the gastrointestinal, respiratory, and genitourinary tracts.
- Barrier function is an underappreciated component of the innate immune system.
- Defects of barrier function, such as epidermolysis bullosa and atopic dermatitis, increase the risk of infection.
- Production of antimicrobial peptides and proteins at barrier sites plays a vital role in preventing invasion by microbes.

Antimicrobial Proteins and Peptides

Among the APPs produced by the skin, GI, GU, and respiratory tract epithelia are bactericidal/permeability-increasing protein (BPI), defensins (β-strand peptides connected by disulfide bonds), and cathelicidins (linear α-helical peptides)[8] (Table 3.1). Most APPs have a net positive charge, which enhances their affinity for negatively charged microbial cell membranes. Binding of APPs to microbes can increase membrane permeability and target cell death.

BPI is a ~55-kilodalton (kDa) cationic and hydrophobic protein with high affinity for the lipid A region of lipopolysaccharide (endotoxin). It is found in neutrophil primary (azurophilic) granules and is also inducible in epithelial cells. BPI inhibits gram-negative bacteria by its endotoxin neutralizing and microbicidal and opsonic properties.[9] Neutralization of endotoxin may also help limit inflammatory responses to gram-negative bacteria.

Some APPs, such as lysozyme (Lz), have enzymatic activities, which cleaves peptidoglycans found in bacterial cell walls. Other APPs bind to and compete for nutrients, a form of so-called nutritional immunity. Lactoferrin (Lf), for example, binds iron, a nutrient essential to bacterial survival.[9]

Defensins are classified by the linking pattern of cysteines and their sizes. α-defensins are expressed in neutrophils and Paneth cells of the small intestine, whereas β-defensins are expressed by mucosal surface epithelia, including those of skin, eyes, and the oral, urogenital, and respiratory tracts.[10] Defensins have a broad specificity of antimicrobial activities against bacteria, mycobacteria, fungi, parasites, and viruses (Table 3.2). They have also been shown to enhance antigen uptake and processing, and to stimulate the chemotaxis of monocytes, macrophages, and mast cells.[10,11] The expression of several of the defensins is constitutive. For others, inflammatory stimuli (bacterial products, proinflammatory cytokines) will increase defensin expression (human neutrophil proteins 1–3 and human β-defensin-2). Given the increasing incidence of antibiotic resistant bacteria, there is great interest in the potential uses of APPs as treatment for bacterial infections and infections with multidrug-resistant organisms.[12,13]

HUMORAL INNATE IMMUNITY

The Acute Phase Response

A variety of soluble proteins found in plasma help recognize PAMPs and function as mediators of innate immunity. Tumor

TABLE 3.1 Epithelial Antimicrobial Proteins and Peptides (APPs)

Antimicrobial Peptide	Source	Target Organism
Dermicidin	Eccrine sweat glands	Broad spectrum
Psoriasin	Keratinocytes, sebocytes	G^-
RNase 7	Keratinocytes	Broad spectrum
RNase 5/angiogenin	Keratinocytes	*C albicans*
Cathelicidin (LL-37)	Keratinocytes, sebocytes	G^+, G^-
BPI	Epithelia-oral, GI, urogenital tract	G^-, (G^+, fungi)
hBD-1	Keratinocytes, sebocytes	G^-
hBD-2	Keratinocytes, sebocytes	G^-
hBD-3	Keratinocytes	Broad spectrum
hBD-4	Keratinocytes	G^+, G^-
SLPI	Keratinocytes	Broad spectrum
Elafin	Keratinocytes	Broad spectrum
Adrenomedullin	Keratinocytes, hair follicles, eccrine/apocrine sweat glands, sebocytes	G^+, G^-
MIP-3α/CCL20	Keratinocytes	Broad spectrum
Lysozyme	Keratinocytes, sebocytes, hair bulb cells	G^+, G^-
Lactoferrin	Milk, saliva, tears, nasal secretions, neutrophils	Broad spectrum

RNase, ribonuclease; BPI, bactericidal/permeability-increasing protein; CCL, chemokine ligand; G^+, gram-positive; G^-, gram-negative; GI, gastrointestinal; hBD, human β-defensin; MIP, macrophage inflammatory protein; SLPI, secretory leukocyte peptidase inhibitor.

TABLE 3.2 Neutrophil-Derived Antimicrobial Proteins and Peptides (APPs)

Neutrophil APP	Granule Type	Target Organism
Lysozyme	Azurophil, specific	G^+, G^-
Azurocidin	Azurophil, secretory	G^+, G^-*Candida albicans*
Elastase	Azurophil	G^+, G^-
Cathepsin G	Azurophil	G^+, G^-
Proteinase 3	Azurophil	G^+, G^-
BPI	Azurophil	G^-, (G^+, fungi)
α-defensins (HNP-1 to -4)	Azurophil	G^+, G^-, fungi, viruses
Cathelicidin (hCAP-18)	Specific	G^+, G^-, mycobacteria
Lactoferrin	Specific	G^+, G^-, fungi, viruses
SLPI	Specific	G^+, G^-, *Aspergillus fumigatus, C. albicans*
NGAL	Specific	G^+, G^-, fungi
Lysozyme	Azurophil, specific	G^+, G^-
Azurocidin	Azurophil, secretory	G^+, G^-, *C. albicans*
Elastase	Azurophil	G^+, G^-
Cathepsin G	Azurophil	G^+, G^-

BPI, bactericidal/permeability-increasing protein; G^+, gram-positive; G^-, gram-negative; hCAP, human cathelicidin antimicrobial protein; HNP, human neutrophil peptide; NGAL, neutrophil gelatinase-associated lipocalin; SLPI, secretory leukocyte peptidase inhibitor.

KEY CONCEPTS

Humoral Innate Immunity

- Cytokines and chemokines are essential mediators of the innate immune response.
- Cytokines are redundant and pleiotropic. To avoid host tissue response, their synthesis is tightly controlled.
- Acute phase reactants (*i.e.,* cross-reactive protein [CRP]) are induced by cytokines (interleukin [IL]-6) and play roles in opsonization of microbes. Plasma CRP is used to monitor infections and inflammation.
- Defects in the complement system result in invasive bacterial infections, primarily from encapsulated bacteria.

necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) induce production of acute phase reactants in hepatocytes, including members of the pentraxin family (*e.g.,* serum amyloid A [SAA], serum amyloid P [SAP], and cross-reactive protein [CRP]). These pentraxins bind to components of the bacterial cell wall.[14] TNFα and IL-1β also induce production of IL-6 from mononuclear phagocytes, endothelial cells, and fibroblasts. IL-6 is another potent inducer of acute phase reactants, including CRP and fibrinogen. CRP, SAA, and SAP function as opsonins and can bind phosphorylcholine and phosphatidylethanolamine expressed on bacteria and apoptotic cells, enhancing phagocytosis of bacteria and apoptotic cells by macrophages.

Lipopolysaccharide-binding protein (LBP) is an acute phase reactant synthesized by the liver in response to gram-negative bacterial infections. LBP binds to LPS and subsequently forms a complex with CD14, TLR4, and MD-2, which functions as a high-affinity receptor for LPS.[15]

Mannose-binding lectin (MBL) is a member of the calcium-dependent (C-type) lectins (collectins) produced by the liver in response to infection. MBL binds to carbohydrates with terminal mannose and fucose residues that are expressed on microbial cell surfaces.[16] MBL can bind to the C1q receptor on macrophages to enhance phagocytosis and can activate the complement system via the lectin pathway (discussed below).

Surfactant protein-A and surfactant protein-D are collectins expressed in the lung and can bind a variety of microbes and inhibit their growth.[13,17] They also function as opsonins that promote ingestion by alveolar macrophages.

Finally, ficolins are plasma proteins capable of binding to several types of bacteria and can activate complement.

CLINICAL PEARLS

Complement

- Deficiency of early components of the complement cascade create susceptibility to invasive infections with encapsulated bacteria and development of a lupus-like syndrome.
- Deficiency of late components of the complement cascade (C5–9) result in susceptibility to meningitis caused by *Neisseria meningitis.*
- Deficiency of C1-inhibitor protein (or function) results in hereditary angioedema.
- Deficiency of factor H is associated with development of membranoproliferative glomerulonephritis, hemolytic–uremic syndrome, and age-related macular degeneration.
- Deficiency of mannose-binding lectin can result in susceptibility to bacterial infection in individuals with comorbid conditions (*e.g.,* cystic fibrosis).

The Complement System

The complement system comprises a collection of plasma proteins activated by microbes (Chapter 21). It helps mediate microbial destruction and inflammation.[18] Complement activation can occur via three pathways: the classical pathway (CP), the alternative pathway (AP), and the lectin pathway (LP).

In the CP, complement C1 detects immunoglobulin M (IgM), IgG1, or IgG3 bound to the surface of a microbe. C1 is composed of the C1q, C1r, and C1s subunits. These form multimeric complexes that recognize IgM or IgG bound to microbial surfaces. C1r and C1s are serine proteases. Activated C1s generates a C3 convertase composed of C4b and C2b (C4b2b) bound to the microbial surface. C3 convertase cleaves C3, generating C3b. C3b binds covalently to C4b2b, generating C5 convertase. C5 convertase then activates the late steps of complement activation leading to assembly of the membrane attack complex (MAC) and subsequent cytolysis.

The AP is initiated by small amounts of C3b, which are spontaneously generated in plasma. C3b that remains unbound to a cell surface is rapidly hydrolyzed and inactivated. C3b bound to a microbe becomes a binding site for factor B. Bound factor B is cleaved by factor D, generating factor Bb that binds covalently to C3b, forming the AP C3 convertase, which activates the late steps of complement activation, as in the CP.

The lectin pathway is activated by MBL or ficolins binding to microbial surfaces. MBL then binds to MBL-associated serine proteases (MASPs)-1, -2, and -3. MASP-2 cleaves C4 and C2 to activate the complement cascade, as in the CP (Fig. 3.1).

Complement components also function as opsonins. Complement-coated microbes can be phagocytosed via complement receptors on phagocytes. Complement receptor type 1 (CR1) is a high-affinity receptor for the C3b and C4b fragments of complement and mediates the internalization of C3b- and C4b-coated particles. On erythrocytes, it mediates clearance of immune complexes from the circulation. Complement type 2 receptor (CR2, also known as CD21) is expressed on B cells and follicular dendritic cells (FDCs). It binds C3 proteolytic fragments, including C3d, C3dg, and iC3b. CR2 augments humoral immune responses by enhancing B-cell activation by antigen and by promoting trapping of antigen–antibody complexes in germinal centers.[19] CR2 is also the receptor for Epstein-Barr virus (EBV), allowing EBV to enter B cells. Complement receptor 3 (CR3) is composed of a heterodimer of CD18 and CD11b and is expressed in polymorphonuclear neutrophils (PMNs) and monocytes or macrophages. CR3 binds to iC3b bound to the surface of microbes, leading to phagocytosis and destruction of the pathogen. Activation of complement via the AP can greatly enhance monocyte-generated TNF-α elicited by gram-positive bacteria, such as group B *Streptococcus.*[20]

There are multiple regulatory proteins within the complement pathways. C1-inhibitor (C1-INH) binds to, and inhibits, the enzymatic functions of C1r and C1s within the CP (21). Properdin stabilizes C3bBb complex, increasing the life span of the AP C3 convertase. Conversely, factor H inhibits the formation of, and degrades, C3bBb complex. Factor I inactivates C3b. CD55 (decay accelerating factor) and CD59 are cell surface, GPI-linked proteins that block complement-mediated cytolysis by inhibiting formation of C3bBb complex and binding of C9 to C5b678 complex, respectively. Paroxysmal nocturnal hemoglobinuria, an acquired defect in the *PIGA* gene that causes a deficiency of GPI-linked proteins, is the result of absent cell surface expression of CD55

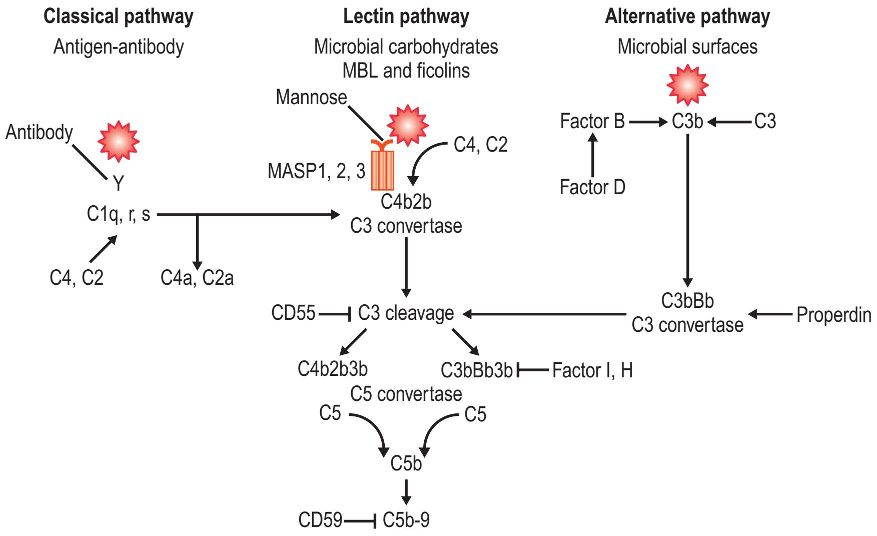

FIG 3.1 **Complement Activation Pathways.** The classical complement cascade is activated by antibody bound to microbial surfaces, which is a binding site for the C1 complex. The alternative pathway is activated by the binding of spontaneously generated C3b to microbial surfaces. Microbe-bound C3b binds factor B, which is converted to factor Bb, forming a C3 convertase. The lectin pathway is activated by the binding of mannose-binding lectin (MBL) to mannose residues on microbial surfaces. MBL binds MBL-associated serine proteases, which bind and cleave C4 and C2, forming a C3 convertase.

and CD59 that leads to hemolytic anemia caused by complement-mediated lysis of red blood cells (RBCs).

Complement Deficiency Diseases

Deficiencies of early components of the complement pathway are associated with invasive bacterial infections caused by encapsulated organisms (Chapter 21). Lack of early components of the complement pathway are also associated with rheumatic disorders, including a lupus-like syndrome that may be caused by impaired immune complex clearance, impaired clearance of apoptotic cells, and loss of complement-dependent B cell tolerance (Chapter 50). Deficiency of factor I is also associated with increased incidence of invasive infection with encapsulated bacteria, as well as glomerulonephritis and autoimmune disease. Deficiency of C1-INH protein and function, either hereditary or acquired, leads to hereditary angioedema (HAE) or acquired angioedema (AAE) (Chapter 42). C1-INH inhibits C1, factors XIa and XIIa, and kallikrein. Dysregulation of these cascades leads to generation of vasoactive products that result in angioedema.[21,22] Deficiencies of late components of complement, including C5 through C9, as well as factors B, D, and properdin create susceptibility to meningococcal infections.[23] Deficiency of factor H function is associated with membranoproliferative glomerulonephritis (Chapter 68), hemolytic–uremic syndrome, and age-related macular degeneration (AMD) (Chapter 74).[24] Deficiency of MBL is associated with increased susceptibility to bacterial infections in infancy and in individuals with other comorbid conditions, such as cystic fibrosis.[25]

CELLULAR INNATE IMMUNITY

Polymorphonuclear Leukocytes

PMNs are the most abundant leukocyte (Chapter 22). They have a short life span of ~6 hours in circulation, and in the healthy adult, $\sim 10^9$ PMNs are produced per hour. PMNs are readily identified by light microscopy by segmented nuclei divided into 3–5 lobules. Their cytoplasm contains four types of granules: azurophilic (or primary), specific (or secondary), gelatinase, and secretory. PMN granules contain a wide variety of APPs with a broad spectrum of antimicrobial activities (see Table 3.2). Azurophilic granules contain enzymes, such as proteinase 3, cathepsin G, and elastase as well as α-defensins and BPI. Specific granules contain lactoferrin and the proforms of cathelicidin peptides. Gelatinase granules are rich in gelatinase and are a marker of terminal neutrophil differentiation. Secretory granules contain a variety of receptors that are inserted into the cell membrane upon activation. Exocytosis of these receptors convert PMNs into cells responsive to inflammatory stimuli. PMNs are

KEY CONCEPTS

Cellular Innate Immunity

- Polymorphonuclear leukocytes (neutrophils) are the most abundant cells of the innate immune system, are short-lived, and are the earliest responders to infection.
- Monocytes and macrophages are the predominant immune cells several days after an infection.
- Activated neutrophils, monocytes, and macrophages kill phagocytosed bacteria through production of reactive oxygen intermediates and antimicrobial proteins and peptides (APPs).
- Dendritic cells (DCs) are efficient in uptake and presentation of foreign antigen and provide a critical link between innate and adaptive immunity.
- Natural killer (NK) cells can kill infected or malignant cells without prior activation.
- Mast cells are present are found at the interface between host and environment and are first responders to microbes and recruit other inflammatory cells.

the earliest responders to infection. Those not recruited to sites of infection undergo apoptosis and are cleared by the reticuloendothelial system. Individuals with severely low numbers of neutrophils (<500 cells/μL [microliter]) are susceptible to overwhelming bacterial infections.

CLINICAL PEARLS

Neutrophils

- Myeloperoxidase deficiency is asymptomatic in the majority of individuals, although *Candida* infections (mucocutaneous and invasive) have been reported.
- Impaired production of reactive oxygen intermediates causes chronic granulomatous disease, which manifests as susceptibility to invasive bacterial and fungal infections and impaired wound healing.
- Severe primary, or secondary, neutropenia (<500 cells/μL [microliter]) creates susceptibility to overwhelming bacterial infections.

Mononuclear phagocytes include monocytes and macrophages. Monocytes originate in bone marrow and migrate into the peripheral circulation. $CD14^+$ monocytes are effective at phagocytosis and production of reactive oxygen intermediates (ROIs) and proinflammatory cytokines in response to a wide variety of microbial stimuli. A subset of monocytes with low CD14 expression ($CD14^{dim}$), but expressing CD16, is associated with vascular endothelia and appears to be specialized for response to viruses and nucleic acid–containing immune complexes and may also be involved in the pathogenesis of autoimmune disorders.[26] $CD14^+$ monocytes enter tissues where they mature into macrophages. Distinct macrophages populations in different tissues are given specific names, including *Kupffer cells* in the liver, *alveolar macrophages* in the lung, *osteoclasts* in bone, and *microglia* within the brain. Macrophages differ from PMNs in that they are not terminally differentiated and can proliferate at sites of infection. They are longer lived than PMNs and are the predominant innate immune cell several days after an infection. Macrophages display plasticity in their functions, depending on the cytokine milieu. Classically activated macrophages (M1) are induced by interferon-γ (IFN-γ) and bacterial products. They have microbicidal activity and proinflammatory functions. In contrast, alternatively activated macrophages (M2) are induced by IL-4 and IL-13 and have anti-inflammatory functions. M2 macrophages have been shown to inhibit T-cell activation through production of IL-10 and transforming growth factor-β (TGF-β).[27]

Activated PMNs and macrophages kill phagocytosed bacteria by releasing microbicidal molecules both extracellularly and within phagolysosomes. Microbes are detected by pattern recognition receptors, as well as by Fc and complement C3 receptors.[28] Bacteria are internalized into phagosomes. Phagosomes fuse with lysosomes containing proteolytic enzymes (elastase, cathepsin G) to form phagolysosomes.

Activated PMNs and macrophages produce ROIs, which are toxic to microbes. ROIs are produced by phagocyte-derived nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, a multisubunit enzyme that consists of five subunits, $p22^{phox}$, $p40^{phox}$, $p47^{phox}$, $p67^{phox}$, and $gp91^{phox}$. The phagocyte oxidase is activated following engulfment of opsonized bacteria (oxidative burst). Genetic defects in components of the NADPH oxidase complex create susceptibility to invasive infections with bacteria and fungi (chronic granulomatous disease), as well as impaired wound healing. A variety of stimuli activate the phagocyte oxidase complex, including the complement fragment C5a; formylated peptides, such as FMLP (N-formyl-methionine-leucine-phenylalanine); LTB4 (leukotriene B4); PAF (platelet-activating factor); and pattern recognition receptors, such as TLR4. Upon cellular activation, $p40^{phox}$, $p47^{phox}$, and $p67^{phox}$ are phosphorylated and recruited to cellular membranes, where they associate with membrane-bound $gp91^{phox}$ and $p22^{phox}$ (flavocytochrome b_{558}) and GTP-bound Rac1 (monocytes) or Rac2 (PMNs).[29] The activated enzyme generates superoxide radicals, which are then converted to hydrogen peroxide by superoxide dismutase. Hydrogen peroxide is combined with halide ions by myeloperoxidase to generate hypohalous acids, which are toxic to bacteria.

The phagocyte oxidase complex also generates an environment within the phagolysosome conducive to proteolytic enzyme activation. The oxidase functions as an electron pump that generates an electrochemical gradient across the phagolysosomal membranes, which is compensated by the movement of ions into the vacuole. This results in the increase in vacuolar pH and osmolarity required for activation of the anti-microbial proteases elastase and cathepsin G.[30]

Macrophages (Chapter 6) produce reactive nitrogen intermediates in response to microbes. Nitric oxide (NO) is produced by inducible nitric oxide synthetase (iNOS). Expression of iNOS is induced by activation of Toll-like receptors (TLRs), and expression is augmented further by IFN-γ.[31] iNOS catalyzes the conversion of arginine to citrulline, releasing diffusible nitric oxide gas. Within phagolysosomes, NO combines with hydrogen peroxide or superoxide to produce peroxynitrite radicals, which contribute to microbial killing. Although ROIs and NO are effective antimicrobial agents, they are nonspecific and are also capable of inducing damage to host tissues.

DCs (Chapter 6) have long membranous extensions for surveying the local environment and are highly phagocytic. They link innate to adaptive immune responses after activation by microbes. DCs express a variety of PRRs, which allow them to respond to microbes by antigen uptake and cytokine secretion. Activated DCs rapidly uptake antigen and then home to draining lymph nodes where they localize to T-cell zones. During their migration to lymph nodes, DCs mature and become efficient antigen presenting cells (APCs). Once in the lymph node, DCs express high levels of costimulatory molecules, such as B7 and IL-12p70, and present antigen to naïve T cells, inducing their differentiation into effector T cells (Th1 T cells). Plasmacytoid dendritic cells (pDCs) are specialized for response to viral infection and secrete large amounts of type 1 IFNs.

One subset of DC characterized by $CD11c^{high}CD103^+$ expression in the lamina propria of the small intestine facilitates the differentiation of regulatory T cells in a retinoic acid- and TGF-β–dependent manner. Such DC subsets may play a role in the development of tolerance to commensal bacteria (Chapter 14).

NK cells are derived from common lymphoid progenitor cells and constitute 5% to 20% of mononuclear cells in the periphery (Chapter 17). They do not express somatically rearranged antigen receptors. Target cells are identified using germline DNA-encoded receptors. NK cells are divided into two subsets, $CD56^{bright}CD16^-$ and $CD56^{dim}CD16^+$, which have different functions. $CD56^{dim}$ NK cells account for roughly 90% of NK cells in the periphery and express the low affinity Fcγ receptor (CD16), which mediates antibody-dependent, cell-mediated cytotoxicity. $CD56^{bright}$ NK cells are poorly cytotoxic but produce large amounts of cytokine and represent the majority of NK cells in peripheral lymphoid organs. NK cells are a major source of IFN-γ, which augments the microbicidal functions of macrophages. Conversely, NK cells are primed by IL-15 derived from DCs and IL-12 or IL-18 derived from macrophages, demonstrating the regulatory interactions that occur between NK cells and other cells of the immune system.

NK-cell function is regulated by a delicate balance between signals generated by inhibitory and activating receptors.[32] NK cells possess the ability to recognize and kill infected or malignantly transformed cells, while leaving healthy host cells unharmed. Inhibitory receptors on NK cells recognize class I major histocompatibility complex (MHC) molecules expressed on most healthy cells in the body.

NK inhibitory receptors include three families of receptors: heterodimers composed of CD94 and NKG2A, the Ig-like transcripts (*i.e.,* ILT-2), and the killer cell Ig-like receptor (KIR) family. The immunoreceptor tyrosine-based inhibition motifs (ITIMs) in their cytoplasmic tails recruit phosphatases (Src homology region 2 [SH2] domain-containing phosphatase-1 [SHP-1], SHP-2, and SHIP [SH2-containing inositol polyphosphate 5-phosphatase]), which oppose the effects of kinases activated by activating receptors. When NK cells encounter host cells expressing MHC class I molecules, protein tyrosine phosphatases are activated, reducing signaling downstream of activating receptors and opposing NK-cell activation (Fig. 3.2).

NK cells also possess activating receptors. CD16 mediates antibody-dependent, cell-mediated cytotoxicity and natural cytotoxicity receptors (*i.e.,* NKp46, NKp30, NKp44, NKG2D, CD94/NKG2C, 2B4). Activating receptors are linked to molecules (*i.e.,* CD3-ζ, FcR-γ, or DAP12) that contain immunoreceptor tyrosine-based activation motifs (ITAMs). Upon ligand binding, tyrosine residues within ITAMs are phosphorylated by Src family kinases. The tyrosine phosphorylated ITAMs serve as binding sites for the activation of other protein tyrosine kinases, such as Syk and ZAP-70, which activate downstream effector molecules in a signaling cascade. Infection of host cells with some viruses can lead to reduced MHC class I expression, thereby reducing viral antigen presentation to T cells. Concomitantly, ligands for activating receptors are expressed by the infected cell, leading to NK-cell activation and killing of the infected cell.

NK cells play an important role in immunosurveillance against tumors.[33] In humans, NK cell receptors that mediate tumor recognition include NKp46, NKp30, NKp44, DNAM-1 (DNAX accessory molecule-1), and NKG2D. Ligands expressed on target cells include MHC I-related chain (MIC)-A, MICB, unique long 16-binding proteins (ULBP), poliovirus receptor (PVR), and Nectin-2. DNAM-1 specific ligands include PVR and Nectin-2, which are expressed in cell lines that include carcinomas, melanomas, and neuroblastomas. Nectin expression is not specific to tumors, since nectins are expressed on normal cells. DNAM-1-nectin interactions on normal cells do not result in NK cell lysis because normal cells are protected by MHC class I expression. Conditions favoring NK cell–mediated lysis include tumors in which nectins are overexpressed and/or MHC class I expression is reduced, favoring NK-cell activation (see Fig. 3.2).

Natural killer T (NKT) cells are a small, but highly variable, population of thymus-derived T cells that express NK cell markers and a restricted repertoire of T-cell receptors (TCRs), which recognize lipids bound to the MHC-like molecule CD1d.[34] Type 1 NKT cells (also referred to as invariant NKT [iNKT] cells) express the invariant Vα24 and Jα28 TCR α chain, whereas type 2 NKT cells have a more diverse TCR repertoire. Mature human NKT cells can be further divided into three groups, including $CD4^{+}CD8^{-}$, $CD4^{-}CD8^{-}$, and $CD4^{-}CD8^{+}$ subsets. The most completely characterized NKT antigen is the lipid α-galactosylceremide (α-GalCer), which is often used to activate NKT cells experimentally. Identification of natural NKT ligands

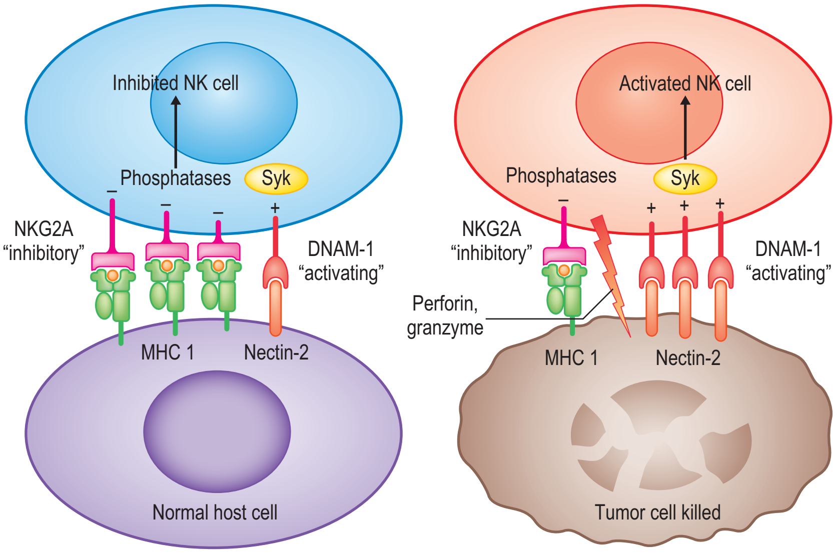

FIG 3.2 Regulation of Natural Killer (NK) Cell Function. Upon encountering normal host cells, inhibitory receptors on NK cells that contain immunoreceptor tyrosine-based inhibitory motifs (ITIMs) preferentially activate phosphatases (e.g., SHP-1/2, SHIP) that send inhibitory signals, inhibiting NK-cell function. NK cells that encounter virally infected cells or tumor cells receive signals through activating receptors that contain immunoreceptor tyrosine-based activation motifs (ITAMs) that activate tyrosine kinases, including Syk, leading to NK-cell activation, release of perforin and granzyme, and target cell death.

has proven difficult. NKT cells express perforin and granulysin and are capable of cytotoxic activity. NKT cells are also able to influence innate and adaptive immune responses through release of large amounts of cytokines, including IFN-γ, TNF-α, IL-4, IL-13, IL-10, and granulocyte macrophage–colony-stimulating factor (GM-CSF). In general, NKTs found in blood can produce large amounts of cytokines, whereas NKTs in the thymus are poor cytokine producers.

Decreased NKT cell frequency and/or function may increase susceptibility to some autoimmune diseases, including type 1 diabetes (Chapter 71) and multiple sclerosis (Chapter 66). Mice with NKT defects are susceptible to tumors and adoptive transfer of normal NKTs can provide protection against tumors (Chapter 77). NKT cells may also contribute to the pathogenesis of the airway hyperresponsiveness (AHR) in asthma (Chapter 72), which is dependent on IL-4 and IL-13 production in the airways. iNKT cells are necessary for AHR in several murine models of asthma, since NKT-deficient mice fail to develop AHR following allergen challenge, ozone challenge, or viral infection.[35] iNKT cell deficiency was associated with severe varicella infection, demonstrating a role for iNKT cells in innate antiviral immunity.[36]

Intraepithelial Lymphocytes, Innate Lymphoid Cells, B1 and MZ B Cells, and Mast Cells

Barrier epithelia of skin and the GI tract contain specific types of lymphocytes, including intraepithelial T lymphocytes (IELs) and B1 B cells (Chapter 7), which respond to commonly encountered microbes. Because of their more limited diversity of receptors, IELs can be considered part of the innate immune system. The main immune cell populations within the epidermal layer include keratinocytes, melanocytes, a type of DC known as the *Langerhans cell*, and IELs (Chapter 19).

Keratinocytes and melanocytes express a variety of PRRs, enabling detection of microbes, resulting in secretion of cytokines that can contribute to innate immune responses through recruitment and activation of phagocytes.[37] Langerhans cells form an elaborate network of dendritic processes that allow them to capture antigens that gain access to skin. Following activation by microbes, Langerhans cells migrate to draining lymph nodes and express chemokine receptor-7 (CCR7), which allows them to migrate to the T-cell zones within lymph nodes in response to the chemokine ligands (CCL)-19 and CCL-21 and present antigen to T cells.[38]

Intraepidermal T lymphocytes constitute roughly 2% of lymphocytes within the skin. This lymphocyte subset expresses a more restricted set of antigen receptors, which include both αβ and γδ TCRs, similar to IELs found in the intestines. These specialized T cells appear to be committed to recognizing microbial peptide antigens commonly found at epithelial surfaces and thus function as components of the innate immune system.[39]

IELs are a significant component of the GI immune system and reside at the basolateral side of the intestinal epithelial cell layer (Chapter 2). IEL are among the first immune cells to encounter pathogens that have breached intestinal epithelia. IEL consist of CD8 T cells, as well as memory-effector T cells bearing αβ or γδ TCRs. IELs contain a greater proportion of TCRγδ$^+$ cells than is found in the peripheral circulation.[40]

CD4$^+$TCRαβ$^+$ and CD8$^+$αβTCRαβ$^+$ IELs are class II and class I restricted, respectively. These IELs have likely undergone thymic selection and subsequently homed to the gut after antigenic stimulation. As such, these IELs are likely specific for foreign antigens.[40] They have a memory phenotype and an oligoclonal TCR repertoire. IELs in the small intestine frequently express of CD8$^+$αα (CD4$^+$CD8$^+$αα or CD8$^+$αβCD8$^+$αα), a characteristic of activated mucosal T cells within the gut microenvironment. Upon antigenic stimulation, CD8$^+$αβTCRαβ$^+$ IELs are cytolytic and kill via granzymes and perforin or through engagement of Fas.[40]

TCRγδ$^+$ IELs emigrate from the thymus and subsequently take up residence in the intestinal epithelium. They constitute roughly 10% of intestinal IELs in humans, and the majority expresses CD8αα. TCRγδ$^+$ IELs recognize nonclassic MHC molecules, such as thymus leukemia antigen or MHC class I-like molecules, MICA (MHC I-related chain [MIC]-A) and MICB, and may help modulate inflammatory immune responses. These IELs can be cytolytic and express FasL. TCRγδ+ IELs can produce keratinocyte growth factor and promote intestinal epithelial integrity.[40]

The B1 and marginal zone (MZ) subsets of B lymphocytes have been characterized as innate-like B cells. They express antigen receptors enriched for germline sequence. These cell types have been mostly studied in mice. Their identity in humans is less clear. B1 cells and MZ B cells can function as APCs, but unlike conventional B cells, B1 cells and MZ B cells do not develop into memory B cells. B1 cells and MZ B cells share characteristics: *(i)* they are the main source of natural antibodies; (ii) they express high surface levels of IgM and low surface levels of IgD; and *(iii)* they are rapidly activated by microbes through pattern recognition receptors to produce large amounts of natural antibodies.[41] B1 cells and MZ B cells produce IL-10 upon activation, which may downregulate immune responses. The natural antibodies produced by B1 cells and MZ B cells function as the first line of defense against invading microbes.

Innate lymphoid cells (ILCs) are a heterogeneous population of cells that have been recently recognized. ILCs do not express rearranged antigen-specific receptors. This lymphoid subset includes killer ILCs (*e.g.,* NK cells) and helper ILCs. Helper ILCs are further classified as ILC1, ILC2, and ILC3.

ILC1 cells express T-bet, similar to NK cells, and produce IFN-γ but lack cytolytic activity. They are found mainly within tissues and are barely detectable in peripheral blood. Oncogene-induced murine cancer model studies suggest that ILC1 cells may play a role in cancer immunosurveillance.[42]

ILC2 development is dependent on expression of the transcription factor GATA-3 and produces the cytokines IL-5 and IL-13. ILC2 cells were first identified in mice as a source of T helper (Th)2 cytokines (IL-4, -5, -13). ILC2 cells may play a role in antihelmintic immunity, immune surveillance, immune regulation, and wound healing. ILC2 cells have been shown to accumulate in the skin of patients with AD and within nasal polyps of patients with chronic rhinosinusitis. ILC2 cells produce IL-4, -5, and -13 in response to epithelial-derived IL-33, IL-25, and thymic stromal lymphopoietin (TSLP). The production of Th2 cytokines by ILC2 cells may represent an early step in the development of atopic disorders.[43]

ILC3 cells express the retinoic acid receptor related orphan receptor γt (RORγt) and produce IL-17 and IL-22 (Fig. 3.3).[44] ILC3 cells include fetal lymphoid tissue inducer (LTi) cells, which drive secondary lymphoid organ development during embryogenesis. LTi cells can induce upregulation of adhesion molecules on stromal cells and the release of chemokines involved in the recruitment of T and B lymphocytes and DCs to lymph nodes, leading to subsequent differentiation of naïve T cells into effector T cells and B-cell activation and production of antibody-secreting

	ILC1	ILC2	ILC3

Biological significance:	Cancer immunosurveillance	Helminth immunity Immune regulation Wound healing Atopic disorders?	Mucosal immunity psoriasis?

FIG 3.3 Developmental Regulation and Functions of Innate Lymphoid Cells. The development of innate lymphoid cells (ILCs) is regulated by master transcriptional regulators, including T-bet, GATA-3, and RORγt. Three subsets are recognized: ILC1, ILC2, and ILC3. ILC play roles in tumor immunosurveillance, immune regulation, wound healing, mucosal immunity, atopic disorders, psoriasis, and mucosal immunity.

cells. Postnatal ILC3 cells influence tissue homeostasis and host defense against extracellular organisms. ILC3-produced IL-22 induces expression of APPs by intestinal epithelial cells. Production of IL-17 by ILC3 cells likely contributes to host defense against *Candida*. ILC3 cells can also produce IL-2, GM-CSF, TNF-α, and leukemia inhibitory factor (LIF). Production of GM-CSF by splenic ILC3 cells is believed to promote survival and activation of splenic neutrophils. A significant population of ILC3 cells has been found in lesional skin of patients with psoriasis.[44]

Mast cells (Chapter 23) are components of innate immunity that are also commonly found at the interface between host and environment. They are derived from progenitors in bone marrow and circulate as immature precursors to the periphery. Mast cells take up residence and mature in skin, airways, and the GI tract. They are positioned to be first responders to environmental stimuli, including infectious agents.[45] Stem cell factor (SCF, also known as *c-kit ligand*) is their main survival and developmental factor. Mast cells express TLR-1 through TLR-9 and therefore are capable of responding to a wide variety of pathogens. TLR-induced mast-cell activation leads to production of proinflammatory cytokines and chemokines. Murine models of peritonitis, such as cecal ligation and puncture, demonstrate that mast cells enhance resistance to bacterial infection.[46] Mast cells are also well known for mediating allergic reactions through IgE-bound allergens that are anchored by FcεRI on the mast-cell surface. Ligation of FcεRI leads to release of tryptase, histamine, leukotrienes, prostaglandins, and cytokines, which cause type 1 hypersensitivity reactions (Chapter 42).

ACTIVATING INNATE IMMUNITY

The innate immune response is initiated when cells of the innate immune system encounter pathogens and recognize them by means of PRRs binding to microbial molecules (*e.g.,* lipopolysaccharide, DNA, RNA). These interactions activate signaling pathways that lead to the production of secreted factors involved in the inflammatory response, including cytokines (Chapter 9) and chemokines (Chapter 10). Characteristics of cytokines include pleiotropism (*e.g.,* the ability to act on multiple cell types) and redundancy. Cytokines can function locally and distantly and can affect the production of other cytokines. Exposure to cytokines can induce changes in gene expression that affect cell function (*e.g.,* enhanced microbicidal activity or proliferation). Secretion of cytokines (IL-1β, IL-6, TNF-α) is a transient event, thereby limiting potential destruction of host tissue. However, severe infections (*e.g.,* bacteremia and sepsis) can lead to overproduction of TNF-α, IL-1β, and IFN-γ, which leads to vascular collapse, disseminated intravascular coagulation, and metabolic disturbances (septic shock), which are often fatal.

Cytokine synthesis is a transient process because the messenger RNA of most cytokines is unstable, thus limiting cytokine production. Production of certain cytokines is also regulated by a posttranslational process. For example, TNF-α is a membrane-bound protein that is proteolytically cleaved by a membrane-associated metalloproteinase. IL-1β is a 33-kDa protein that is proteolytically processed by the IL-1β-converting enzyme caspase-1 to generate the biologically active, 17-kDa, mature IL-1β (described below).

TNF-α and IL-1β can recruit PMNs and monocytes to sites of infection and enhance their ability to eliminate microbes. TNF-α and IL-1β induce expression of adhesion molecules (Chapter 11), such as selectins (P-selectin, E-selectin) and the integrin ligands ICAMs (intercellular adhesion molecules) and VCAMs (vascular cell adhesion molecules) on vascular endothelial cells near the sites of infection. Expression of selectins on vascular endothelium induces leukocyte rolling on endothelium. Chemokines, such as CXCL8, activate PMNs and monocyte integrins and increase their affinity for ligands (ICAMs, VCAMs) on vascular endothelium, allowing migration of PMNs and monocytes through endothelium to sites of infection. TNF-α and IL-1β both induce prostaglandin synthesis in the hypothalamus, which induces fever.

PATTERN RECOGNITION RECEPTORS

Our understanding of the mechanisms by which pathogens are detected has increased greatly over the past decade. Pathogen

KEY CONCEPTS

Pattern Recognition Receptors (PRRs)

- Toll-like receptors consist of an extracellular domain containing leucine-rich repeats (LRRs) for ligand binding and a cytoplasmic Toll/IL-1 receptor domain that links to adapter proteins and complex signaling pathways.
- Nucleotide oligomerization domain (NOD)-like receptors are a family of 22 proteins that contain LRRs for potential ligand binding, a NOD, and a caspase activation and recruitment domain (CARD), Pyrin domain, or a baculovirus inhibitor of apoptosis repeat (BIR) domain for initiation of signaling.
- Retinoic acid-inducible gene (RIG)-like receptors consist of two N-terminal CARD for signaling and an RNA helicase domain.
- C-type lectin receptors (CLRs) contain a C (Ca^{2+})-type recognition domain and mediate diverse functions, depending on the signaling pathways they activate.
- Scavenger receptors are a diverse group of receptors that recognize a variety of ligands and mediate the uptake of oxidized lipoproteins and may be involved in atherosclerotic plaque formation.

recognition by the innate immune system leads to engulfment and destruction of invading pathogens, but clearance is often incomplete. The subsequent adaptive immune response is required to complete clearance.

The innate immune system expresses a wide variety of PRRs that mediate pathogen recognition. These include TLRs, nucleotide oligomerization domain (NOD)-like receptors (NLRs), and the retinoic acid-inducible gene-I (RIG-I)-like receptors (RLRs).[47] These receptors play an essential role in initiating the innate immune response. Unlike T-cell and B-cell antigen receptors, PRRs are germline encoded, do not undergo somatic recombination, and are expressed constitutively by immune and nonimmune cells. PRRs recognize PAMPs, components of pathogens that are invariant and required for pathogen survival (Table 3.3). Although PRRs detect the PAMPs expressed by microbes, they may also recognize self-molecules (*i.e.,* host nucleic acids), which may underlie some autoimmune diseases, such as lupus and rheumatoid arthritis.

TABLE 3.3 Classes of Pattern Recognition Receptors (PRRs)

Pattern Recognition Receptor		Ligand
Toll-like receptors (TLRs)	TLR1/2	Triacyl lipopeptides
	TLR2	Zymosan
	TLR3	dsRNA
	TLR4	LPS, RSV glycoprotein, HSPs, pneumolysin
	TLR2/6	Diacyl lipopeptide
	TLR7	ssRNA
	TLR8	ssRNA
	TLR9	dsDNA, hemozoin
	TLR10	?
	TLR11	Profilin-like protein
NOD-like receptors (NLRs)	NOD1	DAP, MDP
	NOD2	MDP
	CIITA	?
	NAIP	*Legionella pneumophilia,* flagellin?
	IPAF	PAMPs
	NLRP1	PAMPs, MDP, microbial toxins
	NLRP2	?
	NLRP3	PAMPs, toxins, DAMPs
	NLRP4–14	?
RIG-like receptors (RLRs)	RIG-I	dsRNA, ssRNA
	MDA5	dsRNA, ssRNA
C-type lectin receptors (CLRs)	Mannose receptor	Bacterial carbohydrates
	Dectin-1	Fungal wall glucans
Scavenger receptors	SRA, SRB	Oxidized lipoproteins, apoptotic cells
	CD36, CD68,	β-amyloid

dsRNA, double-stranded RNA; CIITA, class II major histocompatibility complex transactivator; DAMP, danger-associated molecular pattern; DAP, meso-diaminopimelic acid; MDP, muramyl dipeptide; IPAF, IL-1beta converting enzyme protease activating factor; LPS, lipopolysaccharide; MDA-5, melanoma differentiation-associated gene-5; PAMP, pathogen-associated molecular pattern; NAIP, neuronal apoptosis inhibitory protein; NLRP, NOD-like receptor related protein; RSV, respiratory syncytial virus; SR, scavenger receptor; ssRNA, single stranded RNA.

CLINICAL PEARLS

Toll-Like Receptors (TLRs), Caspase Activation and Recruitment Domain (CARD), NLR, and Inflammasomes

- TLRs play a nonredundant role in host defense. Impaired TLR function (*i.e.*, IL-1 receptor associated kinase-4 [IRAK-4], myeloid differentiation factor 88 [MyD88] deficiency) results in susceptibility to invasive, pyogenic infections.
- Increased infection in newborns and infants with TLR pathway defects (MyD88, IRAK-4, etc.) suggest this system is particularly important in early life.
- Missense mutations in nucleotide oligomerization domain 2 (NOD2) have been associated with Crohn disease and Blau syndrome.
- Mutations in NLRP3 are associated with Muckle Wells syndrome, familial cold autoinflammatory syndrome, and neonatal-onset multisystem inflammatory disease (NOMID).
- Mutation in CARD9 leads to susceptibility to chronic mucocutaneous candidiasis.

Toll-Like Receptors

Toll was initially identified in *Drosophila melanogaster* as a receptor required for dorsal–ventral patterning. Subsequently, the Toll pathway was found to be an essential component of host defense against fungal infection, which led to cloning of mammalian homologues, the TLRs. Mammalian TLRs consist of 11 members that can recognize a wide variety of PAMPs. TLRs are type 1 integral membrane glycoproteins characterized by an extracellular domain with varying numbers of leucine-rich repeats (LRRs) and a cytoplasmic signaling domain homologous to the IL-1 receptor (IL-1R), referred to as the Toll/IL-1R (TIR) homology domain. The TIR domain links the receptor to adaptor proteins (*e.g.,* myeloid differentiation factor 88 [MyD88]) and downstream signaling molecules. This leads to transcription of genes that regulate inflammation (Fig. 3.4).

TLRs are widely expressed on or within cells of the immune system and the epithelia. TLRs detect a wide variety of pathogens (see Table 3.3). They are classified into subfamilies based on their genetic tree. The TLR1, TLR2, and TLR6 subfamily recognizes bacterial lipoproteins, whereas the TLR3, TLR7, TLR8, and TLR9 subfamily recognizes nucleic acids. TLR4, in conjunction with MD-2, recognizes lipopolysaccharide (LPS), TLR5 binds bacterial flagellin, and TLR11, which is functional in mice but probably not in humans, recognizes a profilin-like molecule of *Toxoplasma gondii.* However, ligand binding by TLRs can be

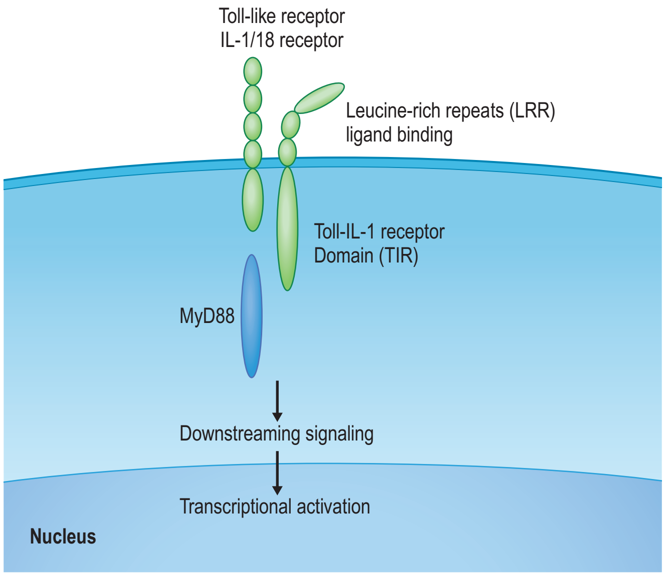

FIG 3.4 Toll-Like Receptors (TLRs) and Interleukin (IL)-1/-18 Receptors Share a Common Signaling Pathway. Upon ligand binding, signals are transduced intracellularly by the interaction of the adaptor protein, MyD88, with the TIR domain of receptor. MyD88 interacts with IL-1 receptor associated kinase (IRAK)-4 through death domain interactions, activating a signaling cascade, which results in transcriptional activation of genes involved in inflammation.

promiscuous. For example, TLR4 can also bind respiratory syncytial virus F protein and pneumolysin of *S. pneumoniae*[48,49]; and TLR9 binds malarial hemozoin and hypomethylated CpG-rich DNA. TLRs can also recognize endogenous danger signals, for example, damage-associated molecular patterns (DAMPs) that include heat shock proteins.[50]

The cellular localization of TLRs varies. TLR1, -2, -4, -5, -6, -10, and -11 are found on cell surfaces, whereas TLR3, -7, -8, and -9 are located within endosomes. The cell surface expression of TLRs, such as TLR4, which recognizes LPS, allows recognition of extracellular molecules released from pathogens. Endosomal expression of TLR3, -7, -8, and -9 allows recognition of microbial nucleic acids following their uptake and degradation in phagolysosomes. Endosomal expression of TLR3, -7, -8, and -9 may prevent activation by host nucleic acids and the development of autoimmunity. The broad cellular expression of TLRs and their diverse and promiscuous agonist recognition allows detection of a wide variety of pathogens despite the existence of a limited number of TLRs.

TLR-mediated cellular responses are essential to host defense. TLR activation stimulates a brief burst of macropinocytosis, which results in antigen uptake at sites of infection and allows antigen presentation to T cells. TLR activation leads to production of proinflammatory cytokines (*e.g.,* TNF-α and IL-6) and chemokines (*e.g.,* CXCL8). TLR pathway engagement induces transcription and translation of messenger RNA (mRNA) encoding pro-IL-1β, but production of mature IL-1β requires activation of the inflammasome (described below). Production of proinflammatory cytokines recruits phagocytes to sites of infection and augments their antimicrobial functions. Production of IL-12p70 leads to activation of naïve T cells and their subsequent differentiation into effector Th1 cells. Presentation of foreign peptides and increased expression of MHC molecules along with expression of costimulatory molecules (*e.g.,* B7–1, B7–2, and IL-12p70) results in subsequent development of adaptive immune responses. IL-12p70 stimulates IFN-γ production by T cells, which further augments the microbicidal activities of phagocytes. Stimulation of TLR3, -7, -8, and -9 elicits the production of proinflammatory cytokines, as well as type 1 IFNs, which play a crucial role in innate antiviral immunity and also influence adaptive immune responses.

Engagement of TLRs activates complex signaling pathways that have been characterized through biochemical analyses and in gene-targeted mice.[51-53] TLR, IL-1R, and IL-18R share similar signaling pathways (Fig. 3.5). Upon ligand binding, the cytoplasmic adaptor protein MyD88 is recruited to the TIR domain of the receptor for all TLRs, except TLR3. Recruitment of MyD88 leads to recruitment of IL-1 receptor associated kinase-4 (IRAK-4), likely through death domain interactions. IRAK-4 activation leads to recruitment and activation of IRAK-1 and IRAK-2. In monocytes, IRAK-M is also recruited to this complex and functions as a negative regulator of signaling. Both IRAK-1 and IRAK-2 activation are required for full activation of NFκB and MAP kinases. IRAK activation leads to interaction with TNF receptor–associated factor 6 (TRAF6), which is an E3 ubiquitin ligase. Along with the E2 conjugating complex of Ubc13 and Uev1a, TRAF6 is K-63 ubiquitinated, recruiting TGF-β–activated protein kinase-1 (TAK-1). TAK-1 then activates the inhibitor of NFκB (IκB) kinase complex (IKK), which consists of NFκB essential modifier (NEMO), IKKα, and IKKβ, leading to phosphorylation of IκB (inhibitor of NFκB) proteins and their subsequent K-48 linked ubiquitination and degradation. NFκB is subsequently released from inhibition, allowing translocation to the nucleus, where it mediates transcriptional activation of numerous genes involved in inflammation. The transcription factor interferon regulatory factor-5 (IRF-5) is also activated downstream of TRAF6 and is required for production of proinflammatory cytokines. TAK-1 activation also leads to activation of p38 MAP kinase and c-Jun N terminal kinase (JNK), which then activates the AP1 transcriptional complex (see Fig. 3.5).

TLR signaling can proceed via multiple pathways, impacting both the kinetics and nature of the subsequent innate response. For example, TLR4 also interacts with the adaptors MAL (MyD88-like adaptor protein), TRAM (translocating chain-associating membrane protein), and TRIF (TIR domain–containing adaptor-inducing IFN-β) (see Fig. 3.5). TLR4 initially recruits MAL and MyD88 to trigger "early phase" NFκB and MAP kinase activation. TLR4 is subsequently endocytosed and trafficked to the endosome, where it forms a signaling complex with TRAM and TRIF, which leads to activation of TANK-binding kinase-1 (TBK-1), IKKε, and IRF-3, and "late phase" activation of NFκB and MAP kinases. Activation of IRF3 induces IFN-β production.

Antiviral TLRs are located in endosomes and interact with an endoplasmic reticulum membrane protein called UNC93B (see Fig. 3.5).[54] Upon activation, TLR3 does not recruit MyD88, but rather TRIF, leading to recruitment of TRAF3 and activation of TBK1, IKKι, IRF-3, and IFN-β production. TRIF also recruits RIP1 and TRAF6, which leads to activation of NFκB. While the other antiviral TLRs, TLR7, -8, and TLR9, are MyD88 dependent; they activate a pathway utilizing IRAK-1, IKKα, TRAF3, and intracellular osteopontin (iOPN), which activates IRF7, leading to production of IFN-α.[55] TLR7, -8, and -9 also utilize a TRAF6-dependent pathway that leads to NFκB/MAP kinase activation.

FIG 3.5 **MyD88-Dependent and -Independent Toll-Like Receptor (TLR) Signaling Pathways.** Engagement of MyD88-dependent TLR (TLR5) results in activation of IL-1 receptor associated kinase (IRAK)-4 and IRAK-1, IRAK-2, leading to activation of TRAF6 and TAK-1. Subsequently, activation of the IκB kinase (IKK) complex and MAP kinases activates NF-κB and AP1 transcription factors, respectively. The transcription factor IRF5 is also activated downstream of TNF receptor–associated factor 6 (TRAF6). The TLR4 signaling pathway utilizes four adaptor proteins. The adaptors MAL and MyD88 are activated upon ligand interaction at the cell surface, leading activation of an "early" signaling cascade through the IRAKs. Subsequently, TLR4 is internalized and a "late" signaling cascade, which is dependent on the adaptors TRAM and TRIF, is activated. TLR3 activates a TRIF-dependent pathway that activates RIP1 and TBK1/IKKι, leading to production of proinflammatory cytokines and IFN-β. TLR7, -8, and -9 are MyD88 dependent and activate the transcription factors NF-κB, IRF5, AP1, and IRF7, resulting in production of proinflammatory cytokines and type 1 interferons.

Bruton tyrosine kinase (BTK) (Chapter 34) also plays a critical role in TLR8- and TLR9-induced production of TNF-α and IL-6.[56]

The innate immune system *in natura* encounters intact pathogens that express multiple PAMPs, including bacterial cell wall components as well as microbial DNA and RNA. Thus DCs and other phagocytes are activated through multiple PRRs. Activation of DCs through combinations of TLRs, such as TLR4 and TLR8, can induce synergistic production of Th1 cell–inducing cytokines, as well as the Th1-inducing ligand, Delta-4, leading to stronger Th1 differentiation of T cells than occurs following activation of single TLR.[57] Interestingly, the use of combinations of TLR agonists on virus-sized nanoparticles containing antigen induce enhanced and better-sustained antibody responses in mice and nonhuman primates.[58] Thus the use of combinations of TLR agonists as adjuvants in vaccines may result in enhanced efficacy of future vaccines (Chapter 90), as well as in immunotherapy against tumors (Chapter 77).

During an infection, multiple factors can mitigate TLR-induced inflammation, and these include adenosine, an endogenous purine metabolite whose levels rise during stress or hypoxia. Adenosine binds receptors expressed on leukocytes, leading to increased intracellular concentrations of cyclic adenosine monophosphate (cAMP), dampening TLR-mediated production of Th1-polarizing cytokines while preserving production of Th2 and antiinflammatory cytokines. Antiinflammatory/proresolving lipid metabolites, such as resolvins and lipoxins, can differentially regulate TLR4-mediated responses of macrophages, inhibiting TNF response to pure LPS but enhancing uptake, killing, and TNF-α production to whole gram-negative bacteria.[59]

Within the GI tract, the factors that maintain tolerance to commensal host flora while detecting/containing pathogenic

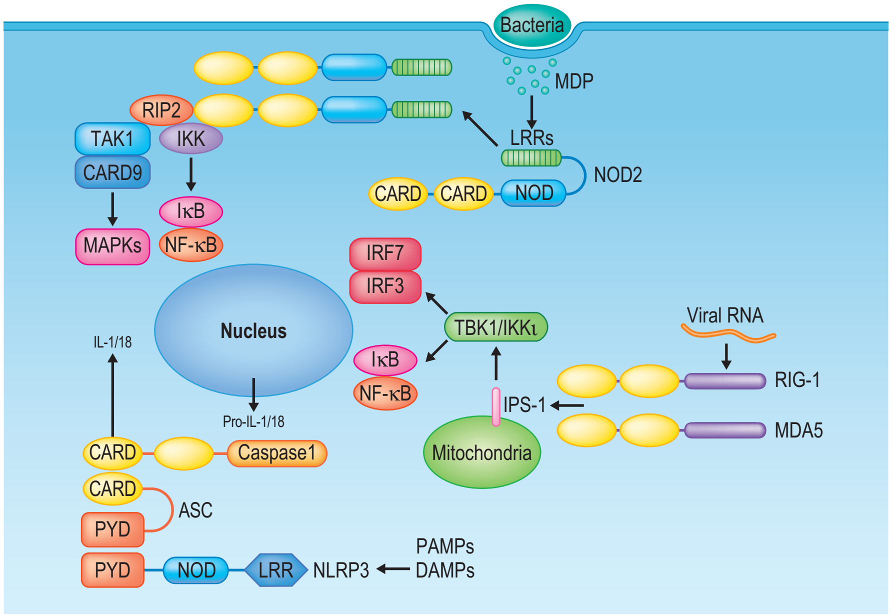

FIG 3.6 NOD-Like Receptor (NLR), RIG-I–Like Receptor (RLR), and Inflammasome Signaling. NOD2 is activated following exposure to bacterial muramyl dipeptide (MDP) and leads to dimerization and activation of RIP2, TAK1, CARD9, and the IκB kinase (IKK) complex. This results in inflammatory gene transcription. RLRs, like RIG-I and MDA-5, are activated by double-stranded RNA generated by intracellular, replicating viruses, inducing activation of transcription factors, including NF-κB, IRF3, and IRF7, leading to production of proinflammatory cytokines and type 1 interferons. Inflammasomes can be activated by microbial products (PAMPs), as well as endogenous products released by damaged host cells (DAMPs), leading to processing of pro-IL-1β to active IL-1β.

bacteria with appropriate inflammatory responses are incompletely understood. The detection of common PAMP in pathogenic and nonpathogenic bacteria would be anticipated to activate the same inflammatory response. Nevertheless, the detection of commensal bacteria within the intestines can induce tolerance. TLR signaling can contribute to intestinal homeostasis by regulating intestinal epithelial cell proliferation and epithelial integrity. Expression and localization of TLRs in the intestinal epithelium may directly relate to their role in maintaining homeostasis versus inducing inflammation. For example, within the intestinal epithelium, TLR9 activation through the apical membrane induces tolerance, whereas TLR9 activation via the basolateral membrane induces an inflammatory response through the canonical NF-κB pathway.[60] Differential spatial expression of PRR in epithelia may constitute a critical mechanism of distinguishing nonpathological from pathological bacteria.

NOD-Like Receptors

NLRs are cytoplasmic PRRs that are unrelated to the transmembrane PRRs. NLRs mediate detection of intracytoplasmic bacterial products. Among the NLRs are five members of the NOD family, 14 members of the NALP family, CIITA, IPAF, and NAIP (see Table 3.3). NLR family proteins possess LRRs for ligand detection; a NOD domain (also referred to as a NACHT domain); a domain for initiation of signaling, such as caspase activation and recruitment domain (CARD); pyrin domains; or baculovirus inhibitor of apoptosis repeat (BIR) domains. NOD1 and NOD2 were the first NLRs identified. They detect components of bacterial peptidoglycan: NOD1 detects mesodiaminopimelic acid, and NOD2 detects muramyl dipeptide. Direct ligand binding by NLR has not yet been demonstrated, leaving open the possibility that detection of pathogens and other signals by NLRs may be indirect. Following activation, NODs oligomerize and recruit the protein kinase RIP2 and CARD9 via CARD domains, leading to activation of NF-κB and MAP kinases, respectively (Fig. 3.6). NOD2 may also play a role in activation of some inflammasomes (described below). In humans, missense mutations in NOD2 that impair function have been associated with susceptibility to Crohn disease. Conversely, missense mutations in NOD2 that lead to constitutive activation of NF-κB lead to Blau syndrome, an autosomal dominant disorder characterized by granulomatous arthritis, iritis, and skin granulomas.[61]

RIG-I–Like Receptors

RLRs detect the presence of viral nucleic acids generated by intracellular, replicating viruses. The RLRs consist of two receptors: RIG-I and melanoma differentiation-associated gene-5 (MDA-5). Both have two N-terminal CARDs and an RNA helicase domain and mediate virus-induced type 1 IFN expression in fibroblasts and conventional DCs. A third RLR, laboratory of genetics and physiology 2 (LGP2), lacks the N-terminal CARD domains and plays a role in repression of signaling. RIG-I and MDA-5 are activated by double-stranded RNA (dsRNA) generated during viral replication with distinct specificities for viral recognition. RIG-I detects Orthomyxoviridae, Rhabdoviridae, Paramyxoviridae, and Flaviviridae, whereas MDA-5 detects Picornaviridae, Caliciviridae, and Coronaviridae. Poly inosine:cytosine (poly I:C) is a nonspecific dsRNA analogue used experimentally to activate TLR3 and RIG-I/MDA-5. Relatively short poly I:C (<1 kb) is recognized preferentially by RIG-I, whereas long poly I:C (>1 kb) is preferentially recognized by MDA-5.[48]

dsRNA-induced activation of RIG-I and MDA-5 induces their association with a mitochondria-associated adaptor known as interferon-β promoter stimulator-1 (IPS-1) or mitochondrial antiviral signaling protein (MAVS) through CARD domain interactions. Downstream effectors include TBK-1 and IKKι, which activate IRF3 and IRF7, leading to production of type-1 interferons (see Fig. 3.6). Of note, live bacteria are more effective inducers of STAT-1, type I IFN, and inflammasome pathways compared with killed organisms, a property that may reflect the importance of bacterial RNA to innate recognition of live infection.[62]

C-Type Lectin Receptors

C-type lectin receptors (CLRs) are a diverse group of receptors originally identified as Ca^{2+}-dependent carbohydrate-binding proteins.[63] CLRs are defined as any protein that contains a C-type carbohydrate recognition domain (CRD), regardless of calcium- or carbohydrate-binding ability. CLRs include numerous members with diverse functions, including cell adhesion, regulation of NK-cell function, phagocytosis, endocytosis, platelet activation, complement activation, tissue remodeling, and innate immunity. In myeloid cells, CLRs can mediate internalization of microbes to allow for antigen processing and presentation. Some CLRs function analogously to TLR, resulting in direct cellular activation and generation of inflammatory responses. Other CLRs are capable of binding PAMPs, but function to modulate cell activation. The functions of myeloid CLRs are dictated by the signaling pathways they activate.

Dectin-1 is a CLR expressed on DCs and other myeloid cells that recognizes β-1, 3-linked glucans present in the cell wall of fungi, mycobacteria, and plants. Dectin-2 recognizes high mannose structures and α-mannans found in fungi, mycobacteria, and dust mites. Following ligand binding, Dectin-1 and Dectin-2 activate signaling pathways by utilizing the tyrosine kinase Syk, CARD9, and Raf-1, leading to activation of the transcription factors NF-κB, NFAT, and AP-1 and production of proinflammatory cytokines (Fig. 3.7). The production of cytokines (IL-1, IL-6, TGF-β, IL-23) downstream of Dectin-1 and Dectin-2 induces the subsequent differentiation of naïve T cells into Th17 T cells, which play a critical role in antifungal immunity. Activation of Syk induces generation of ROIs, which can activate the NLRP3 inflammasome, leading to processing of pro-IL-1β to mature IL-1β. The importance of CLR function in antifungal immunity is demonstrated by inactivating mutations in Dectin-1 and CARD9 that lead to chronic mucocutaneous candidiasis, as well as invasive fungal infections in the case of CARD9-deficiency.[64]

Mincle (macrophage inducible C-type lectin) recognizes α-mannans and glycolipids and associates with the FcRγ chain. Upon ligand binding, Syk is recruited to the ITAM of FcRγ, leading to cellular activation. Mincle also binds the endogenous nucleoprotein SAP130, which is exposed by dead cells. The Mincle-mediated response to dead cells leads to infiltration of PMNs into damaged tissue and may contribute to tissue repair.

Other CLRs, such as DCIR (DC-inhibitory receptor), possess an inhibitory ITIM motif. DCIR is expressed on myeloid cells, DCs, and B cells. DCIR inhibits TLR8-induced IL-12p70 and TNF-α production by myeloid DCs and TLR9-induced IFN-α/β production by pDCs. Inhibition of TLR responses may reflect inhibition of tyrosine kinases and/or PI3 kinase pathways.

Pathogens express multiple PAMPs that activate a variety of PRRs. Indeed, CLRs and TLRs cooperate in antimicrobial responses. Coordinate activation of Dectin-1 and TLR2, for example via stimulation with zymosan, enhances production of proinflammatory cytokines, via activation of both Dectin-1-Syk and TLR2-MyD88 signaling pathways (see Fig. 3.7). DC-SIGN, which recognizes mycobacteria and viruses, can enhance TLR-induced NF-κB activation through a Raf-1–dependent signaling pathway.[65]

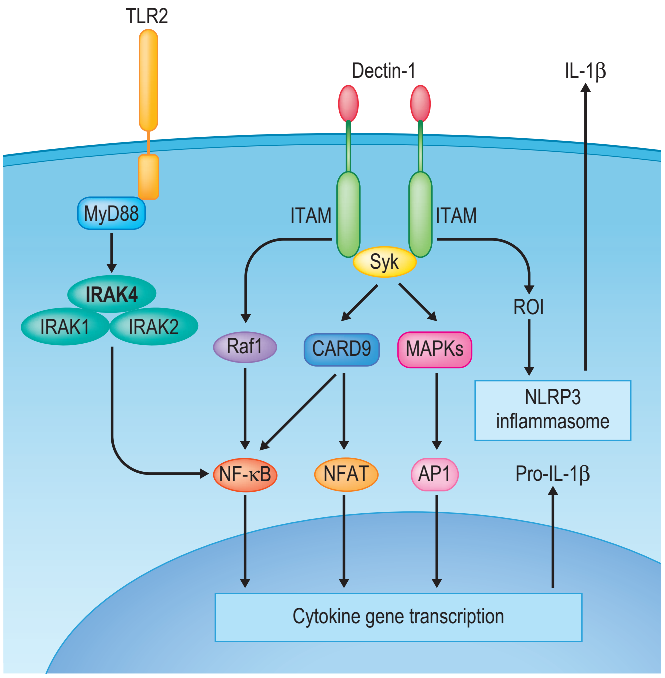

FIG 3.7 **C-Type Lectin Signaling.** C-type lectin receptors (CLRs), like Dectin-1, contain immunoreceptor tyrosine-based activation motifs (ITAMs) that interact with the cytosolic tyrosine kinase, Syk, leading to activation of transcription factors including NF-κB, NFAT, and AP1. Dectin-1 activates the serine kinase, Raf1, which contributes to NF-κB activation. Toll-like receptors (TLRs), such as TLR2, can cooperate with Dectin-1 signaling to activate NF-κB, leading to an enhanced inflammatory response.

Scavenger Receptors

Scavenger receptors are a diverse group of receptors that include CD36, CD68, SR class A, and SR class B.[66] The receptors mediate the uptake of oxidized lipoproteins into cells. Scavenger receptors also mediate the uptake of microbes and contribute to the response of macrophages to mycobacteria. SR class A can also mediate an inflammatory response to β-amyloid fibrils that may contribute to Alzheimer disease (see Table 3.3). Scavenger receptors play a pathological role in the generation of cholesterol-laden foam cells that comprise atherosclerotic plaques in blood vessels.

Inflammasomes

A variety of stimuli, including PAMPs, bacterial toxins, the common vaccine adjuvant aluminum hydroxide (alum), and ultraviolet (UV) light, as well as endogenous "danger signals" released by stressed or damaged host cells, referred to as DAMPs (*e.g.*, adenosine triphosphate [ATP], uric acid, hyaluronan), induce the processing of pro-IL-1β to mature IL-1β. The cytosolic cellular machinery responsible for IL-1β processing is termed the *inflammasome*. Prototypical inflammasomes include the NOD-like receptor-related protein-1 (NLRP1) inflammasome, the NLRP3

ON THE HORIZON

- Better understanding of populations of innate immune cells found within tissues affected by a variety of diseases (*e.g.,* psoriasis, atopic dermatitis, nasal polyps, tumors) will likely lead to targeted therapies (*e.g.,* anti–interleukin [IL]-17 for treatment of psoriasis).
- Knowledge of how individual and combined pattern recognition receptor (PRR) activation directs both innate immune activation (including trained immunity) as well as differentiation of naïve T cells may inform development of more effective vaccines.
- A better understanding of age-specific innate immune function should lead to development of new vaccine strategies to protect vulnerable populations, including newborns, young infants, and older adults.

inflammasome, and the IL-1β-converting enzyme protease-activating factor (IPAF) inflammasome. NLRP recruit ASC (apoptosis-associated speck-like protein containing a CARD) via homotypic PYRIN domain interactions. ASC is an adaptor protein that contains a PYRIN domain and a CARD domain. Caspase-1 is subsequently recruited via CARD domains, leading to proteolytic processing of IL-1β and IL-18 (see Fig. 3.6). Although NLRP1, NLRP3, and IPAF form prototypical inflammasomes, other NLR, including NOD2 and neuronal apoptosis inhibitory protein (NAIP), can also form inflammasomes or modulate their activities.[67]

Mutations in the *NLRP3* gene are associated with a spectrum of autosomal dominant inherited autoinflammatory diseases, including Muckle Wells syndrome (sensorineural deafness, urticaria, fevers, chills, arthritis), familial cold autoinflammatory syndrome (rash, conjunctivitis, fever, chills, arthralgias elicited by cold exposure), and neonatal-onset multisystem inflammatory disease (NOMID) (rashes, arthritis, chronic meningitis). These disorders are the result of constitutive production of IL-1β. Treatment of these disorders involves antiinflammatory therapy, including IL-1 antagonists.[68]

INNATE IMMUNITY IN CLINICAL PRACTICE

Our growing understanding of the molecular and cellular basis for innate immunity is paralleled by increasing appreciation of its importance to clinical medicine. Examples include *(i)* recognition of novel primary immunodeficiencies in the innate immune pathways presenting with heightened susceptibility to bacterial (*e.g.,* MyDD88-deficiency and IRAK-4-deficiency) and fungal (*e.g.,* CARD9-deficiency) infection; *(ii)* appreciation of immune ontogeny (*i.e.,* the change in immune function in a given individual across their life span, which parallels age-specific susceptibility to infection); *(iii)* clinical studies of the potential use of APP congeners to prevent or treat infection; *(iv)* leveraging PRR agonists, such as TLR agonists, as vaccine adjuvants (e.g., the TLR4 agonists monophosphoryl lipid A [MPLA] a detoxified form of lipopolysaccharide or endotoxin used in a licensed human papillomavirus [HPV] vaccine [Cervarix]); and *(v)* employing certain live attenuated vaccines, such as Bacille Calmette-Guérin (BCG) or measles, mumps, rubella (MMR) vaccine that activate multiple PRRs to reduce infections to antigenically distinct pathogens—so called beneficial heterologous or “nonspecific” effects—that may be mediated via epigenetic reprograming of monocytes and enhancement of innate immune responses.[2,12,69,70]

Our understanding of the complexity of innate immunity has advanced considerably over the past decade. The importance of the innate immune system to human health is underscored by single gene mutations, such as IRAK4 deficiency, that result in immune deficiencies and infection, particularly in early life.[71] Continued elucidation of the cell types comprising the innate immune system has expanded our understanding of the delicate balance between tolerance to nonpathogenic commensal bacteria and inflammatory responses to pathogenic, invasive microbes. As innate immunity is expressed in an age-specific manner, a better understanding of the ontogeny of the innate immune system, as well as the mechanisms by which innate and adaptive immunity interact, will guide development of adjuvants, resulting in more effective vaccines and tumor immunotherapy.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following statements regarding the complement system is true?
   - **A.** Defects in early components of the complement cascade (*i.e.,* C1, C2, or C3) are associated with increased susceptibility to meningococcal infections.
   - **B.** Paroxysmal nocturnal hemoglobinuria results from mutations within the *CD55* gene.
   - **C.** The classical complement pathway is initiated by the spontaneous generation of C3b in the plasma.
   - **D.** Hereditary angioedema results from mutations in the C1 esterase inhibitor gene.

2. Which of the following are characteristics of natural killer (NK) cells?
   - **A.** NK cells require two signals to kill targets.
   - **B.** NK-cell function is regulated by a balance between inhibiting and activating signals.
   - **C.** CD56$^{\text{bright}}$ NK cells have potent cytotoxicity activity.
   - **D.** NK cells express somatically rearranged receptors.

3. Which of the following cell types is responsible for mediating type 1 hypersensitivity reactions:
   - **A.** Dendritic cells
   - **B.** Neutrophils
   - **C.** Natural killer T (NKT) cells
   - **D.** Mast cells

4. Inflammasome activation leads to release of mature interleukin-1 (IL-1) and IL-18. Activation of which of the following receptors leads to activation of the inflammasome?
   - **A.** Nucleotide-binding oligomerization domain (NOD)-like receptor–related proteins
   - **B.** Toll-like receptors (TLRs)
   - **C.** Complement receptors
   - **D.** RIG-I–like receptors

4

Antigen Receptor Genes, Gene Products, and Coreceptors

Harry W. Schroeder, Jr., John B. Imboden, Raul M. Torres

In 1890, von Behring and Kitasato reported the existence of an agent in blood that could neutralize the diphtheria toxin. The following year, glancing references were made to "*Antikörper*" in studies describing the ability of the agent to discriminate between two immune bodies, or substances. The term *antigen* is a shortened form of "*Antisomatogen + Immunkörperbildner,*" or the substance that induces the production of an antibody (Chapter 6). Thus the definition of antibody and antigen represent a classic tautology.

In 1939, Tiselius and Kabat used electrophoresis to separate immunized serum into albumin, α-globulin, β-globulin, and γ-globulin fractions. Absorption of the serum against the antigen depleted the γ-globulin fraction; yielding the terms *gammaglobulin, immunoglobulin* (Ig), and *IgG.* Subsequently, "sizing" columns were used to separate Igs into those that were "heavy" (pentameric IgM), "regular" (IgA, IgE, IgD, IgG, monomeric IgM), and "light" (light-chain dimers), culminating with the discovery of the last major class of immunoglobulin, IgE, in 1966.

In 1949, Porter used papain to digest IgG molecules into two types of fragments, termed *Fab* (fragment antigen-binding) and *Fc* (fragment crystallizable). The constancy of the Fc fragment permitted its crystallization and thus the elucidation of its sequence and structure. The variability of the Fab fragment precluded analysis until Bence-Jones myeloma proteins were identified as clonal, isolated light chains.

In 1976, Hozumi and Tonegawa demonstrated that the variable portion of κ chains was the product of the rearrangement of variable (V) and joining (J) gene segments. In 1982, Alt and Baltimore reported that terminal deoxynucleotidyl transferase (TdT) could be used to introduce non-germline–encoded sequence between rearranging V, D (diversity), and J gene segments, potentially freeing the preimmune heavy-chain repertoire from germline constraints. In 1984, Weigert et al. determined that during affinity maturation, variable domains could undergo mutation at a rate of 10^{-3} per base pair (bp), per generation. These discoveries clarified how lymphocytes could generate an astronomically diverse antigen receptor repertoire from a handful of gene elements.

In 1982, Allison et al. raised antisera against a cell surface molecule that could uniquely identify individual T-cell clones. A year later, Kappler and a consortium of colleagues demonstrated that these surface molecules were heterodimers composed of variable and constant region domains, just like Igs. Subsequently, Davis and Mak independently cloned the β chain of the T-cell receptor (TCR). Initial confusion regarding the identity of the companion α chain led to the realization that there were two mutually exclusive forms of TCR, αβ and γδ.

PARATOPES AND EPITOPES

Igs and TCRs both belong to the eponymous Ig superfamily (IgSF).[1] The study of antibodies precedes that of TCR by decades; hence much of what we know is based on knowledge first gleaned from the study of Igs.

Ig–antigen interactions typically take place among the *paratope,* the site on the Ig at which the antigen binds, and the *epitope,* which is the site on the antigen that is bound. Thus lymphocyte antigen receptors do not recognize antigens, but they recognize the epitopes borne on those antigens. This makes it possible for the cell to discriminate between two closely related antigens, each of which can be viewed as a collection of epitopes. It also permits the same receptor to bind divergent antigens that share equivalent or similar epitopes, a phenomenon referred to as *cross-reactivity.*

Although both Igs and TCRs can recognize the same antigen, they do so in markedly different ways. Igs tend to recognize intact antigens in soluble form, and thus preferentially identify surface epitopes that are often composed of conformational structures noncontiguous in the antigen's primary sequence. In contrast, TCRs recognize fragments of antigens, both surface and internal, that have been processed by a separate antigen-presenting cell (APC) and then bound to a major histocompatibility complex (MHC) class I or class II molecule (Chapters 5, 6).

THE BCR AND TCR ANTIGEN RECOGNITION COMPLEX

Although the ability of the surface antigen receptor to recognize antigen was appreciated early on, the mechanism by which the membrane-bound receptor relayed this antigen recognition event into the cell interior was not understood, since both B-cell receptor (BCR) and TCR cytoplasmic domains are exceptionally short. This conundrum was solved when it was shown that BCR and TCR each associate noncovalently with signal transduction complexes: heterodimeric Igα:Igβ (also known as CD79a:CD79b, respectively) for B cells and multimeric CD3 for T cells. Loss of function mutations in either of these complexes leads to cell death, which becomes clinically manifest as hypogammaglobulinemia in the case of B cells (Chapter 34), or severe combined immune deficiency (SCID) in the case of T cells (Chapter 35).

IMMUNOGLOBULINS AND TCR STRUCTURES

The Ig Domain, the Basic IgSF Building Block

Igs consist of two heavy (H) and two light (L) chains (Fig. 4.1). The L chain can be either a κ or a λ chain. TCRs consist of either an αβ or a γδ heterodimer. Each component chain contains two or more IgSF domains, each of which consists of two sandwiched β pleated sheets "pinned" together by a disulfide bridge between two conserved cysteine residues.[1] Considerable variability is allowed to the amino acids that populate the external surface of the IgSF domain and the loops that link the β strands. These solvent exposed surfaces offer multiple targets for docking with other molecules.

Two types of IgSF domains, "constant" (C) and "variable" (V), are used in Igs and TCRs (see Fig. 4.1). C-type domains, which are the most compact, have seven antiparallel strands distributed as three strands in the first sheet and four strands in the second. Side chains positioned to lie between the two strands tend to be nonpolar in nature, creating a hydrophobic core of considerable stability. V-type domains add two additional antiparallel strands to the first sheet, creating a five-strand–four-strand distribution. The two additional strands, which encode framework region 2 (FR2), are used to steady the interaction between heterodimeric V domains, allowing them to create a stable antigen-binding site.[2]

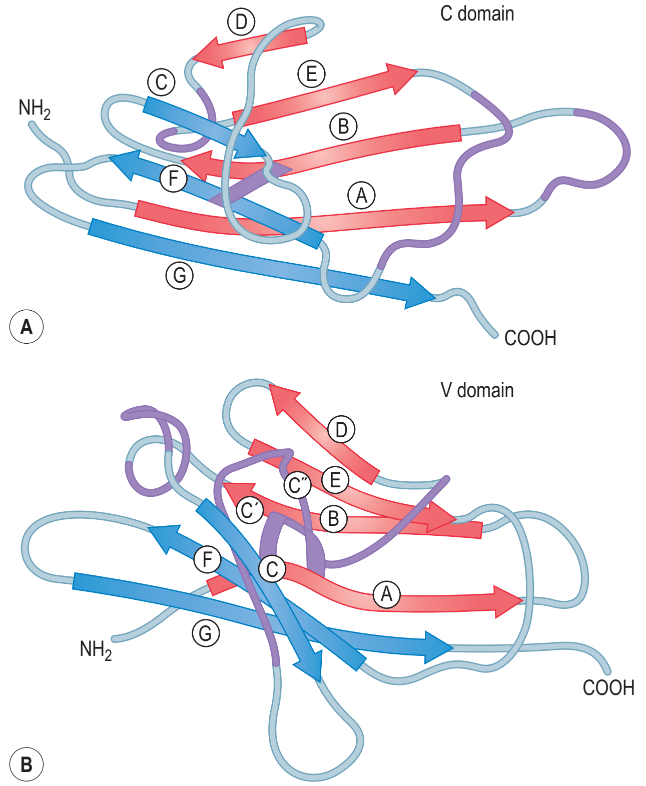

FIG 4.1 Immunoglobulin Superfamily (IgSF) Domain Structures. (**A**) A typical compact C domain structure. The β strands are labeled A through G. The sequence at the core is conserved and nonpolar. The external surface and the β-loops are available for docking and often vary in sequence. (**B**) A typical V domain structure. Two additional strands, C′ and C″, have been added. Note the projection of the C-C′ strands and loop away from the core.

Although each Ig or TCR chain contains only one amino-terminal V Ig domain, the number of carboxy-terminal C domains varies. Ig H chains contain between three and four C domains, whereas both Ig L chains and all four TCR chains contain only one C domain each. IgH chains with three C domains tend to include a spacer hinge region between the first (C_H1) and second (C_H2) domains. Each V or C domain consists of approximately 110–130 amino acids, averaging 12 000–13 000 kilodaltons (kDa). A typical L chain will mass approximately 25 kDa, whereas a three C domain Cγ H chain with its hinge and tail will mass approximately 55 kDa.

Idiotypes and Isotypes

Immunization of heterologous species with monoclonal antibodies (mAbs; or a restricted set of Igs) has shown that Igs and TCRs contain both common and individual antigenic determinants. Individual determinant(s), termed *idiotype(s)*, are contained within V domains. Common determinants, termed *isotypes*, are specific for the constant portion of the antibody and allow grouping of Igs and TCRs into recognized classes. Each class defines an individual type of C domain. Determinants common to subsets of individuals within a species, yet differing between other members of that species, are termed *allotypes* and define inherited polymorphisms that result from allelic forms of the genes.[3]

The V Domain

Early comparisons of the primary sequences of V domains identified three hypervariable intervals, termed *complementarity-determining regions* (CDRs), situated between four framework regions of stable sequence (Fig. 4.2). The current definition of these regions integrates sequence diversity with three-dimensional structure.[4] The international ImMunoGeneTics information system (IMGT) maintains an extremely useful website (http://www.imgt.org), which contains a large database of Ig and TCR sequences and numerous software tools for their analyses.

Antigen Recognition and Fab

Studies of Ig structure were facilitated by the use of papain and pepsin to fragment IgG molecules. Papain digests IgG into two antigen-binding fragments (Fab) and a single crystallizable (or constant) fragment (Fc). Pepsin splits IgG into an Fc fragment and a single dimeric $F(ab')_2$ that can cross-link as well as bind antigens. Fab contains one complete L chain in its entirety and the V and C_H1 portion of one H chain (see Fig. 4.2). Fab can be further divided into a variable fragment (Fv) composed of the V_H and V_L domains and a constant fragment (Fb) composed of the C_L and C_H1 domains. Single Fv fragments can be genetically engineered to recapitulate the monovalent antigen-binding characteristics of the original, parent antibody.[5] The extracellular domains of TCRαβ and TCRγδ correspond to Ig Fab.

Effector Function and Fc

The Fc portion (see Fig. 4.2) encodes the effector functions of the Ig. These functions are generally inflammatory reactions, which include fixation and activation of complement, and binding of antibody to Fc receptors on the surface of other cells. Each Ig class and subclass exhibits its own set of effector functions.[6]

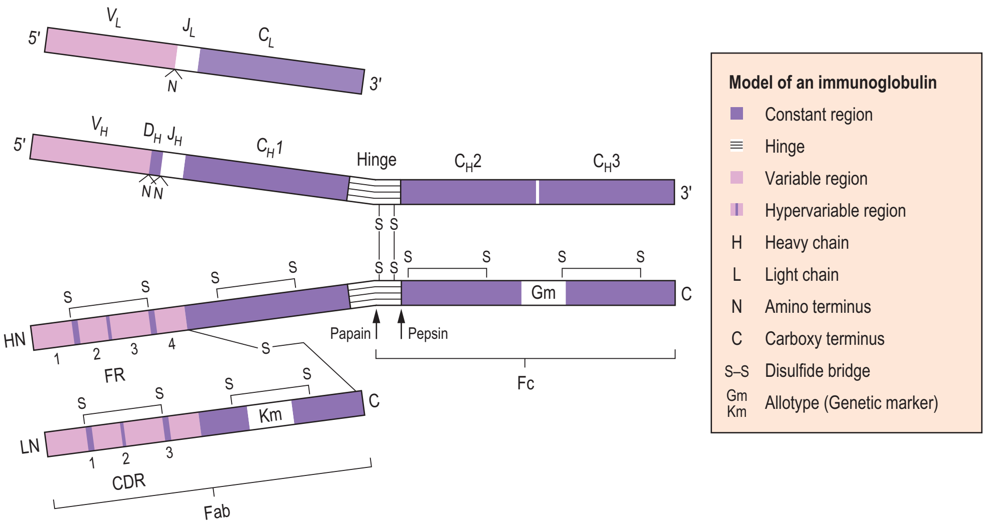

FIG 4.2 **A Two-Dimensional Model of an Immunoglobulin G (IgG) Molecule.** The top H and L chains illustrate the composition of these molecules at a nucleotide level. The bottom chains illustrate the nature of the protein sequence. See text for further details.

TABLE 4.1 Selected Properties of Immunoglobulin (Ig) Classes

	IgG	IgA	IgM	IgD	IgE
Molecular weight	160 000	170 000 or polymer	900 000	160 000	180 000
Approximate concentration in serum (mg/dL)	1000–1500	250–300	100–150	0.3–30	0.0015–0.2
Valence	2	2 (monomer)	10 (small antigen) 5 (large antigen)	2	2

Half-life (days)	23	6	5	3	2.5
Special property	Placental passage	Secretory Ig	Primary response lymphocyte surface	Lymphocyte surface	Immediate hypersensitivity reactions

KEY CONCEPTS

Immunoglobulin (Ig) and T-Cell Receptor (TCR) Structure

- Both Igs and TCRs are heterodimeric proteins.
- Igs consist of two identical H and two L chains.
- αβ TCRs consist of one α and one β chain.
- γδ TCRs consist of one γ and one δ chain.
- Igs and TCR contain two or more immunoglobulin superfamily (IgSF) domains, which are identified by their characteristic β barrel structure.
- Each Ig and TCR chain contains a V-type IgSF domain that will form one-half of the antigen-binding site.
- Each V domain contains three hypervariable intervals known as complementarity determining regions (CDRs). The CDRs of paired heterodimers chains are juxtaposed to form the antigen-binding site.
- The C domains of Ig H chains define the Ig class or subclass.
- The two distal C IgH domains determine the effector function of the antibody.

For example, the IgG C_H2 domain plays a key role in complement fixation and in binding to class-specific Fc receptors on the surface of effector cells. Both these interactions are important in initiating the process of phagocytosis, in allowing certain subclasses to traverse the placenta, and in influencing the biological functions of lymphocytes, platelets, and other cells.

Gm Allotype System

A series of serologically defined C domain allotypes have been identified. In the case of the H chain, they are termed *Gm* for the gammaglobulin fraction of the serum in which they were first identified.[3] Allotypes have been identified for γ1, γ2, γ3, γ4, α2, and ε H chains and for the κ L chain. Associations between certain Gm allotypes and predisposition to develop certain diseases of immune function have been reported.

Ig CLASSES AND SUBCLASSES

The constant domains of the H chain define the class and subclass of the antibody. Table 4.1 lists the five major classes of Igs in humans and describes some of the physical and chemical features of these Igs. Two of the five major H chain classes, α and γ, have undergone duplication. IgG1, IgG2, IgG3, and IgG4 all have the same basic structural design and differ only in the primary sequence of their constant regions and in the location of their interchain disulfide bonds. The H chain in each of these subclasses is referred to as γ1, γ2, and so on. IgA consists of the two subclasses, α1 and α2. Table 4.2 compares the four subclasses of IgG, the two of IgA, and the classes of IgM, IgD, and IgE from the standpoint of their biological functions. In humans, the two L chain classes, κ and λ, are expressed at roughly equal frequencies. No specific effector function has been identified for either L chain class.

TABLE 4.2 **Selected Biological Properties of Classes and Subclasses of Immunoglobulins (Igs)**

	IgG				IgA

IgM

IgM exists in monomeric, pentameric, and hexameric forms. The 8S monomeric 180 kDa IgM has the molecular formula μ_2L_2. It is a minor fraction in serum, but in its transmembrane form IgM plays a key role in B-cell development and function as the antigen recognition portion of the B-cell antigen receptor. The major form in serum is the 19S, 900 000 Da pentameric IgM, which contains five subunits $[(\mu_2L_2)_5]$ linked together by disulfide bridges and by one molecule of an additional polypeptide chain, the J chain, which joins two of the subunits by a disulfide bridge.[7]

IgM is the predominant Ig produced during the primary immune response. Occasionally, particularly in the case of carbohydrate antigens such as isohemagglutinins, it will remain the major or sole antibody class. IgM differs from most other Igs in having an extra C_H domain in place of a hinge.

IgM avidly fixes complement. This property is focused in CH3, the homologue of IgG CH2.[8] Although the valence of each μ_2L_2 subunit is 2, when binding to large protein antigens, five of the 10 antigen-binding sites in pentameric IgM appear blocked because of steric hindrance. As a consequence, the valence for large antigens is five.

IgG

IgG, the major Ig class, accounts for the bulk of serum antibody activity in response to most protein antigens. The four IgG subclasses are numbered in relation to their serum levels relative to each other, with IgG1 being predominant and IgG4 being the least common. IgG1 and IgG3 fix complement and bind phagocyte Fcγ receptors well, whereas IgG2 fixes complement but binds Fcγ receptors more poorly. IgG4 does not fix complement effectively in the native state but has been reported to do so after proteolytic cleavage.[9] IgG1 and IgG3 are most frequently elicited by viral antigens,[10] IgG2 by carbohydrates,[11] and IgG4 by helminthic parasites.[12]

IgG4 can attenuate allergic responses by inhibiting the activity of IgE.[13] IgG4 can function as a blocking antibody, preventing cross-linking of receptor-bound IgE. It can costimulate the inhibitory IgG receptor FcγRIIb, which can negatively regulate FcεRI signaling and thus inhibit effector cell activation. Finally, the disulfide bonds of the IgG4 hinge are easily reduced, which allows the H chains to separate and randomly reassociate to produce a mixed population of IgG4 molecules with randomized heavy-chain and light-chain pairs. This impairs the ability of IgG4 to form immune complexes and thus has an anti-inflammatory effect, facilitating immunotherapy for allergic diseases (allergy shots).

Overproduction of IgG4 is seen in a disparate group of inflammatory diseases. Fibroinflammatory masses can develop in virtually all organs except the brain and have an unexplained preference for salivary glands, lymph nodes, and the pancreas. Together, these are referred to as *IgG4-related disease* (IgG4-RD).[14]

IgA

Although IgA generally exists in a monomeric form (α_2L_2) in serum, it can interact with the J chain to form a polymer $(\alpha_2L_2)_{2,3}$-J. Second in concentration to IgG in serum, IgA functions as the predominant form of Ig in mucosal secretions.[15]

Secretory IgA (sIgA) is largely synthesized by plasma cells associated with mucosal tissues. In secretions, the molecule typically exists in polymeric form with two subunits in association with the 70 kDa secretory component $(\alpha_2L_2)_2$-SC. SC is synthesized by the epithelial cells that line the lumen of the gut. It appears to render the secretory IgA complex more resistant to proteolytic digestion, and it enhances the immune functions of SIgA.

IgE

IgE is largely found in extravascular spaces. Its plasma turnover is rapid, with a half-life of about 2 days. IgE antibodies help protect the host from parasitic infections (Chapter 31). In Westernized, affluent societies, IgE is primarily associated with allergy. Through their interaction with Fcε receptors on mast cells and basophils, IgE antibodies, in the presence of antigens, induce the release of histamine and various other vasoactive substances, which are responsible for clinical manifestations of various allergic states.[16]

IgD

Although the H chain of IgD can undergo alternative splicing to a secretory form, IgD serum antibodies in humans are uncommon and are absent in the serum of mice and primates. Instead, IgD typically is coexpressed with IgM on the surface of mature lymphocytes. The appearance of IgD is associated with the transition of a B lymphocyte from a cell that can be tolerized to the antigen to a cell that will respond to antigen with the production of antibody (Chapter 7).

TCR αβ AND γδ

TCR α, β γ, and δ chains are members of the IgSF and thus share a number of structural similarities with Igs. Each chain contains a leader peptide and extracellular, transmembrane, and intracytoplasmic components. The extracellular component can be divided into three domains: a polymorphic V domain encoded by VJ (α and γ chains) or VDJ (β and δ chains) gene segments, a C domain, and a hinge region.[17] The hinge region typically contains an extra cysteine (none in γ chains encoded by Cγ2) that forms a disulfide bond with the other partner of the heterodimer. All of the transmembrane domains include a lysine plus or minus an arginine residue that facilitates the association of the TCR heterodimer with components of the CD3 signal transduction complex, each of which has a matching negatively charged residue in its own transmembrane portion (see below). The intracytoplasmic components are tiny and play a minimal role in signal transduction.

TCR αβ

The TCR α and β chains are glycoproteins with molecular weights that vary from 42 to 45 kDa, depending on the primary amino acid sequence and the degree of glycosylation. Deglycosylated forms have a molecular mass of 30 to 32 kDa. These chains share a number of invariant residues in common with Ig heavy and light chains, in particular residues that are thought to be important for interactions between heavy and light chains. The structures of over 30 partial or full length TCRs have been solved by X-ray crystallography (Fig. 4.3).[18] In general, the structure of the TCR αβ heterodimer is similar, but not identical, to that of an Ig Fab fragment.

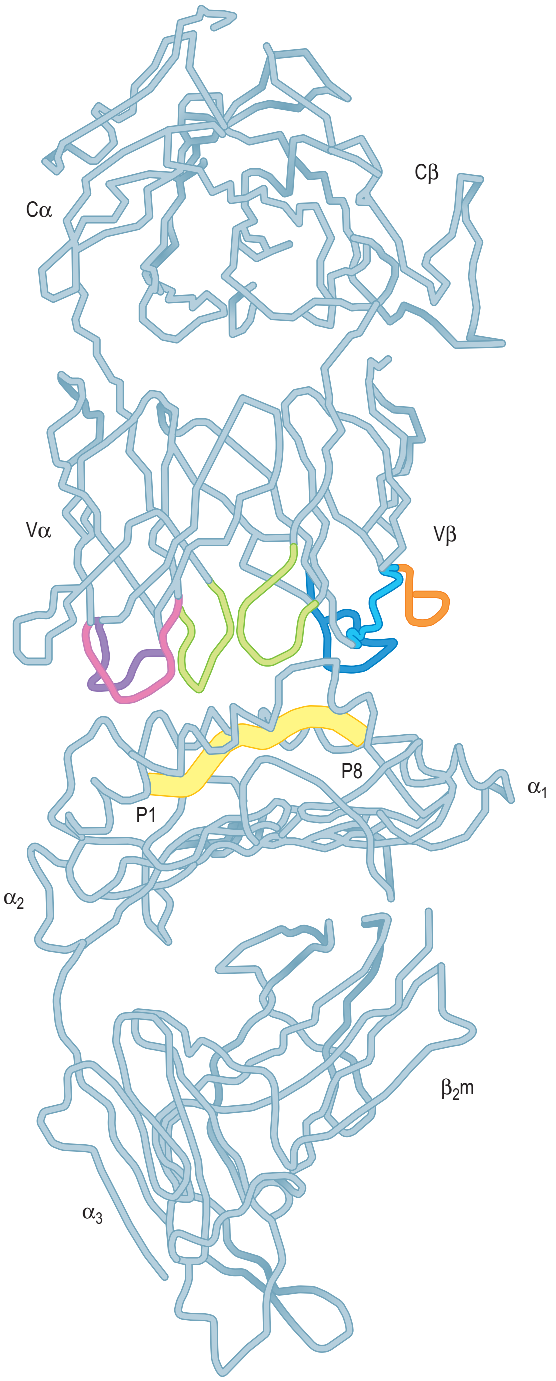

FIG 4.3 **Backbone Representation of Murine αβ T-Cell Receptor (TCR) Bound to Murine Major Histocompatibility Complex (MHC) Class I and an Octamer Peptide.** The TCR is above. The Vα CDR1 and CDR2 are depicted in magenta, Vβ CDR1 and CDR2 in blue, both CDR3s in green, and the Vβ HV4 in orange. β2M refers to β_2 microglobulin. The peptide is in yellow, and the NH_2-terminal and COOH-terminal residues are designated P1 and P8. (Reproduced with permission from Garcia KC, Degano M, Stanfield RL, Brunmark A, Jackson MR, Peterson PA, et al. An alphabeta T cell receptor structure at 2.5 A and its orientation in the TCR-MHC complex. Science. 1996;274(5285):209-19.Garcia et al.)

TCR γδ

The TCR γ and δ chains are glycoproteins with a more complex molecular size pattern than α and β chains. TCRs that use the Cγ1 gene segment, which contains a cysteine-encoding exon, are disulfide-linked (MW 36–42 kDa). TCRs that use Cγ2 exist in two non–disulfide-linked forms, one of 40–44 kDa and one of 55 kDa.[19] The differences in molecular size result from the variability of both N-linked glycosylation and primary amino acid sequence. The 55-kDa form uses a Cγ2 allele that contains three (rather than two) exons encoding the connecting piece, as well as more N-linked carbohydrate. The TCR δ chain is more straightforward, being 40–43 kDa in size and containing two sites of N-linked glycosylation. The overall architecture of the γδ TCR closely resembles that of αβ TCRs and antibodies, although the angle between the V and C domains, known as the *elbow angle,* appears more acute.

Ligand Recognition

TCR αβ T cells primarily recognize peptide-MHC complexes (pMHC) (see Fig. 4.3; Chapters 5, 6); however, other types of ligands exist. For example, some αβ TCRs can bind nonpeptidic antigens (atypical antigens) that are bound to “nonclassic” MHC class Ib molecules. The αβ TCR expressed by NKT cells recognizes lipid antigens associated with the MHC class I related CD1 surface receptor. Many γδ T cells recognize atypical antigens that may or may not be associated with an antigen-presenting molecule, although some can bind peptides. Finally, many αβ TCRs bind superantigens (SAgs) in a predominantly Vβ-dependent fashion (Chapter 6).

Binding to pMHC

TCRs recognize peptide antigens bound to the binding groove of MHC-encoded glycoproteins (see Fig. 4.3). TCR recognition of pMHC requires a trimolecular complex in which all the components (antigen, MHC, and TCR) contact one another.[18] Thus recognition is highly influenced by polymorphisms in the MHC molecule (Chapter 5). As in the case of Igs, TCR CDR1 and CDR2 are encoded in the germline V regions, whereas CDR3 is formed at the junction of the V gene with a J gene segment (TCR α and γ) or D and J gene segments (TCR β and δ chains). Vβ also has a fourth region of variability within Framework 3 that is juxtaposed to the other CDRs in the tertiary structure. This region, variously termed hypervariable region 4 (HV4) or CDR4, can participate in SAg binding.

The cocrystallization of different combinations of soluble TCR αβ interacting with MHC class I bound to antigen peptide (pMHC) has made it possible to directly address the manner in which antigen recognition occurs (see Fig. 4.3). The TCR αβ combining site is relatively flat, allowing it to interact with a rather broad surface at the point of contact with pMHC.

The TCR footprint on the pMHC complex tends to occur in a diagonal across the MHC antigen-binding groove, with TCR Vα positioned over the MHC α_2 helix and TCR Vβ overlying the MHC α_1 helix. This geometry would permit consistent access of the CD8 coreceptors to the MHC class I molecule. The CDR1 and CDR2 loops, which are entirely encoded by germline sequence, tend to interact more with the MHC molecule, whereas the CDR3 loops, which are composed of both germline and somatic (N addition) sequences, appear to dominate the interaction with the MHC-bound peptide.

The binding of TCR to pMHC appears to be driven by enthalpy—that is, binding increases the stability of the CDR loops, especially CDR3. These results have led to the suggestion that initial binding focuses on the interaction between CDRs 1 and 2 and the MHC. After this initial recognition, the CDR3s change their shape to maximize the area of contact. Conformational flexibility, or "induced fit," would allow TCRs to rapidly sample many similar pMHC complexes, stopping only when their CDR3s are able to stabilize the interaction.

TCR Binding Affinity

The affinity with which the TCR ultimately binds its ligand is a critical determinant of T-cell activation. It is, however, only one factor in determining the overall avidity of the interaction, since other cell surface molecules of the T cell (e.g., CD4, CD8, CD2, and various integrins) bind to cell surface molecules on the antigen-bearing cell to stabilize cell–cell TCR–ligand interactions. Furthermore, since both the TCR and the pMHC ligand are surface membrane proteins, each T cell can provide multiple TCRs in the same plane that can bind multiple pMHC molecules on the surface of the APC. This makes binding of TCR to pMHC functionally multivalent, enhancing the apparent affinity of the interaction.

Atypical Antigens

Some αβ T cells can recognize lipid antigens when they are complexed with members of the CD1 family.[20] The interaction of TCR αβ with CD1 resembles that of TCR αβ with MHC class I. Allelic polymorphism in CD1 is limited, which theoretically would restrict the range of lipid antigens that can be bound.

Rather than binding to a single groove on the MHC, lipids attach themselves to one of several hydrophobic pockets that can be found on the surface of CD1. Pocket volume can range from 1300 to 2200 $Å^3$. The number and length of the pockets differ between the various CD1 isoforms. For example, CD1b has three pockets that share a common portal of entry, as well as a fourth pocket that connects two of the three pockets to each other. This connecting pocket permits the insertion of lipids with a long alkyl chain, such as mycobacterial mycolic acid.

γδ T cells are activated by conserved stress-induced ligands, enabling them to rapidly produce cytokines that regulate pathogen clearance, inflammation, and tissue homeostasis in response to tissue stress.[21]

Antigen recognition by γδ TCRs resembles recognition of intact antigens by antibodies more closely than recognition of pMHC by αβ TCR.[22] γδ TCRs can recognize protein antigens, such as nonclassic MHC molecules and viral glycoproteins, as well as small, phosphate- or amine-containing compounds, such as pyrophosphomonoesters from mycobacteria and alkylamines.

Binding to non-peptide antigens plays an important role in the biology of γδ T cells. About 5% of peripheral blood T cells bear γδ TCRs, and most of these are encoded by Vγ9 JγP and Vδ2 gene segments. (In an alternative nomenclature, Vγ9 is known as *Vγ2* and JγP as *Jγ1.2.* See the IMGT database at http://www.imgt.org.) These Vγ9 JγPVδ2 TCRs recognize nonpeptide pyrophosphate- or amine-containing antigens, such as pyrophosphomonoesters from mycobacteria or isobutylamine from various sources. Other common naturally occurring small phosphorylated metabolites that stimulate γδ T cells include 2,3-diphosphoglyceric acid, glycerol-3-phosphoric acid, xylose-1-phosphate, and ribose-1-phosphate. In addition to mycobacteria, Vγ9JγPVδ2 T-cell populations are seen to expand in response to listeriosis, ehrlichiosis, leishmaniasis, brucellosis, salmonellosis, mumps meningitis, malaria, and toxoplasmosis.

Superantigens

SAgs are a special class of TCR ligands that have the ability to activate large fractions (5–20%) of the T-cell population. Activation requires simultaneous interaction between the SAg, the TCR Vβ domain, and a MHC class II molecule on the surface of an APC.[23]

Unlike conventional antigens, SAgs do not require processing to allow them to bind class II molecules or activate T cells. Instead of binding to the peptide antigen-binding groove, SAgs interact with polymorphic residues on the periphery of the class II molecule. Rather than binding to TCR β CDR3 residues, SAg can interact with polymorphic residues in CDR1, CDR2, and HV4. Soluble TCR β chains can also bind the appropriate SAg in the absence of a TCR α chain. As a consequence, although the SAg links the TCR to the MHC, the T-cell responses are not "MHC restricted" in the conventional sense, since a T cell with the appropriate Vβ will respond to a SAg bound to a variety of polymorphic class II molecules.

IMMUNOGLOBULIN GENE ORGANIZATION

Each of the component chains of Igs and TCRs is encoded by a separate multigene family.[24,25] The paradox of variability in the V region in conjunction with a nearly invariable constant region was resolved when it was shown that Ig V and C domains are encoded by independent elements, or gene segments, within each gene family. As a result, several gene elements are used to

KEY CONCEPTS

Features Common to Immunoglobulin (Ig) and T-Cell Receptor (TCR) Genes

- Ig and TCR variable domains are created by site-specific V(D)J recombination.
- Starting with a small set of individual gene segments, combinatorial gene segment rearrangement, combinatorial association of heavy and light chains, and mechanisms of junctional diversity generate a broad repertoire of antigen-binding structures.
- Each receptor is assembled in a stepwise fashion
    - *Immunoglobulins:* $D_H \rightarrow J_H$; $V_H \rightarrow D_H J_H$; cytoplasmic μ chain expression; Vκ→Jκ and, if needed, Vλ→Jλ; surface IgM expression.
    - *TCRαβ:* Dβ→Jβ; Vβ→DβJβ; cytoplasmic β-chain expression; Vα→Jα; surface αβ TCR expression.
- Complementarity determining regions (CDRs) 1 and 2 begin with exclusively germline sequence.
- CDR3 is created by the (V[D]J) joining reaction and often includes non-germline N nucleotides between the V and the D, and between the D and the J.
    - Thus CDR-H3, CDR-B3, and CDR-D3 are the most variable components of IgM, TCRαβ, and TCRγδ, respectively.
- The antigen-binding site is a product of a nested gradient of diversity. Conserved framework regions surround CDR1 and CDR2, which, in turn, surround the paired CDR3 intervals that form the center of the antigen-binding site.
- The variability of the Ig and TCR repertoires is restricted during perinatal life, limiting the immune response of the infant.

KEY CONCEPTS

Features Specific to Immunoglobulin (Ig) Genes

- Variable domain somatic hypermutation (SHM) permits affinity maturation, which further diversifies the B-cell repertoire.
- Class-switch recombination (CSR) allows replacement of an upstream C domain by a downstream one, altering effector function while maintaining antigen specificity.

encode a single polypeptide chain. For example, κ constant domains are encoded by a single Cκ exon in the κ locus on chromosome 2, whereas κ variable domains represent the joined product of Vκ and Jκ gene segments (Fig. 4.4).

V_L gene segments typically contain their own promoter, a leader exon, an intervening intron of ≈ 100 nucleotides, an exon that encodes the first three framework regions (FR 1, 2, and 3), the first two complementarity determining regions in their entirety, the amino terminal portion of CDR3, and a recombination signal sequence (RSS). A J_L (J for joining) gene segment begins with its own recombination signal, the remaining portion of CDR 3, and the complete FR 4 (see Fig. 4.2).

(Use of the same abbreviation—that is, "V"—for the complete variable domain of an Ig peptide chain as well as the gene segment that encodes only a portion of that same variable domain is the result of historic precedent. It is unfortunate that one must depend on the context of the surrounding text to determine which V region of the antibody is being discussed. The same holds true for the use of "J" to represent both the J gene segment and the J joining protein.)

The creation of a V domain is directed by the RSSs that flank the rearranging gene segments.[26] Each RSS contains a strongly conserved seven base-pair, or heptamer, sequence (e.g., CACAGTG) that is separated from a less well-conserved nine bp, or nonamer, sequence (e.g., ACAAAACCC) by either a 12- or 23- bp spacer. For example, Vκ gene segments have a 12-bp spacer and Jκ elements have a 23-bp spacer. These spacers place the heptamer and nonamer sequences on the same side of the DNA molecule, separated by either one or two turns of the DNA helix. A one-turn

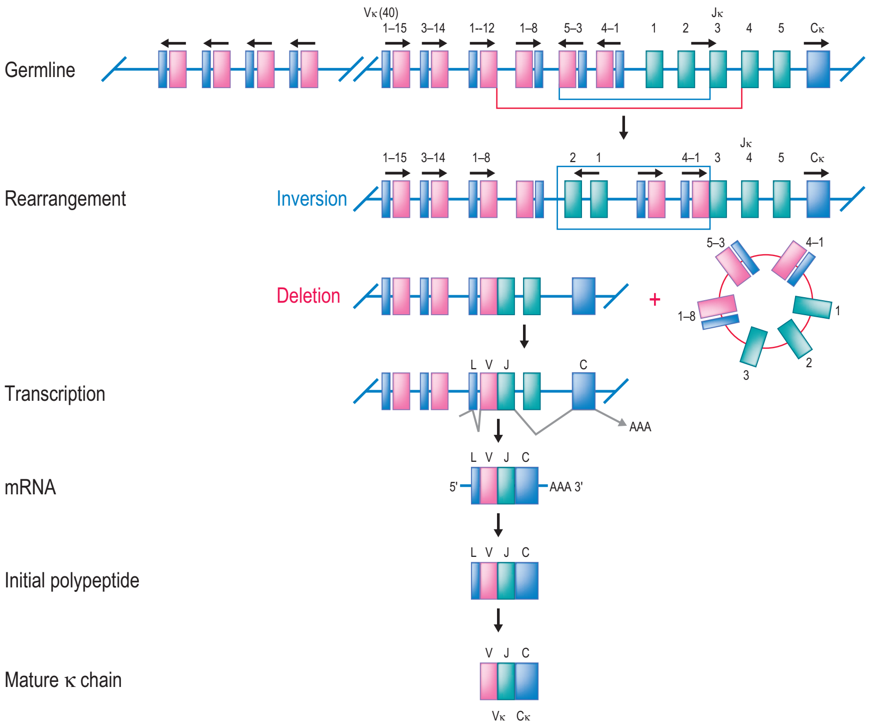

FIG 4.4 **Rearrangement Events in the Human κ Locus.** V, variable region; J, joining region; C, constant region of the κ light chain; mRNA, messenger RNA. See text for further description.

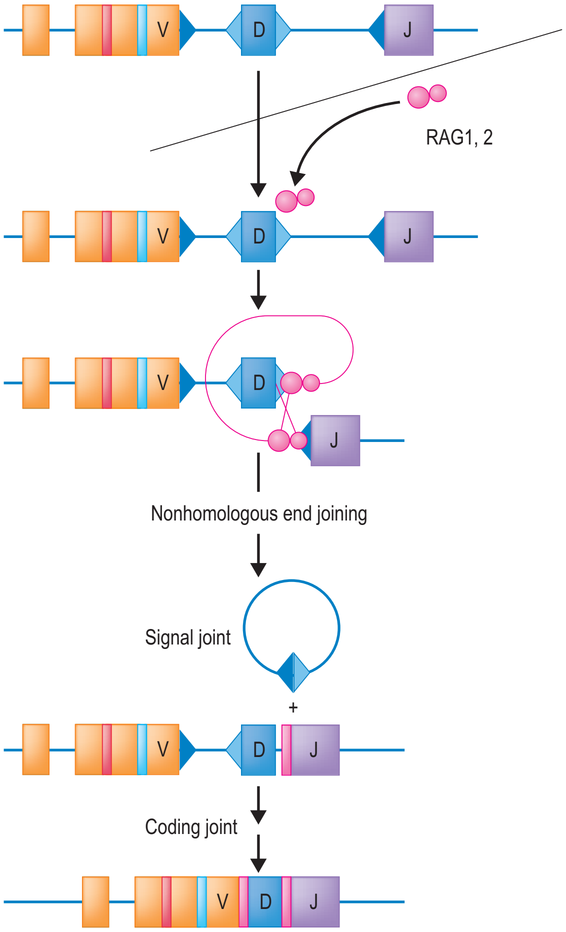

FIG 4.5 **VDJ Recombination.** Lymphoid-specific recombinase activating gene (RAG)-1 and RAG-2 bind to the recombination signal sequences (RSSs) flanking V, D, or J gene segments, juxtapose the sequences, and introduce precise cuts adjacent to the RSS. Components of the nonhomologous end joining repair pathway subsequently unite the cut RSS to form a signal joint, and the coding sequences of the rearranging gene segments to form a coding joint.

RSS (12-bp spacer) will preferentially recognize a two-turn signal sequence (23-bp spacer). This helps prevent wasteful V-V or J-J rearrangements.

Initiation of the V(D)J recombination reaction requires recombination activating genes 1 and 2 (RAG-1 and RAG-2). These genes are expressed only in developing lymphocytes.[27] The gene products RAG-1 and RAG-2 act by precisely introducing a DNA double-strand break (DSB) between the terminus of the rearranging gene segment and its adjacent RSS (Fig. 4.5). These breaks are then repaired by ubiquitously expressed components of a DNA repair process that is known as *nonhomologous end joining* (NHEJ). Lack-of-function mutations in NHEJ proteins yields susceptibility to DNA damage in all cells of the body and can lead to an SCID phenotype (Chapter 35).

The NHEJ process creates precise joins between the RSS ends and imprecise joins of the coding ends. TdT, which is expressed only in lymphocytes, adds non-germline–encoded nucleotides (N nucleotides) to the coding ends of the recombination product.

Lymphoid-specific expression of RAG-1 and RAG-2 limits V(D)J recombination to B and T lymphocytes. To ensure that TCR genes are rearranged to completion only in T cells and Ig genes are rearranged to completion only in B cells, V(D)J recombination is further regulated by limiting the accessibility of the appropriate gene segments to the specific lineage as well as to the specific stage of development. For example, H chain genes are typically assembled before L chain genes are.

The RAG-1 and RAG-2 recombinases cooperatively associate with 12-bp and 23-bp RSSs and their flanking coding gene segments to form a synaptic complex. Typically, the initial event will be recognition of the nonamer sequence of a 12-bp spacer RSS by RAG-1, which appears to function as the catalytic component of the recombinase. RAG-1 binding to the heptamer provides specificity. RAG-2 does not bind DNA independently but does make contact with the heptamer when in a synaptic complex with RAG-1. Binding of a second RAG-1 and RAG-2 complex to the 23-bp, two-turn RSS permits the interaction of the two synaptic complexes to form what is known as a *paired complex*. Creation of this paired complex is facilitated by the actions of the DNA-bending proteins HMGB1 and HMGB2 and by the presence of a divalent metal ion.

After paired complex assembly, the RAG proteins single-strand cut the DNA at the heptamer sequence. The 3' OH of the coding sequence ligates to 5' phosphate and creates a hairpin loop. The clean-cut ends of the signal sequences enable formation of precise signal joints. However, the hairpin junction created at the coding ends must be resolved by renicking the DNA, usually within 4–5 nucleotides from the end of the hairpin. This forms a 3' overhang that is amenable to further diversification. It can be filled in via DNA polymerases, nibbled back, or serve as a substrate for TdT-catalyzed N addition. DNA polymerase μ, which shares homology with TdT, appears to play a role in maintaining the integrity of the terminus of the coding sequence.

The cut ends of the coding sequence are then repaired by the NHEJ proteins. NHEJ proteins involved in V(D)J recombination include Ku70, Ku80, DNA-PKcs, Artemis, XRCC4, XLF (Cernunnos), and ligase 4.

Ku70 and Ku80 form a heterodimer (Ku) that directly associates with DNA double-strand breaks to protect the DNA ends from degradation, permit juxtaposition of the ends to facilitate coding end ligation, and help recruit other members of the repair complex. The DNA protein kinase catalytic subunit (DNA-PKcs) phosphorylates Artemis, inducing an endonuclease activity that plays a role in the opening of the coding joint hairpin. Thus absence of DNA-PKcs or Artemis inhibits proper coding joint formation. Signal joint formation is normal in Artemis deficiency, but it is impaired in the absence of DNA-PKcs. Finally, XRCC4, XLF, and ligase 4 help rejoin the ends of the broken DNA.

Depending on the transcriptional orientation of the rearranging gene segments, recombination can result in either inversion or deletion of the intervening DNA (see Fig. 4.3). The products of inversion remain in the DNA of the cell, whereas deletion leads to the loss of the intervening DNA. The increased proximity of the V promoter to the C domain enhancers promotes the subsequent transcription of the Ig gene product.

There is a price to the use of V(D)J recombination to create antigen receptor diversity. Aberrant recombination in nonreceptor genes can create deleterious genomic rearrangements that promote B-cell and T-cell neoplasias.[26] For example, deletional recombination at the SIL/SCL locus and in *Notch1*, *Izkf1*, *PTEN*, and other

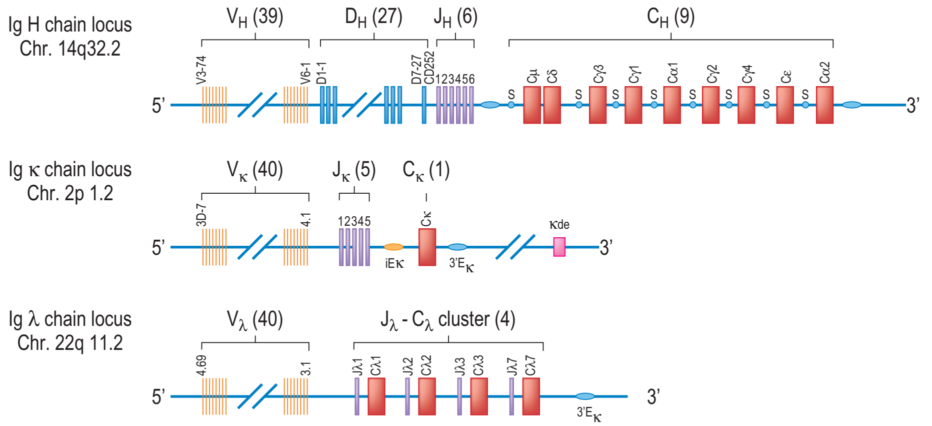

FIG 4.6 **Chromosomal Organization of the Immunoglobulin H (IgH), κ, and λ Gene Clusters.** The typical numbers of functional gene segments are shown. The κ gene cluster includes a κ deleting element that can rearrange to sequences upstream of Cκ in cells that express λ chains, reducing the likelihood of dual κ and λ light chain expression. These maps are not drawn to scale.

critical genes appear to be major drivers of lymphoid neoplasms in humans and in mice.

The κ Locus

The κ locus is located on chromosome 2p11.2. It contains 5 Jκ and 75 Vκ gene segments upstream of Cκ (Fig. 4.6). The Vκ gene segments can be grouped into six different families of various sizes.[28] Each family comprises gene segments that share extensive sequence and structural similarity.[29]

One-third of the Vκ gene segments contain frameshift mutations or stop codons that preclude them from forming functional protein, and of the remaining sequences, <30 of the Vκ gene segments have actually been found in functional Igs. Each of these active Vκ gene segments has the potential to rearrange to any one of the 5 Jκ elements, generating a potential repertoire of >140 distinct VJ combinations. Even more diversity is created at the site of gene segment joining. The terminus of each rearranging gene segment can undergo a loss of 1–5 nucleotides during the recombination process. In humans, but not in mice, N-addition can either replace some or all of the lost nucleotides or can be inserted in addition to the original germline sequence. Each codon created by N-addition increases the potential diversity of the repertoire 20-fold. Thus the focus for the diversity of the κ repertoire lies in the VJ junction that defines CDR-L3.

The λ Locus

The λ locus, on chromosome 22q11.2, contains four functional Cλ exons, each of which is associated with its own Jλ (see Fig. 4.6). The Vλ genes are arranged in three distinct clusters, each containing members of different Vλ families.[30] Depending on the individual haplotype, there are approximately 30–36 potentially functional Vλ gene segments and an equal number of pseudogenes.

In addition to normal κ and λ peptides, H chains can also form a complex with unconventional λ light chains, known as surrogate or pseudo light chains (SLC). The genes encoding the SLC proteins, λ14.1 (λ5) and VpreB, are located within the λ light-chain locus on chromosome 22 and are restricted in expression to discreet B cell developmental stages.[31] Together, these two genes create a product with considerable homology to conventional λ light chains. The λ14.1 gene contains Jλ and Cλ-like sequences and the VpreB gene includes a Vλ-like sequence. A critical difference between these unconventional ψLC genes and other L chains is that rearrangement of λ14.1 and VpreB is not required for SLC expression.

The H Chain Locus

The H chain locus, on chromosome 14q32.33, is considerably more complex than the κ and λ loci. There are ≈ 80 V_H gene segments near the telomere of the long arm of chromosome 14.[32] Of these, approximately 39 are functional (the number varies by haplotype) and can be grouped into seven different families of related gene segments. Adjacent to the most centromeric V_H, V6-1, are 27 D_H (D for diversity) gene segments (see Fig. 4.6) and 6 J_H gene segments. Each V_H and J_H gene segment is associated with a two-turn RSS, which prevents direct V → J joining. A pair of one-turn RSSs flanks each D_H. Recombination begins with the joining of a D_H to a J_H gene segment, followed by the joining of a V_H element to the amino terminal end of the DJ intermediate. The V_H gene segment contains FR1, 2, and 3, CDR1 and 2, and the amino terminal portion of CDR3; the D_H gene segment forms the middle of CDR3; and the J_H element contains the carboxy terminus of CDR3 and FR4 in its entirety (see Fig. 4.1). For example, random assortment of one of 50 active V_H and one of 27 D_H with one of the 6 J_H gene segments can generate up to 10^4 different VDJ combinations (Fig. 4.7).

Although combinatorial joining of individual V, D, and J gene segments maximizes germline-encoded diversity, the major source of variation in the preimmune repertoire is focused on the CDR-H3 interval, which is created by VDJ joining (see Fig. 4.7). First, D_H gene segments can rearrange by either inversion or deletion and thus have the potential to be read backward as well as forward. Each D_H can be spliced and translated in each of the three potential reading frames. Thus each D_H gene segment has the potential to encode six different peptide fragments. Second, the terminus of each rearranging gene segment can undergo a loss of ≥1 nucleotides during the recombination process. Third, the rearrangement process proceeds through a step that creates a hairpin ligation between the 5' and 3' termini of the rearranging gene segment. Nicking to resolve the hairpin structure leaves a 3' overhang that creates a palindromic extension, termed *P*

FIG 4.7 **The Antigen-Binding Site Is the Product of a Nested Gradient of Diversity.** (**A**) VDJ rearrangement yields 38 thousand different combinations. The CDR-H3 sequence contains both germline V, D, and J sequence and non-germline–encoded N-nucleotides. The addition of nine N-nucleotides on either side of the D gene segment yields 64 million different combinations. (**B**) The antigen-binding site is created by the juxtaposition of the three complementarity determining regions (CDRs) of the H chain and the three CDRs of the light chain. The view is looking into the binding site as an antigen would see the CDRs. The V_H domain is on the right side. The central location of CDR-H3, which, because of the N addition, is the focus for repertoire diversity, is readily apparent.

junction. Fourth, non–germline-encoded nucleotides (N regions or N additions) can be used to replace or add to the original germline sequence. Every codon that is added by N region addition increases the potential diversity of the repertoire 20-fold. N regions can be inserted both between the V and the D and between the D and the J. Together, the imprecision of the joining process and variation in the extent of *N* addition permits generation of CDR-H3's of varying length and structure. As a result, more than 10^{10} different H chain VDJ junctions, or CDR-H3's, can be generated at the time of gene segment rearrangement. Together, somatic variation in CDR3, combinatorial rearrangement of individual gene segments, and combinatorial association between different L and H chains yields a potential preimmune antibody repertoire of greater than 10^{16} different Igs.

Class-Switch Recombination

Located downstream of the VDJ loci are nine functional C_H gene segments (see Fig. 4.7). Each C_H contains a series of exons, each encoding a separate domain, hinge, or terminus. All C_H genes can undergo alternative splicing to generate two different types of carboxy termini: either a membrane terminus that anchors the Ig on the B lymphocyte surface or a secreted terminus that occurs in the soluble form of the Ig. With the exception of $C_H1\delta$, each C_H1 constant region is preceded by both an exon that cannot be translated (an I exon) and a region of repetitive DNA termed the *switch* (S). Through recombination between the Cμ switch region and one of the switch regions of the seven other H chain constant regions (a process termed *class switching* or *class-switch recombination* [CSR]), the same VDJ heavy chain variable domain can be juxtaposed to any of the H chain classes (Fig. 4.8).[33] Thus

FIG 4.8 **Immunoglobulin H (IgH) Chain Class Switching.** The molecular events involved in switching from expression of one class of Ig to another are depicted. At the top is the gene organization during μ chain synthesis. At the bottom, a class-switch recombination event has resulted in the deletion of the intervening DNA. Exposure to the appropriate cytokine or T cell–B cell interaction through the CD40–CD40L pathway results in activation of the I exon that yields a sterile epsilon transcript (Iε-Cε) (Chapter 7). The CD40–CD40L interaction is necessary for the subsequent replacement of Cμ by another constant gene (in this case, Cε). The S loci indicate switch-specific recombination signals.

the system can tailor both the receptor and the effector ends of the antibody molecule to meet a specific need.

Somatic Hypermutation

A final mechanism of Ig diversity is engaged only after exposure to antigen.[33] With T-cell help, the variable domain genes of germinal center lymphocytes undergo *somatic hypermutation* (SHM) at a rate of up to 10^{-3} changes per base pair per cell cycle. SHM is correlated with transcription of the locus, and recent studies have suggested that at least two separate mechanisms are involved. The first mechanism targets mutation hot spots with the RGYW (purine/G/pyrimidine/A) motif, and the second mechanism incorporates an error-prone DNA synthesis that can lead to a nucleotide mismatch between the original template and the mutated DNA strand. SHM allows affinity maturation of the antibody repertoire in response to repeated immunization or exposure to antigen, as B cells bearing receptors that have mutated to higher affinity for the cognate antigenic epitope are preferentially stimulated to proliferate, especially under conditions of limiting antigen concentration.

Activation-Induced Cytidine Deaminase

Activation-induced cytidine deaminase (AID) plays a key role in both CSR and SHM.[33] AID is a single-strand DNA (ssDNA) cytidine deaminase that can be expressed in activated germinal center B cells. Both SHM and CSR require transcription. Transcription helps target AID to the requisite chromosomal location and contributes to formation of requisite ssDNA substrates. For example, transcription of an Ig V domain or of the switch region upstream of the C_H1 domain opens the DNA helix to generate ssDNA that can then be deaminated by AID to form mismatched dU/dG DNA bps. Both CSR and SHM then co-opt the activities of normal cellular base excision repair (BER) and mismatch repair (MMR) to convert AID cytidine deamination lesions to mutations and/or double-strand breaks. The BER protein uracil-DNA glycosylase (UNG) removes the mismatched dU base, creating an abasic site. Cleavage of the DNA backbone at this abasic site by an apurinic/apyrimidinic (AP) endonuclease generates a ssDNA nick adjacent to the abasic site. The nick is then processed to a single-nucleotide gap. The gap is filled in by DNA polymerase β and then sealed by DNA ligase 1 or DNA ligase 3. The MMR proteins MSH2 and MSH6 can also bind and process the dU:dG mismatch. Deficiencies of AID, UNG underlie some forms of the hyper-IgM syndrome (Chapter 34). UNG and MMR double deficiency ablates CSR. It also eliminates both C/G transversion mutations and spreading of mutations, leaving only C/G transition mutations.

The benefits of diversity created by AID are balanced by the tendency of AID to target non-Ig genes. AID can create clusters of mutations in a number of genes, including *BCL6, CD95, CD79A, CD79B, PIM1, MYC, RHOH,* and paired box 5 (*PAX5*).[34] The process is termed *kataegis.* These mutations clusters can contribute to the development of lymphoproliferative disorders.

Diversity and Constraints on Immunoglobulin Sequence

In theory, combinatorial rearrangement of V(D)J gene segments, combinatorial association of H and L chains, flexibility in the site of gene segment joining, N region addition, P junctions, somatic hypermutation, and class switching can create an antibody repertoire whose diversity is limited only by the total number of B cells in circulation at any one time. In practice, constraints and biases on both the structure and sequence of the antibody repertoire are apparent.

The representation of individual V gene elements is nonrandom. Among Vκ and V_H elements, half the potentially functional V gene elements contribute minimally to the expressed repertoire. Among Vλ elements, these restrictions are even greater, with three gene segments contributing to half the expressed repertoire.

Particular patterns of amino acid composition in the sequences of the V domains create predictable canonical structures for several of the hypervariable regions. In κ chains, CDR2 is found in a single canonical structure, whereas four structures are possible for CDR1.[35] In the H chain, most germline CDR1 and CDR2 elements encode one of three or one of five distinct canonical structures, respectively.[36] Preservation of these key amino acids during affinity maturation tends to maintain the canonical structure of CDR1 and CDR2 even while they are undergoing somatic hypermutation.[37]

The enhanced sequence diversity of the CDR3 region is mirrored by its structural diversity. Few canonical structures have been defined for the H chain CDR3, and even in κ chains, 30% of the L chain CDR3 can be quite variable. However, at the sequence level, there is a preference for tyrosine and glycine residues and a bias against the use of highly charged or hydrophobic amino acids in the H chain CDR3, which reflects preferential use of only one of the six potential D_H reading frames, natural selection of reading frame content, and selection during development.[38]

The TCR αδ Chain Locus

The α and δ loci are located on chromosome 14q11-12. This region is unusual in that the gene segments encoding the two different TCR chains are actually intermixed (Fig. 4.9). There are 38–40 Vα, 5 Vα/Vδ, no Dα, and 50 Jα functional gene segments, as well as one Cα gene.[39]

The δ locus lies between the Vα and Jα gene segments. There are three committed Vδ, 5 Vα/Vδ, 3 Dδ, and 3 Jδ gene segments, as well as one Cδ gene. Vδ3 lies 3' of Cδ, and thus must rearrange by inversion. Although V region use by α and δ chains is largely independent of one another, this unusual gene organization is accompanied by sharing of 5 V gene segments. For example, Vδ1 can rearrange either to Dδ/Jδ or to Jα elements and thus can serve as the V region for both γδ and αβ TCRs.

In the large majority of αβ T cells analyzed, the α chain on both chromosomes was rearranged. This occurs by the rearrangement of the 5' RSS δRec to a pseudo-J segment, ψJα, at the beginning of the Jα cluster (see Fig. 4.9) as well as by the subsequent rearrangement of Vα to Jα on both chromosomes. Both types of rearrangement delete all of the Dδ, Jδ, and Cδ genes, thus preventing coexpression of αβ and γδ TCRs.

The TCR β Chain Locus

The β locus is positioned at chromosome 7q35.44 It contains 40–48 functional Vβ genes, two Dβ, two Jβ clusters, each containing six or seven gene segments, and two Cβ genes (see Fig. 4.9). There is one Vβ immediately downstream of Cβ2, which rearranges by inversion. Each Cβ is preceded by its own Dβ–Jβ cluster. There is no apparent preference for Vβ gene rearrangement to either Dβ–Jβ cluster. Dβ1 can rearrange to the Jβ1 cluster or the Dβ2–Jβ2 cluster. Dβ2 can only rearrange to Jβ2 gene segments. The two Cβ segments differ by only six amino acids and are functionally indistinguishable from each other.

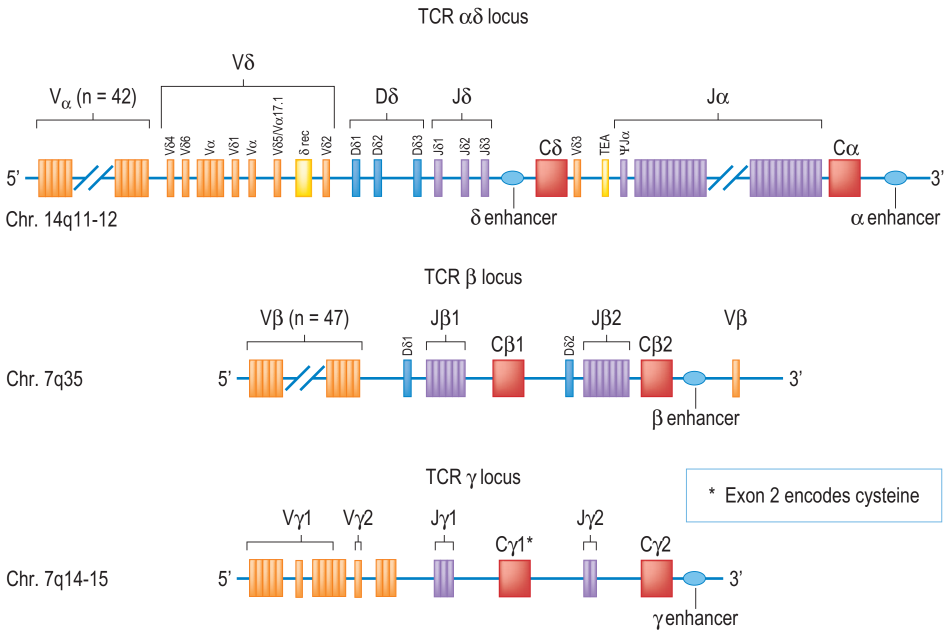

FIG 4.9 Chromosomal Organization of the T-Cell Receptor (TCR) αδ, β, and γ Gene Clusters. Typical numbers of functional gene segments are shown. These maps are not drawn to scale.

The TCR γ Chain Locus

The γ locus is located at chromosome 7p14-15.[39] There are 4–6 functional Vγ region segments intermixed with pseudogenes, no Dγ, and two J clusters with a total of 5 J segments. Each J cluster is 5' to its C region (see Fig. 4.9). The Vγ segments have been divided into six families, although only Vγ1 (nine members, five of them functional) and Vγ2 (one member) encode functional proteins. The number of Cγ gene exons varies: Cγ1 has three, whereas there are two alleles of Cγ2 that have four and five, respectively. The first Cγ exon encodes most of the extracellular portion of this region. The last Cγ exon encodes the intracytoplasmic portion of the molecule. The middle exon(s) (one for Cγ1, two or three for Cγ2) encode the connecting piece, which does (Cγ1), or does not (Cγ2), include a cysteine. Since this cysteine can form a disulfide bond with another cysteine in the δ chain, TCRs using Cγ1 contain a covalently linked γ–δ pair, whereas TCRs using Cγ2 do not.

The nomenclature of the human γ locus differs among laboratories and reports and is extensively cross-referenced on the IMGT website (http://www.imgt.org).

Allelic Exclusion

Because of the inherently imprecise nature of coding joints, only one in three V(D)J Ig or TCR rearrangements will be in-frame and capable of creating a functional protein.[40] Theoretically, one in nine cells might be expected to express two different Ig or TCR chains. However, almost all B cells express the functional products of only one IgH allele and one IgL allele, and mature αβ T cells express only one functional TCRβ gene. The process of limiting the number of receptors expressed by an individual cell is known as *allelic exclusion.*[41]

The mechanisms that ensure monoallelic expression are most commonly regulated at the level of gene rearrangement. Mechanisms that have been shown to contribute to allelic exclusion include asynchronous replication of the two alleles, with rearrangement occurring at the allele that replicates early; localization of the active allele to a more central, euchromatic region of the nucleus; and DNA demethylation of the active allele. Once a functional V domain has been generated, rearrangement terminates with the expression of a membrane-bound Ig or TCR product capable of transducing a signal. In preB cells, a functional μ H chain associates with the surrogate light chain to form the preBCR. Similarly, in developing T cell progenitors, a productive TCR β chain associates with preTα to form the preTCR. These preliminary antigen receptors signal to shut down RAG expression, promote cell division, and limit the accessibility of the IgH and TCRβ loci to further rearrangement while promoting the accessibility of the IgL and TCRα loci, respectively.

In preB cells, the κ locus is typically the first to rearrange, with λ rearrangement primarily occurring in cells that have failed to produce a proper κ chain. Surface expression of an acceptable membrane-bound IgM BCR invokes the mechanism of allelic exclusion among the L chain loci, termed *isotypic exclusion,* and promotes further maturation of the B cell.

Productive TCRα rearrangement in $CD4^+CD8^+$ T-cell progenitors allows the expression of a functional TCR αβ heterodimer (Chapter 9). Unlike IgH and TCRβ, TCRα does not undergo allelic exclusion at the level of gene rearrangement. Instead, in cells that express two functional TCRα alleles, one of the two alleles tends to preferentially pair with the one functional TCRβ chain. This is termed *phenotypic allelic exclusion.*

Allelic exclusion can be overcome by selection pressures. Developing lymphocytes that express self-reactive antigen receptors can downregulate IgH or TCR expression and reactivate gene rearrangement to replace one of the two offending chains. This process, termed *receptor editing,*[42] occurs most often in the IgL or TCRα loci, whose gene structures lend themselves to repeated rearrangement. Less commonly, the V_H in the H chain can be replaced by means of rearrangement to a cryptic RSS located at the terminus of the V_H gene segment.

KEY CONCEPTS

B Cell Receptor (BCR) and Coreceptors

- The BCR–antigen complex consists of a membrane-bound immunoglobulin (mIg) that is responsible for antigen recognition and an Igα/β heterodimer that is responsible for transducing the recognition signal into the cell.
- BCR engagement leads to the phosphorylation of tyrosines in the Igα/β immunoreceptor tyrosine-based activation motif (ITAM) motifs. This signal is then transmitted to one or more other intracellular signaling pathways.
- Recognition of antigen by B lymphocytes can also involve binding of antigen complexed with C3d and IgG to additional B-cell coreceptors.
- Binding of complexed antigen by individual coreceptors can lead to either positive or negative signals, each of which can influence the ultimate outcome of an antigen–B lymphocyte interaction.
- Deficiency of the components of the BCR antigen complex impairs B cell development and can lead to agammaglobulinemia.

B CELL RECEPTOR COMPLEX: STRUCTURE AND FUNCTION

Although the ability of surface Ig to recognize antigen was appreciated very early, the mechanism by which membrane immunoglobulin (mIg) transmitted an antigen recognition event to the cell took longer to understand. Specifically, as the predominant isotypes expressed on the surface of mature B cells, mIgM, and mIgD contain only three amino acid residues exposed to the cytoplasm, it was thought unlikely that these Ig heavy chains could function as signal transduction molecules by themselves. This presumption was eventually proved correct when it was shown that all membrane Ig isotypes associated noncovalently with a heterodimeric complex consisting of two transmembrane proteins, Igα (CD79a) and Igβ (CD79b), each of which is capable of transducing signals into the cell (Table 4.3).

TABLE 4.3 **The B-Cell Receptor (BCR) and Its Coreceptor Molecules**

Molecule	M_r	Chromosome	Function

Membrane-Bound Immunoglobulin

Igs mediate their effector functions as secreted products of plasma cells. However, as membrane-bound structures on mature B cells, Igs serve as the antigen-recognition component of the BCR complex. Although all Ig classes can be expressed at the cell surface, the vast majority of circulating mature B cells coexpress membrane-bound IgM and IgD. Appropriate activation of a naïve IgM- and IgD-expressing B cell leads to plasma cell differentiation and antibody secretion. The membrane-bound forms of IgM and IgD are the product of alternative splicing of the Ig transcript at the 3', or carboxy terminus, of the heavy chain (Fig. 4.10). The two membrane exons encode the transmembrane hydrophobic stretch of amino acids and an evolutionarily conserved cytoplasmic tail terminating in lysine, valine, and lysine.

Signal Transduction and the Ig-α/β (CD79a/CD79b) Heterodimer

The heterodimeric signal transduction component of the BCR complex that associates with mIg has been designated CD79. It is composed of an Igα (CD79a) and Igβ (CD79b) heterodimer. CD79 is responsible for transporting mIg to the cell surface and for transducing BCR signals into the cell.[43,44]

CD79a/Igα is encoded by *CD79a/MB-1* (chromosome 19q13.2) as a 226 amino acid glycoprotein of approximately 47 kDa. The exact molecular weight depends on the extent of glycosylation. *CD79b/B29* (chromosome 17q23) encodes CD79b/Igβ, which is a 229-amino acid glycoprotein of approximately 37 kDa. *CD79a* and *CD79b* share an exon–intron structure, which is similar to that of the genes that encode the CD3 TCR coreceptor molecules. These similarities suggest that both BCR and TCR coreceptors are the progeny of a common ancestral gene. Igα and Igβ both contain a single IgSF Ig domain (111 residue C-type for Igα and 129 residue V-type for Igβ). Each also contains a highly conserved transmembrane domain and a 61-(Igα) or 48-(Igβ) amino acid cytoplasmic tail that also exhibits striking amino acid evolutionary conservation.

Igα and Igβ are expressed by the earliest committed B-cell progenitors prior to Igμ H chain rearrangement. The CD79 heterodimer has been observed on the surface of early B-cell progenitors in the absence of Igμ, although neither protein is required for progenitors to commit to the B-cell lineage.[45] Later

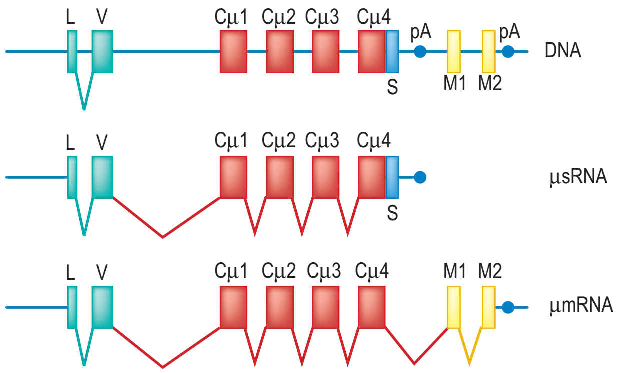

FIG 4.10 **Membrane and Secretory Immunoglobulin M (IgM) Are Created by Alternative Splicing.** Alternative splicing of the Cm carboxy-terminal exons results in messenger RNA (mRNA) transcripts encoding either secreted IgM (μ_s RNA) or membrane-bound IgM (μ_m RNA).

in development, Igα and Igβ are coexpressed together with Igs of all isotypes on the surface of B cells as a mature BCR complex.[43] The CD79 proteins are specific to the B lineage and are expressed throughout B lymphopoiesis. This has led to their use as markers for the identification of B-cell neoplasms.[46,47]

The signaling capacity of both Igα and Igβ resides within an immunoreceptor tyrosine-based activation motif (ITAM) that has the consensus sequence of D/IxxYxxL(x)7YxxL, where x is any amino acid. Similar ITAMs are also found within the cytoplasmic domain of the molecules that associate with, and signal for, the T-cell antigen receptor (CD3) and certain Fc receptors (Chapter 15). The phosphorylation of both tyrosines in both Igα/β ITAMs is considered an obligate initial step in the propagation of antigen receptor engagement to the cell nucleus.[44,48]

Tyrosine-phosphorylated ITAMs serve as efficient binding sites for Src homology 2 (SH2) domains, which are present within a large number of cytosolic signaling molecules. Whether Igα and Igβ make qualitatively different contributions toward BCR signaling or are functionally redundant remains unclear, as evidence exists to support both views. Moreover, the high degree of evolutionary conservation within the non-ITAM portion of the cytoplasmic domains suggests additional, as yet uncharacterized, signaling roles for the cytoplasmic tails of these molecules over and above positive signaling via the ITAMs.

Igα and Igβ are covalently associated by a disulfide bridge via cysteine residues that exist within the IgSF extracellular domains of both molecules. The association of the Igα/β heterodimer with membrane-bound Ig occurs through interaction within the transmembrane domains of these proteins.[43] The core BCR complex consists of a single Ig molecule associated with a single Igα/β heterodimer (H_2L_2/Igα/Igβ) (Fig. 4.11).[49]

A current model for the initiation of signals originating from the BCR (see Fig. 4.11) proposes that antigens induce the clustering of BCR complexes, increasing their local density. The increase in density leads to the transfer of phosphate groups to the tyrosine residues of the Igα/β ITAM motifs.[44,48]

Src-family tyrosine kinases, of which LYN, FYN, and BLK are most often implicated, are believed to be responsible for ITAM phosphorylation upon aggregation of Igα/β. They have been shown to physically associate with the heterodimer. It has been suggested that only a fraction of Src-family tyrosine kinases is associated with the Igα/β heterodimer and, upon aggregation, transphosphorylate juxtaposed heterodimers. However, the exact mechanism by which Igα/β undergoes initial tyrosine phosphorylation after antigen engagement remains uncertain. Regardless of mechanism, phosphorylated ITAMs subsequently serve as high-affinity docking sites for cytosolic effector molecules that harbor SH2 domains. The recruitment of the SYK tyrosine kinase, via its tandem SH2 domains, to doubly phosphorylated Ig-α/β ITAMs is thought to be a next step in propagating a BCR-mediated signal. Association of SYK with the BCR leads to its subsequent tyrosine phosphorylation by either Src-family or other Syk tyrosine kinases, further increasing kinase activity. Together, the concerted actions of the Syk and Src-family protein tyrosine kinases activate a variety of intracellular signaling pathways that can lead to the proliferation, differentiation, or death of the cell.[50]

Clinical Consequences of Disruptions in BCR Signaling

Both the development of B lymphocytes and the maintenance of the mature antigen-responsive B-cell pool demand the presence of an intact BCR and its downstream signaling pathway(s). Disruption of these pathways can present clinically with hypogammaglobulinemia and an absence of B cells.

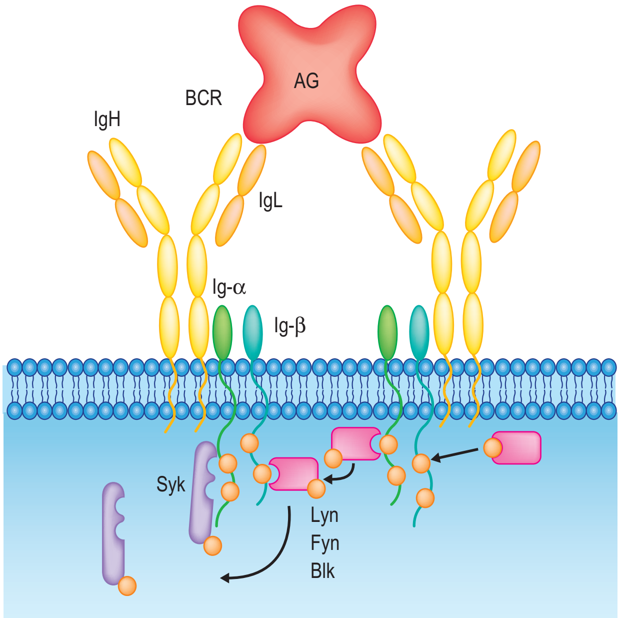

FIG 4.11 The B-Cell Receptor (BCR) Core Complex. The BCR core complex can be divided into an antigen-recognition unit fulfilled by mIgM and a noncovalently associated signal transduction unit composed of the Igα/β (CD79ab) heterodimer. Antigen engagement of mIgM oligomerizes the BCR, allowing preassociated Src-family protein tyrosine kinases to phosphorylate neighboring Igαβ immunoreceptor tyrosine-based activation motif (ITAM) tyrosines. This promotes association of the SYK tyrosine kinase with the tyrosine phosphorylated ITAMs, allowing SYK to become a substrate for other Syk or Src-family tyrosine kinases and leading to its activation.

The most common among such genetic lesions is BTK deficiency, which is an X-linked trait (Chapter 34). BTK plays an important role in BCR signaling both during development and in response to antigen. Loss of function mutations in BTK results in the arrest of human B-cell development at the preB cell stage.

BTK is intact in approximately 10–15% of patients with hypogammaglobulinemia and absence of B cells. Mouse models where BCR components or signaling pathways have been disrupted by targeted mutagenesis have provided insight into the basis of these atypical hypogammaglobulinemia disorders.[44] These studies have shown that an inability to express either a functional μ IgH chain, Igα, Igβ, or the signaling adaptor molecule, BLNK, lead to an early, severe arrest in B lymphopoiesis, with subsequent agammaglobulinemia.[50] Together, these experimental findings highlight the central role of the BCR in the generation and function of B lymphocytes. Thus mutations in any component of the antigen receptor complex or immediate downstream effectors have the potential to disrupt B-cell development and create an agammaglobulinemic state.

Besides its important role in the maturation, differentiation, and survival of B lymphocytes, the B cell antigen receptor is responsible for initiating the humoral response to foreign antigen. Some of the variables that can influence the ultimate outcome of BCR–antigen interaction include the nature of the foreign antigen, the mode of activation, the developmental stage of the B cell, and the microenvironment in which antigen encounter occurs. Exactly how these variables ultimately result in the differential activation of diverse intracellular signaling pathways with fundamentally divergent outcomes is still under study. Emerging from these studies is an appreciation of the role of BCR coreceptors, which have been shown to be capable of modulating antigen receptor signaling in response to antigen.

BCR Coreceptors

The initiation of a humoral immune response results from antigen interaction with the antigen receptors on mature peripheral lymphocytes. However, the manner in which mature B and T lymphocytes recognize antigen is fundamentally different (Chapter 6). Surface Ig, as a component of the BCR on B lymphocytes, typically recognizes an antigenic epitope in its native three-dimensional configuration which, upon engagement with mIg, is capable of transmitting a signal to the cell interior. In contrast, the antigen receptor expressed by T lymphocytes typically recognizes an antigen-derived peptide associated with an appropriate MHC structure (Chapter 5). Further, for this T-cell recognition event to be productive, a CD4 or CD8 coreceptor must also bind to the MHC structure presenting the foreign antigen.

Antigen recognition by the BCR on B lymphocytes is also influenced by coreceptors present on mature B cells (see Table 4.3). In this case, the coreceptors may also recognize antigen, but only in a form that has been modified by other components of the immune system, as described below. In general, these coreceptors and coreceptor complexes can be divided into those that regulate BCR signaling in a positive manner and those that regulate in a negative manner. Thus the ultimate outcome of signaling via the BCR depends not only on the signals transduced via the Igα/β heterodimer but also how these signals are perceived by the cell in association with the signals propagated by the various coreceptors that are concomitantly engaged.

Coreceptors That Positively Regulate BCR Signaling

CD21

Mature B lymphocytes express two receptors for complement C3 components, CD35 (CR1) and CD21 (CR2) (Chapter 21). Of these, CD21 fulfills the requirements of a BCR coreceptor (*vide infra*). The expression of CD21 is restricted to mature B cells and follicular dendritic cells (FDCs), whereas CD35 is also found on erythrocytes, monocytes, and granulocytes. CD21 is a 140 kDa surface glycoprotein encoded by the *CR2* locus on chromosome 1q32 (see Table 4.3). Expression of CD21 begins at approximately the same time as IgD during B lymphopoiesis (Chapter 7). CD21 is subsequently expressed on all mature B cells until terminal differentiation, albeit at different levels depending on B cell population. The extracellular domain of CD21 is composed of 15–16 short consensus regions (SCRs), each composed of 60–70 amino acids, and a relatively short 34-amino acid cytoplasmic tail. The two-amino terminal SCRs constitute the region that interacts with one of the third complement component (C3) cleavage products, iC3b, C3d, g, and C3d (Chapter 21).[51]

CD21 is a receptor for Epstein-Barr virus (EBV), which similarly binds the two N-terminal SCRs via its major envelope glycoprotein gp350/220. CD21, through its oligosaccharide chains, also binds CD23, the low-affinity IgE receptor (FcεRII). Whereas EBV utilization of CD21 for cell entry has clear physiological consequences in terms of infection, B-cell immortalization, and the potential for oncogenesis, the *in vivo* relevance of any CD21–CD23 interaction remains unclear.

CD19

CD19 is an IgSF surface glycoprotein of 95 kDa that is expressed from the earliest stages of B cell development until plasma cell terminal differentiation, when its expression is lost.[52] FDCs also express CD19. *CD19* maps to chromosome 16p11.2, where it encodes a 540 amino acid protein with two extracellular C-type IgSF domains as well as a large, approximately 240 residue, cytoplasmic tail that exhibits extensive conservation between mice and humans. This relatively large cytoplasmic domain includes nine conserved tyrosine residues which, upon phosphorylation, serve as docking sites for other SH2-containing effector molecules. The signaling capacity of CD19 has been shown to result from tyrosine phosphorylation, which occurs upon engagement of the BCR, CD19 or, optimally, by collication of CD19 and IgM. Known signaling effector molecules that have been identified in association with tyrosine-phosphorylated CD19 include the LYN and FYN protein tyrosine kinases, the Rho-family guanine nucleotide exchange factor, VAV, and phosphatidylinositol 3-kinase.[52] Although specific ligands for CD19 have been proposed, the physiological relevance of CD19 engagement by putative ligands has not been demonstrated.

In vitro studies using mAbs directed against CD21 or CD19 provided initial evidence that these B-cell surface antigens could influence mIg-mediated signaling.[51-53] Genetic deficiencies of CD21 (CVID7) or CD19 (CVID3) promote the development of common variable immune deficiency (CVID), which is characterized by hypogammaglobulinemia (Chapter 34). In mice, CD21 and CD19 deficiencies demonstrate impaired antibody response to T-dependent antigens. The paucity of $CD5^+$ B cells in CD19-deficient mice suggests a role for this molecule in the generation and maintenance of the B1 lineage of B cells (Chapter 7). CD19 is expressed from the earliest stages of B cell ontogeny and, accordingly, a signaling function for CD19 in B lymphopoiesis has been demonstrated.[54]

CD21–CD19 Coreceptor Complex

A mechanism by which these molecules could augment BCR-mediated signaling was provided by the identification of a CD21–CD19 coreceptor complex on mature B cells that also includes CD81 (Fig. 4.12). CD81, also known as TAPA-1, is a 26-kDa tetraspan molecule widely expressed on a number of cell types, including lymphocytes. The CD21–CD19 coreceptor model predicted that as a result of complement activation, C3d would be deposited on an antigen, thereby providing a bridge by which a CD21–CD19 receptor complex could associate with mIgM and the BCR complex.[51-53] Clustering of CD19 close to the BCR by the C3d–antigen complex would effectively recruit the signal transduction effector molecules associated with CD19 to the Igα/β heterodimer. As a consequence, the CD19-associated LYN and FYN tyrosine kinases, VAV, and PI3-kinase signaling effector molecules would be in a position to exert their activities on the Igα/β heterodimer–mediated signaling events initiated by antigen engagement of mIgM.

Strong support for CD21–CD19 coreceptor physiological function in BCR signaling was subsequently provided by experiments using a murine model of immune response. Immunization with an antigen covalently attached to C3d dramatically reduced the signaling threshold necessary for antigen to elicit an immune

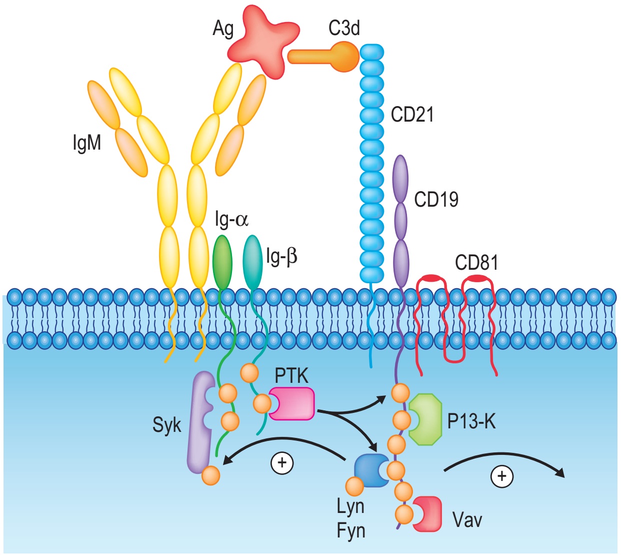

FIG 4.12 Proposed Mechanisms for the Augmentation of B-Cell Receptor (BCR) Signaling by the CD21/19 Coreceptor. Coligation of the BCR and CD21–CD19 complex by C3d–antigen complex allows a CD79-associated Src-family tyrosine kinase to phosphorylate tyrosine residues within the CD19 cytoplasmic domain. Subsequently, tyrosine-phosphorylated CD19 effectively recruits key SH2-containing signaling molecules to the BCR complex, allowing the initial BCR-mediated signal to quickly disseminate along different intracellular signaling pathways.

response.[55] Antigen bearing either two or three copies of C3d was respectively 1000 and 10 000 times more immunogenic than antigen alone. Thus the CD21–CD19 coreceptor complex provides a link between the innate and adaptive immune responses. *In vivo*, CD19-deficient mice appear to have more severely affected T-dependent immune responses compared with CD21-deficient animals, suggesting alternative roles for CD19 in regulating BCR signals beyond the CD21–CD19 coreceptor complex.

Coreceptors That Negatively Regulate BCR Signaling

FcγRIIB

Among the several receptors for the Fc portion of Ig expressed by B cells, the Fc receptor for IgG, FcγRIIB (a member of the CD32 cluster), has an important role in negatively regulating BCR-mediated signal transduction.[56] FcγRIIB is a 40 kDa single-chain molecule that is encoded by single gene located on chromosome 1q23-24. Alternative splicing of different cytoplasmic exons permits expression of three isoforms. The extracellular domain of FcγRIIB is composed of two C-type IgSF domains that can bind with low affinity to IgG. All three FcγRIIB isoforms share a common cytoplasmic region that is important for negatively regulating activation signals delivered by associated surface receptors. The region within the cytoplasmic domain of FCγRIIB responsible for the inhibitory activity of this Fc receptor toward the BCR has been identified as a sequence that contains a tyrosine residue critical for its activity.[57] Analogous to the ITAM, which provides an activation signal, this inhibitory sequence has been referred to as an *immunoreceptor tyrosine-based inhibitory motif* (ITIM). The ITIM is carried by the canonical sequence of I/L/VxYxxI/V/L (where x is any amino acid).[56] ITIMs are found in a number of other transmembrane structures, all of which share the ability to negatively regulate signaling by activating receptors.

The ability of passively administered soluble antibody to inhibit humoral responses has long been appreciated and was initially thought to occur by soluble antibody effectively masking all available antigen epitopes. The molecular mechanism accounting for this suppression is now known to be mediated by the binding of IgG to FcRγIIB and the subsequent recruitment of cytosolic phosphatases to the FcRγIIB ITIM upon tyrosine phosphorylation. Thus the inhibitory effect of IgG on BCR-mediated B cell activation is explained by the interaction of the FcγRIIB ITIM, and specifically associated phosphatases, with the BCR (Fig. 4.13). Coligation of the BCR and FcRγIIB by antigen–IgG complexes results in the tyrosine phosphorylation of the FcRγIIB ITIM, presumably by the BCR-associated tyrosine kinases. Phosphorylated FcRγIIB ITIMs then recruit two different SH2-containing phosphatases, SHIP and SHP-1, which function to remove phosphate groups from inositol lipids or tyrosines, respectively. Although both phosphatases can negatively regulate BCR-mediated signaling events, SHIP appears to be the most relevant phosphatase in FcRγIIB inhibition of BCR signaling (see Fig. 4.13).[58] Thus once the majority of antigen exists in immune complexes together with antigen-specific IgG, attenuation of an ongoing immune response occurs by the juxtaposition of FcRγIIB with the BCR.

CD22

CD22 is a 135-kDa to 140-kDa transmembrane glycoprotein that is restricted in its expression to the B lineage.[59] CD22 expression is limited to the cytoplasm of progenitor and pre-B cells in early B-cell development. Expression on the surface of the B cell occurs concomitant with the appearance of surface, or membrane, IgD. Upon B-cell activation, CD22 expression is initially transiently upregulated and subsequently downmodulated upon terminal differentiation to Ig-secreting plasma cells. Although the onset of CD22 expression follows a similar pattern during murine B lymphopoiesis, it is not restricted to the cytoplasm in early B lymphopoiesis but rather is expressed on the surface from the progenitor stage onward. The basis or function of CD22 intracellular retention in human B cell development is not understood.

CD22 maps to chromosome 19q13.1 and encodes alternatively spliced forms of CD22, CD22α, and CD22β, of which the latter is the predominant species expressed by B cells. The CD22β isoform contains seven extracellular IgSF domains, of which all but one are of the C type. The single exception is the N-terminal domain, which is of the V type. CD22α lacks the IgSF third and fourth domains, although the significance of this minority alternatively spliced product remains unclear. The CD22 murine homologue has only been found as a full-length CD22β isoform. The extracellular domain of CD22 is homologous to the carcinoembryonic antigen subfamily of adhesion molecules, which includes the myelin-associated glycoprotein (MAG) and CD33. CD22 also functions as an adhesion molecule belonging to the Siglec subfamily of the IgSF, whose members function as mammalian sialic acid–binding Ig-like lectins.[59] The two N-terminal IgSF domains have been shown to mediate adhesion to both B and T lymphocytes via the binding of structures carrying α2,6 sialic acids.

In addition to acting as an adhesion molecule, CD22 is also capable of modulating BCR signaling (see Fig. 4.13). A fraction of CD22 associates with the BCR, and CD22 is rapidly tyrosine-phosphorylated upon mIgM engagement.

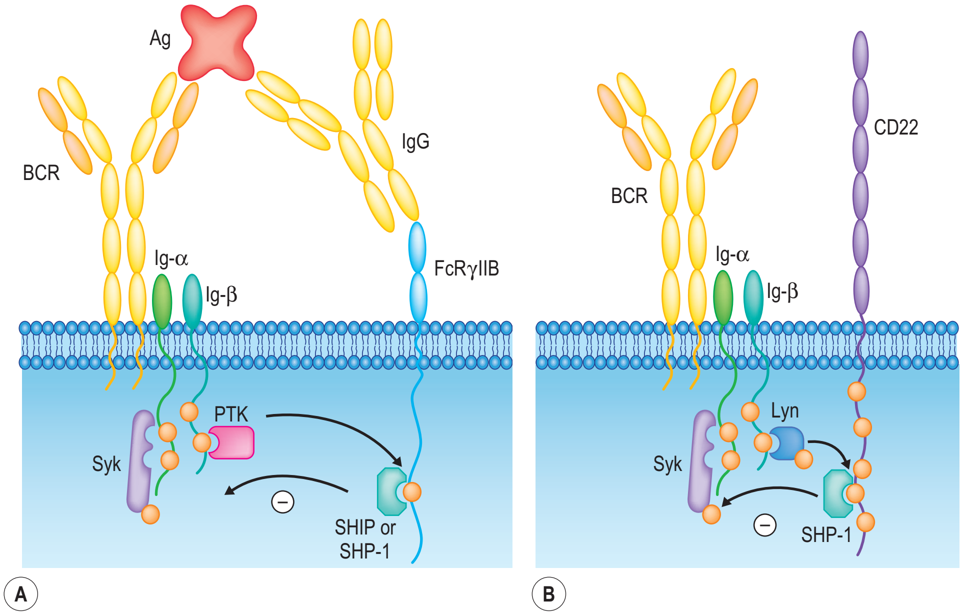

FIG 4.13 **Negative Regulation of B Cell Receptor (BCR) Signaling by FcγRIIB and CD22.** (**A**) Soluble immunoglobulin G (IgG)–antigen immune complexes juxtapose the BCR with FcγRIIB. The BCR-associated LYN tyrosine kinase subsequently tyrosine phosphorylates the FcγRIIB immunoreceptor tyrosine-based inhibitory motif (ITIM). In turn, this leads to the recruitment of the SRC homology 2 (SH2)-containing inositol phosphatase SHIP and tyrosine phosphatase SHP-1 to the phosphorylated FcRγIIB ITIM. Both of these phosphatases have demonstrable inhibitory activity on BCR-mediated signaling. Although SHIP is believed to be the major effector in the FcRγIIB-mediated inhibition of BCR signaling, the exact mechanism of its action in this context has not yet been elucidated. (**B**) CD22 associated with the BCR is tyrosine-phosphorylated upon antigen–BCR engagement. SH2-containing signaling molecules dock on tyrosine phosphorylated residues, including the SHP-1 tyrosine phosphatase that can subsequently dephosphorylate signaling molecules previously activated by a mIgM-mediated signal.

Tyrosine-phosphorylated CD22 associates with several SH2-containing signaling molecules, including the LYN and SYK tyrosine kinases, PI3-kinase, phospholipase C-γ, and SHP-1. The 140-amino acid cytoplasmic domain of CD22 includes six conserved tyrosine residues. Three of these tyrosines are located within conserved consensus ITIM sequences and possess a demonstrable capacity to bind the SH2 domain of the SHP-1 phosphatase. The presence of the multiple ITIMs and association with SHP-1 indicated that CD22 might impinge on BCR signaling in a negative manner. Physiological evidence that CD22 could act as a coreceptor to negatively regulate mIgM signaling was provided by the generation of CD22-deficient mice by targeted mutagenesis.[59] CD22-deficient B cells exhibit hyperactive B-cell responses upon BCR triggering and an increased incidence of serum autoantibodies. This suggests that B-cell tolerance is altered and that B cells are more readily activated in the absence of this negative regulator of BCR signaling.

KEY CONCEPTS

T-Cell Receptor (TCR)–CD3 Complex

- Cell-surface expression of the TCR heterodimers requires association with a complex of invariant proteins designated CD3.
- Each TCR–CD3 complex contains three CD3 dimers.
- Assembly of the TCR–CD3 complex involves interactions between TCR transmembrane basic residues and transmembrane acidic residues in each of the CD3 subunits.
- Signal transduction by the TCR involves the phosphorylation of immunoreceptor tyrosine-based activation motifs (ITAMs) in the cytoplasmic domains of CD3 proteins.
- Phosphorylated CD3 ITAMs recruit and activate the zeta chain-associated protein kinase 70 (ZAP-70) protein tyrosine kinase.
- Deficiency of CD3 proteins impairs T-cell development and can produce severe combined immunodeficiency (SCID).

THE TCR–CD3 COMPLEX

The αβ and γδ TCR heterodimers, which are responsible for the recognition of specific antigen by T lymphocytes, associate with a complex of invariant proteins designated CD3. This association is necessary for TCR cell-surface expression and enables the TCR heterodimers, which have only short cytoplasmic domains, to couple to the intracellular signaling events that lead to the activation of T-cell effector function.[60] There are four CD3 proteins: γ, δ, ε, and ζ (Fig. 4.14).

CD3 Proteins

CD3γ, CD3δ, and CD3ε are structurally similar, and the genes encoding them map to a locus in chromosome 11q23. The

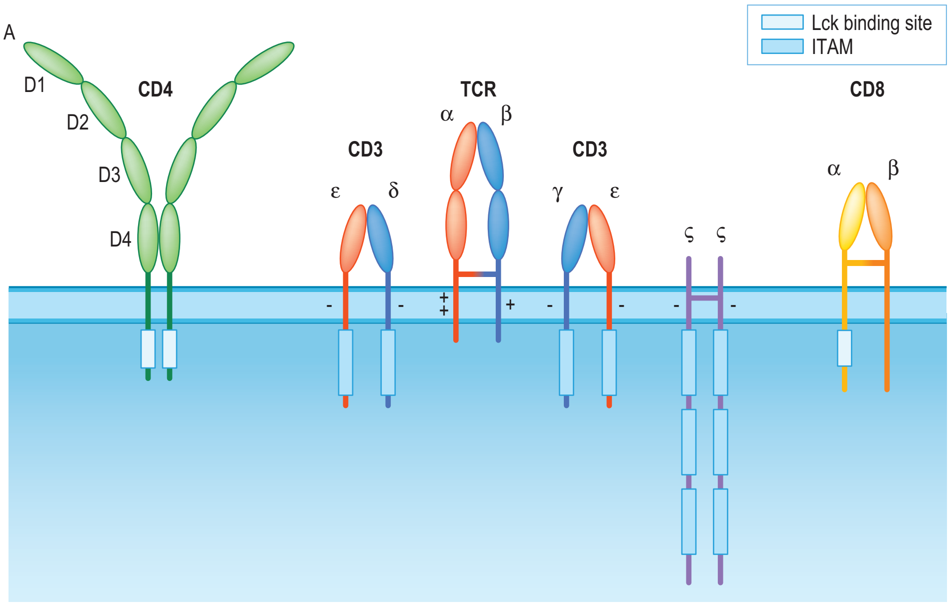

FIG 4.14 Schematic Representation of the Human T-Cell Receptor (TCR) and CD4 and CD8 Coreceptors. Immunoglobulin superfamily (IgSF) domains are represented by ovals. The four extracellular domains of CD4 are labeled D1-D4. Basic (+) and acidic (–) transmembrane charged residues are indicated, as are known and predicted sites of disulfide bonds. For schematic simplicity the cytoplasmic domains of the CD3 chains are shown as extending into the cytoplasm. The cytoplasmic domains of CD3ε and CD3ζ are positively charged and likely are associated with the inner leaflet of the plasma membrane. ITAM, immunoreceptor tyrosine-based activation motifs.

polypeptides range in size from 20 kDa to 25 kDa. Each has an extracellular C-type IgSF domain, a transmembrane region that contains an acidic residue (aspartic acid in CD3δ and CD3ε glutamic acid in CD3γ), and a cytoplasmic domain with a single ITAM. The cytoplasmic domain of CD3ε (but not of CD3δ or CD3γ) has a net positive charge and can bind to the negatively charged inner leaflet of the plasma membrane with its ITAM inserted into the lipid bilayer. The CD3 chains are present in the TCR–CD3 complex in the form of noncovalently linked CD3γε and CD3δε heterodimers; interactions between the extracellular IgSF domains lead to the formation of these CD3 heterodimers.

The 16 kDa CD3ζ differs substantially from the other CD3 proteins and is structurally homologous to the γ chain of the high-affinity IgE receptor (FcRγ chain). The extracellular domain of CD3ζ has only nine amino acids and is of unknown structure. As is the case with the other CD3 chains, the transmembrane region of CD3ζ contains an acidic residue (aspartic acid). The large cytoplasmic domain of CD3ζ has three ITAMs in tandem which, like the ITAM of CD3, also associate with the inner leaflet of the plasma membrane.[18] CD3ζ is usually present in the TCR–CD3 complex in the form of disulfide-linked CD3ζζ homodimers that form through interactions within the transmembrane domain.

Stoichiometry of the TCR–CD3 Complex

The αβTCR–CD3 complex is univalent and consists of a single αβ TCR heterodimer together with three CD3 dimers: CD3γε, CD3δε, and CD3ζζ (see Fig. 4.14). The γδTCR–CD3 complex, in contrast, lacks CD3δ. On naïve T cells, this receptor complex contains two CD3γε heterodimers and one CD3ζζ homodimer. Following activation of γδT cells, the TCR–CD3 complex incorporates the FcRγ chain, either as a homodimer or as a heterodimer with CD3ζ.[18,60,61]

Assembly and Cell-Surface Expression of the TCR–CD3 Complex

Assembly begins with formation of the individual TCRαβ, CD3δε, and CD3γε heterodimers, processes that are driven by interactions between the extracellular domains of the pairing polypeptides. The subsequent higher order assembly of the TCRαβ with the CD3 dimers depends on the interactions between the potentially charged residues within their transmembrane regions. As noted above, each of the CD3 subunits has a transmembrane acidic residue, whereas the transmembrane domains of the αβ and γδ TCRs contain basic residues. Mutation of any of these transmembrane acidic or basic residues to neutral alanine impairs formation of the TCR–CD3 complex. TCRαβ appears to associate first with CD3δε and then with CD3γε. TCRα binds CD3δε, and TCRβ likely interacts with CD3γε. The incorporation of a CD3ζζ homodimer into the complex requires the prior formation of a TCRαβ–CD3γε–CD3δε hexamer and involves interactions between the arginine residue in the transmembrane domain of TCRα and the two colocalized aspartic acids in the transmembrane domains of the CD3ζζ homodimer.[18,62]

Formation of the TCR–CD3 complex is tightly regulated. For example, when there are deficiencies of CD3γ, CD3δ, or CD3ε, TCRα and β are retained in the endoplasmic reticulum and are rapidly degraded. In the absence of CD3ζ, the TCRαβ–CD3γε–CD3δε hexamer is exported to the Golgi apparatus but then is targeted to a lysosomal degradation pathway rather than to the cell surface.[18,60-62]

Because the structures of most of the individual components of the TCR–CD3 complex are known, a model of the overall structure of the receptor has been proposed. This model envisions a compact TCR–CD3 complex, with trimeric contacts occurring within the transmembrane regions of all components (i.e., TCRα–CD3ε–CD3δ, TCRβ–CD3ε–CD3γ, and TCRα–CD3ζ–CD3ζ) and with the TCRαβ projecting further from the membrane (80 Å) than the CD3 chains (40 Å).[18,62]

Mutations in the *CD3D, CD3E, CD3G,* and *CD3Z* genes have been described in humans.[63-65] The clinical consequences of these mutations underscore the importance of the CD3 proteins for the normal development and function of T cells.

Homozygous mutations leading to complete deficiencies of either CD3δ, CD3ε, or CD3ζ protein produce a form of SCID (Chapter 35) characterized by severe T-cell lymphopenia, but in the presence of phenotypically normal B cells and NK cells ($T^-B^+NK^+$SCID).[63,64]

Mutations in *CD3G* leading to deficiency of CD3γ produce considerable clinical heterogeneity ranging from severe immunodeficiency in infants to mild forms of autoimmunity in adulthood. Homozygous deficiency in CD3γ impairs, but does not abrogate, T-cell development, leading to mild T lymphopenia, reduction in cell-surface expression of the TCR–CD3 complex on peripheral T cells by 75–80%, and impaired *in vitro* proliferative T-cell responses to lectins and to anti-CD3 mAbs. In peripheral blood, there are differential effects on phenotypically defined T-cell subsets, with very few CD8 T cells, a 10-fold reduction in $CD45RA^+$ CD4 T cells ("naïve helper" subset), and normal numbers of $CD45RO^+$ CD4 T cells ("memory" cells).[65]

Early Events in TCR–CD3 Signaling

Stimulation of the TCR–CD3 complex by pMHC leads to the phosphorylation of tyrosine residues in the CD3 ITAMs by the SRC-like protein tyrosine kinase, LCK.[66] The phosphorylated CD3 ITAMs, in turn, create high-affinity binding sites for the SH2 domains of the zeta chain-associated protein kinase 70 (ZAP-70) protein tyrosine kinase, leading to its recruitment to the TCR–CD3 complex and to its activation (Chapter 12).[66,67] The consequences of ZAP-70 deficiency (selective T-cell immunodeficiency in humans) underscore the centrality of its role in T-cell activation (Chapter 35).

The TCR appears to act as a mechanosensor to trigger the cascade of complex biochemical events leading to the activation of T-cell effector function. As the T cell migrates over the cell surface of an APC or target cell, the binding of the pMHC complex to the TCR causes the TCR to act as a lever, converting horizontal force into a vertical force that acts on the CD3 chains, exposing their ITAMs for phosphorylation. Following the initiation of signaling, sustained signaling appears to involve multimerization of TCR–CD3 complexes and engagement of coreceptors.[18,62]

T-CELL CORECEPTORS: CD4 AND CD8

Expression of CD4 and CD8 divides mature T cells into two distinct subsets: CD4 T cells (Chapter 16), which recognize peptides in the context of class II MHC molecules, and CD8 T cells (Chapter 17), which recognize antigens presented by class I MHC molecules. Indeed, CD4 binds directly to class II MHC molecules, and CD8 interacts directly with class I MHC molecules (Fig. 4.15). During antigen recognition, CD4 and CD8 are thought to bind the same pMHC complex as the TCR and thus are true coreceptors for the TCR.[68] The cytoplasmic domains of CD4 and CD8 associate with LCK and serve to bring LCK into contact with the CD3 chains of the pMHC-engaged TCR/CD3 complexes, leading to the phosphorylation of CD3 ITAMs and initiation of TCR signaling (Chapter 12).

The expression of the CD4 and CD8 coreceptors is highly regulated during T-cell development in the thymus (Chapter 8). Thymocytes initially express neither coreceptor ("double negative"). $CD4^-CD8^-$ thymocytes destined to become TCRαβ T cells progress through a $CD4^+CD8^+$ ("double-positive") stage to become mature CD4 or CD8 T cells. Positive and negative selection of thymocytes on the basis of their TCR specificities, and commitment to the CD4 or CD8 lineages occur during the double-positive stage.

CD4: Structure and Binding to MHC Class II Molecules

A member of the IgSF, CD4 is a 55 kDa glycoprotein whose relatively rigid extracellular region contains four IgSF domains (designated D1–4). Its cytoplasmic domain contains two cysteine residues that mediate a noncovalent interaction with LCK through a "zinc clasp"–like structure formed with a dicysteine motif in the N-terminal region of LCK.[66,69-71]

The N-terminal domain (D1) of CD4 binds between the membrane-proximal α_2 and β_2 domains of MHC class II. Thus CD4 interacts with pMHC class II at a distance from the α helices and peptide contacted by the TCR, enabling the TCR and CD4 to bind the same MHC class II molecule simultaneously.

Although MHC molecules are highly polymorphic, the CD4 contact sites are highly conserved. In humans, CD4 targets nonpolymorphic residues shared by all three MHC class II molecules (HLA-DR, -DP, and -DQ). The crystal structure of the TCRαβ–pMHC–CD4 ternary complex assumes a V-shape with pMHC at the apex and with TCRαβ and CD4 forming the arms of the V. There is no direct interaction between the coreceptor and the TCR heterodimer, indicating that pMHC brings the TCR and CD4 together. The approximately 70 Å of separation between the membrane-proximal domains of TCRαβ and CD4 would allow the CD3 chains to lie within the open angle between TCRαβ and CD4, promoting interactions between CD3 chains and CD4-associated LCK.[66,69,71]

Experiments using soluble forms of CD4 and pMHC have revealed that monomeric CD4 binds pMHC with very low affinity (Kd approximately 200 μM). The binding of CD4 to pMHC is of lower affinity than that of TCRαβ to pMHC (Kd 1–10 μM) and displays a far more rapid off time. Because of the low affinity and the rapid off time, it is unlikely that interactions of CD4 with MHC class II molecules initiate the interaction between a T cell and an APC (Chapter 6). Rather, these binding characteristics are more compatible with a model in which the initial event is the interaction between the TCR and pMHC, followed by the recruitment of CD4, which acts primarily to promote signaling events through the delivery of LCK.[66,69,71]

CD8: Structure and Binding to MHC Class I Molecules

There are two CD8 polypeptides, α and β, and these are expressed on the cell surface either as a disulfide-linked CD8αα homodimer or as a disulfide-linked CD8αβ heterodimer. On most αβ T cells, CD8αβ is the predominant form of CD8 while natural killer (NK) cells (Chapter 17), intestinal intraepithelial T cells, and γδ T cells exclusively express CD8αα.[66,69-71]

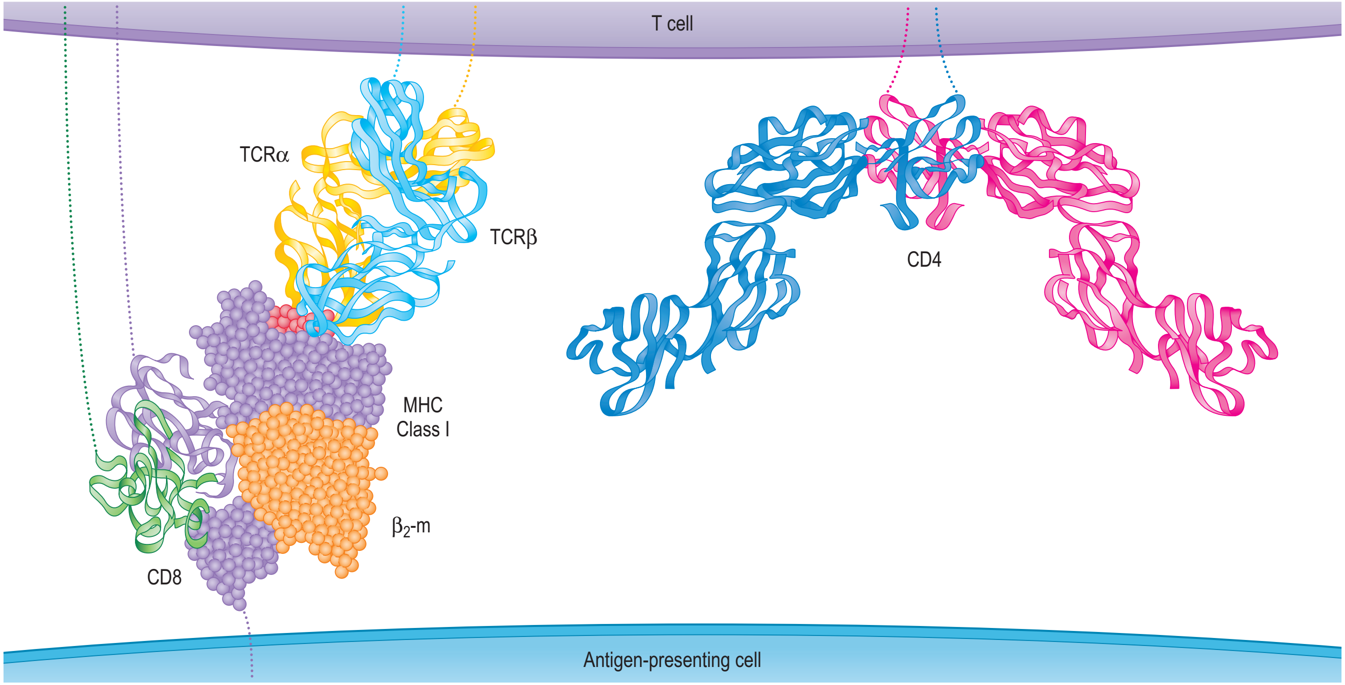

FIG 4.15 Illustration of the Interactions between the T-Cell Receptor (TCR), Peptide Major Histocompatibility Complex (pMHC), and CD8. A composite illustration of the human leukocyte antigen (HLA)-A*0201 structure in complex with a Tax peptide and its cognate TCR α and β chains (protein data bank (pdb) designation 1BD2) with the human CD8αα/HLA-A*0201 structure (pdb designation 1AKJ) was generated by superposition of the HLA moiety of the two structures. The HLA heavy chain is indicated as MHC, its light chain (β_2 microglobulin) as β_2-m, the CD8αα homodimer as CD8, the TCR α and β chains as TCRα and TCRβ. In addition, the CD4 homodimer (pdb file 1WIO) is shown to scale. Connecting peptides, transmembrane, and cytoplasmic domains are drawn by hand and indicated by dotted lines. (Figure courtesy of David H. Margulies, National Institute of Allergy and Infectious Diseases, National Institutes of Health.)

CD8α, a 34- to 37-kDa protein, and CD8β, a 32-kDa protein, share about 20% amino acid sequence homology. Both are glycoproteins and IgSF members. Although CD8 subserves a coreceptor function similar to that of CD4, in structure it differs substantially from CD4. The CD8 extracellular regions have single N-terminal IgSF V domains at the end of extended mucin-like stalk regions of 48 amino acids (CD8α) or 35–38 amino acids (CD8β). A striking difference between the two forms of CD8 lies within the cytoplasmic domain. CD8α, like CD4, contains a cysteine-based motif that enables it to interact with LCK through a "zinc clasp"–like structure. In contrast, CD8β lacks this motif and does not associate with LCK. Interestingly, CD8αβ appears to be a more effective activator of TCR signaling than CD8αα. This may reflect the palmitoylation of the cytoplasmic domain of CD8β, which allows CD8αβ to associate with lipid rafts during T-cell activation.[66,69,71,72]

The structure of CD8αα–pMHC class I complexes demonstrates that CD8αα binds to conserved residues in the α_3 domain of MHC class I (i.e., a nonpolymorphic, membrane-proximal region of the molecule distinct from the peptide-binding groove engaged by the TCR) (Chapter 5). Compared with the interaction of CD4 and MHC class II, binding is more antibody-like, with a loop of the MHC α_3 domain locked between the CDR-like loops of the two CD8α IgSF V domains. Models of the structure of the TCRαβ–pMHC–CD8 ternary complex propose a "V" shape similar to that of the crystal structure of TCRαβ–pMHC–CD4, with pMHC at the apex of the "V" and the TCR and CD8 forming the arms of the "V." CD8 binds to pMHC with lower affinity and with faster kinetics compared with the TCR. Thus the binding properties of the CD8 coreceptor, like those of CD4, are consistent with a model in which the TCR initiates pMHC binding, followed by engagement of CD8 to the same pMHC.[66,69-72]

COSTIMULATORY AND INHIBITORY T-CELL MOLECULES: THE CD28 FAMILY

Although the T-cell response to antigen requires the binding of the TCR and its coreceptors to pMHC, additional receptor–ligand interactions affect the outcome by delivering signals that promote activation (costimulation) or that inhibit it (Table 4.4). Prominent among these are the interactions of members of the CD28 family with their cell-surface ligands on APCs.[73] This family includes CD28, inducible T-cell costimulator (ICOS), cytotoxic T lymphocyte antigen-4 (CTLA-4), B- and T lymphocyte attenuator (BTLA), and programmed death 1 (PD-1). CD28 and ICOS are costimulatory receptors; the major functions of CTLA-4, PD-1, and BTLA are inhibitory. CD28 and CTLA-4 are T-cell specific, whereas BTLA and PD-1 are also expressed by B cells and ICOS by NK cells. CD28, CTLA-4, and PD-1 are the targets of therapeutic interventions in current clinical practice.

TABLE 4.4 CD28 Superfamily

Receptor	Expression	Ligand	Function on T Cells
CD28	Most CD4 T cells 50% CD8 T cells	B7-1 (CD80) B7-2 (CD86)	Costimulation of interleukin (IL)-2 production and proliferation; Promotes T cell survival
Inducible T cell costimulator (ICOS)	Activated and memory T cells Natural killer (NK) cells Not expressed by naïve T cells	ICOS ligand	Promotes T cell differentiation and effector T-cell function
Cytotoxic T lymphocyte antigen-4 (CTLA-4)	Upregulated after T-cell activation	B7-1 (CD80) B7-2 (CD86)	Inhibits IL-2 production and proliferation; Promotes peripheral T cell tolerance
Programmed death 1 (PD-1)	Upregulated after activation of T and B cells, myeloid cells	PD-L1 (B7-H1) PD-L2 (B7-DC)	Inhibits proliferations and cytokine production Promotes peripheral T cell tolerance
B and T lymphocyte attenuator (BTLA)	T and B cells, myeloid cells, dendritic cells	HVEM (herpesvirus-entry mediator)	Inhibits T cell proliferation

All members of the CD28 family have a single extracellular IgSF V domain and have, as their ligands, members of the B7 family of cell surface molecules. CD28, CTLA-4, and ICOS are disulfide-linked homodimers whose cytoplasmic domains contain the SH2-binding motif YXXM. In contrast, PD-1 and BTLA are monomers whose cytoplasmic domains each contain an ITIM and an immunoreceptor tyrosine-based switch motif (ITSM).

CD28 and CTLA-4

Half of CD8 T cells and virtually all human CD4 T cells constitutively express CD28. CD28 binds to B71 (CD80) and B7.2 (CD86) through an MYPPPYY motif in its extracellular domain. Interactions with these ligands leads to the phosphorylation of the YMNM sequence in the CD28 cytoplasmic domain and to the recruitment of phosphatidylinositol 3-kinase and Grb2. CD28 stimulation usually does not elicit a cellular response in the absence of TCR signaling. Rather CD28 signals act in concert with those of the TCR to promote cytokine production, T cell expansion, and T cell survival. TCR signaling in the absence of CD28 costimulation can induce T cell anergy (Chapter 12).

CTLA-4 inhibits the response to TCR and CD28 signals and acts to terminate peripheral T cell responses. Its importance in human immunology is underscored by observations that *CTLA4* haploinsufficiency produces a syndrome of immune dysregulation characterized by decreased numbers of regulatory T cells (Tregs), hyperactive effector T cells, hypogammaglobulinemia, and clinical autoimmunity.

The majority of CTLA-4 resides in intracellular compartments. T cell activation promotes the cell-surface expression of CTLA-4 by regulating both its transport to the surface and its subsequent internalization. CTLA-4 also binds B7.1 and B7.2 but does so with substantially greater affinity than does CD28. Moreover, the binding of CTLA-4 to these ligands is divalent, whereas that of CD28 is monovalent. Thus the inhibitory complexes formed by CTLA-4 are more stable than the costimulatory interactions involving CD28. CTLA-4 can inhibit T-cell activation by outcompeting CD28 for B7 ligands and, through trans-endocytosis, by removing B7 molecules from the APC. In addition, CTLA-4 can induce "reverse signaling" through B7.1 and B7.2 to the APC, upregulating the enzyme indoleamine 2,3-dioxygenase (IDO), which, in turn, breaks down tryptophan, a requirement for T cell proliferation.

The importance of CD28 costimulation has made it an attractive target for therapeutic intervention.[74,75] Indeed, two soluble fusion proteins composed of the extracellular domain of human CTLA-4 and the constant regions of human IgG1, abatacept and belatacept, are effective therapies for the treatment of rheumatoid arthritis (Chapter 52) and the prevention of renal allograft rejection (Chapter 81). These fusion proteins are thought to inhibit CD28 costimulation through blockade of its B7 ligands, but some of their immunosuppressive effects may be indirect through the induction of IDO and consequent local depletion of tryptophan. Conversely, inhibition of CTLA-4 by mAbs can promote durable immune responses against certain malignancies.

PD-1

PD-1 is a key inhibitory receptor that attenuates TCR signaling, promotes T-cell tolerance, and is associated with T-cell exhaustion. PD-1 is not found on resting T cells, and its expression during T-cell activation requires transcriptional activation. PD-1 binds to two ligands: programmed death ligand 1 (PDL-1), which is widely expressed, and PDL-2, which is found primarily on professional antigen presenting cells. Engagement of ligand induces tyrosine phosphorylation of the ITIM and the ITSM in the cytoplasmic domain of PD-1, leading to the recruitment of the tyrosine phosphatase SHP-2. Continued stimulation of T cell by antigen leads to sustained expression of PD-1 and differentiation into a state of hyporesponsiveness termed *T-cell exhaustion*. Blockade of PD-1 has shown considerable promise in the treatment of diverse human malignancies.

ON THE HORIZON

- Elucidation of the mechanisms that regulate which epitopes will be preferentially bound by normal and abnormal antigen receptor repertoires
- Elucidation of the mechanisms that create constraints on the diversity of antigen receptor repertoires and the role they play in diseases of immune function
- Targeting of vaccines to elicit responses to specific epitopes
- Development of additional new therapies focused on regulating signal transduction from the B cell receptor or T cell receptor to either dampen or enhance the immune response, especially at critical checkpoints

MULTIPLE-CHOICE QUESTIONS

1. The mechanism that generates the greatest diversity in immunoglobulins (Igs) is:
   A. Combinatorial V(D)J rearrangement
   B. Combinatorial H and L chain association
   C. N nucleotide addition
   D. Somatic hypermutation (SHM)
   E. Class-switch recombination (CSR)

2. The mechanism that generates the greatest diversity in T-cell receptors (TCRs) is:
   A. Combinatorial V(D)J rearrangement
   B. Combinatorial H and L chain association
   C. N-nucleotide addition
   D. SHM
   E. CSR

3. Signal transduction through the B-cell receptor (BCR) is inhibited by:
   A. CD3ζ
   B. CD19
   C. CD21
   D. CD22
   E. CD81

4. Signal transduction through the TCR is enhanced by:
   A. FcγRII
   B. CD28
   C. Cytotoxic T lymphocyte antigen-4 (CTLA-4)
   D. Programmed death 1 (PD-1)
   E. CD79a

The Major Histocompatibility Complex

Dimitrios S. Monos, Robert J. Winchester

A primary objective of the immune system is to protect our bodies against pathogens. The major histocompatibility complex (MHC) comprises a genomic region that has evolved to include many genes responsible for coordinating the immune response. It is named the *histocompatibility complex* because it was first identified as the site of numerous genes that determined whether transplanted tissue would be accepted or rejected. We now know that this region coordinates immunological functions far beyond those related to histocompatibility. The MHC region includes genes that determine both innate and adaptive immunities and thus influences responses to pathogens (viruses, bacteria, fungi, and parasites), transplantation, autoimmunity, cancer biology, vaccinations, responses to drugs, and possibly other functionalities presently unknown. This chapter describes some aspects of the genomic organization of the MHC region and its immunological importance, focusing primarily on the human leukocyte antigen (HLA) genes and their encoded molecules. These HLA molecules play a central role in adaptive immunity. They serve as the structures that present self and foreign peptides to T cells (Chapter 6). They also participate in aspects of innate immunity by interacting with receptors on the surface of natural killer (NK) cells (Chapter 17). The terms HLA and MHC are often used interchangeably. However, in this chapter, "MHC" is reserved for the broader genomic region, and "HLA" is used to indicate the genes and their respective encoded protein products in humans.

CLINICAL RELEVANCE

- HLA molecules regulate antigen-specific immune responses by binding pathogen-derived peptides and then presenting them to either CD4 or CD8 T cells.
  - CD4 T cells activated by MHC class II peptide complexes can stimulate B cells to produce antigen-specific antibodies.
  - CD8 T cells activated by MHC class I peptide complexes become cytotoxic and can kill the cells that present the pathogen-derived peptides.
- Certain HLA alleles are the major genetic determinants of susceptibility to many autoimmune diseases or drug hypersensitivity reactions.
  - The process involves a combination of self peptides or small molecules (drugs) bound to specific HLA alleles and then recognized by T-cell receptors.
- HLA molecules play a key role in governing transplant rejection and appear to regulate placental development in pregnancy.
- Cancerous cells modify expression of their HLA genes to avoid recognition by the immune response.

GENOMIC ORGANIZATION OF THE MHC

The human MHC region includes approximately 3.8 million base pairs (Mbps) of DNA on the short arm of chromosome 6 (6p21.3) and is defined as the region spanning from the gamma-aminobutyric acid receptor (*GABBR1*) gene on the telomeric side of the region to the kinesin family member C1 (*KIFC1*) gene toward the centromere (ENSEMBL 86 GRCh38.p7 coordinates chr6: 29555629-33409924).[1] More recent work has suggested that the functional MHC region may include additional downstream and upstream sequences totaling seven or more Mbps.

The classic 3.8Mbp MHC region is among the most gene-dense segments of the human genome. It includes 158 protein-coding genes and 86 pseudogenes of unknown functionality (ENSEMBL 86 GRCh38.p7).[2] At least 65 (41%) of the coding genes are involved in innate and adaptive immunities.[2] The MHC is one of the most studied regions of the genome because it includes the genes that encode the highly polymorphic HLA proteins, which play a pivotal role in immune recognition. The MHC is divided into three regions: class I, class II, and class III (Fig. 5.1). The class I region is at the telomeric end and includes the classic HLA class I genes (*HLA-A, HLA-B,* and *HLA-C*), the class I–related (like) genes (*MICA, MICB*), the nonclassic HLA class I genes (*HLA-E, HLA-F,* and *HLA-G*), and four pseudogenes (*HLA-H, HLA-K, HLA-J,* and *HLA-L*). The class II region occupies the centromeric end and contains the *DRA* and *DRB1* genes and, depending on the DR haplotype, one or none of the *DRB3, DRB4, DRB5* genes that code for the DR, DR52, DR53, or DR51 molecules, respectively; the *DQA1* and *DQB1* genes that encode the DQ molecule; and the *DPA1* and *DPB1* genes that encode the DP molecule. It also includes the *DM* and *DO* genes encoding the antigen-processing molecules DM and DO involved in the class II antigen presentation pathway (Chapter 6), as well as the *TAP* and *LMP* genes encoding proteins involved in the classic class I antigen presentation pathway (Chapter 6). The class III region, interposed between class I and II regions, is a very gene-dense region and contains many immune and non-immune related genes, including those encoding some complement components, lymphotoxin α and β, tumor necrosis factor (TNF), heat shock proteins (HSPs), *NFKB, NOTCH4,* and 21-hydroxylase (*CYP21*). The genes within the HLA class I and class II regions demonstrate the sequence and structural homology that marks evolution through mechanisms of gene conversion, gene duplications, insertions, deletions, and subsequent mutations, resulting in divergence of function. Although the genomic organization of class I and class II genes is quite distinct, the

FIG 5.1 Gene Map of the Extended Major Histocompatibility Complex (MHC) Complex. The core of the MHC complex consists of three major regions: class I, class III, and class II. The extended regions of the complex fare denoted as extended class I and extended class II. Sequence numbering begins at the telomere. The map depicts immune-related expressed genes as well as certain reference genes. The approximate locations of these selected genes near the start or end of the regions are indicated. [Modified from Beck S, Trowsdale J. The human major histocompatibility complex: lessons from the DNA sequence. Annu Rev Genomics Hum Genet 2000; 1:117–37.]

structures of the derived molecules have a striking resemblance that presents a unique example of convergent evolution, perhaps driven by the shared role of these molecules in presenting peptide to the T-cell receptor (TCR).

Another unique characteristic of the MHC is the extensive linkage disequilibrium (LD) observed among the very distant genomic regions of *HLA-A, HLA-B, HLA-C, HLA-DR,* and *HLA-DQ* genes, but not the *HLA-DP* gene. LD is the phenomenon whereby particular alleles of gene loci on the same strand of DNA are inherited together more often that would be expected by chance. Anthropological population studies have suggested that the particular combinations of alleles of the different genes, as distant as they may be, provide a survival advantage, perhaps reflecting functional interdependence in antigen-specific immune responses.

A particular combination of alleles of different loci in LD on the same strand of DNA is called a *haplotype*. The frequency of a given haplotype varies among different populations, reflecting distant selection by pathogens, ethnic admixture, and drastic population reductions (genetic bottlenecks). LD is strongest between *HLA-B* and *HLA-C* and between *HLA-DR* and *HLA-DQ*, most likely because of their physical proximity. However, there is no LD between *DP* and the rest of the haplotype because of a hot spot of recombination between *DQ* and *DP*, even though these two loci are relatively proximal to each other.

The haplotype is the unit of inheritance of the MHC from either parent. Each parent shares one haplotype with each of the children and typically differs from a child by one haplotype. Two siblings may share two, one, or no haplotypes and thus range from being HLA identical, through haploidentical, to HLA disparate. Parents are usually only haploidentical with their children. Exceptions to this rule may occur in inbred populations, where both parents may share an identical HLA allele by descent. The HLA alleles originating from the maternal and paternal haplotypes are both expressed.

Ten years of genome-wide association studies (GWAS) have revealed a large number (884) of single nucleotide polymorphisms (SNPs) within the MHC that are associated with many (479) traits and diseases, establishing the MHC as the only region in the genome with this high density of SNPs that is associated with so many diseases.[3] The complexity of the region, with its many insertions, deletions, duplications, and LD, does not allow for an easy dissection of disease-causing variants. However, recent developments in next-generation sequencing (NGS) of the entire MHC[4] will most likely advance our understanding of the principles underlying this complex genomic organization, how this complexity results in so many biological interdependencies, and how it contributes to the pathophysiology of the diseases associated with the MHC.

STRUCTURE AND FUNCTION OF THE HLA MOLECULES

The main function of both class I and class II HLA molecules is to bind peptides derived from self or nonself antigens and

KEY CONCEPTS

Genomic Organization of the MHC

- The major histocompatibility complex (MHC) is the most complex genomic region in the whole human genome. It is associated with more diseases than any other genomic region of comparable size.
- The class I region contains the polymorphic human leukocyte antigen (*HLA*)*-A, -B,* and *-C* genes; the less polymorphic nonclassic class I *HLA-E, HLA-F,* and *HLA-G* genes; and the class I-related *MICA* and *MICB.*
- The class II region contains the *HLA-DR A* and *B, DQ A* and *B,* and *DP A* and *B* genes. It also contains the *TAP, LMP, DM,* and *DO* genes, which encode molecules that help process antigens into peptides that can bind class I and class II molecules.
- Genes within the MHC demonstrate extensive linkage disequilibrium. A string of alleles of polymorphic MHC genes that commonly exist in linkage disequilibrium within a given population is termed an MHC haplotype.
  - Haplotypes are preserved by means of natural selection, which acts to secure survival advantages for reproductive fitness within a given environment.
  - Common haplotypes within a given population appears to reflect functional interdependencies of the MHC gene alleles.
  - Haplotypes can be different in different populations.
  - The HLA genes of the two chromosomes (haplotypes) are coexpressed.

then traffic to the cell surface, where these peptides can be displayed, or presented, for recognition by the appropriate T cells. Their structure has evolved to satisfy this particular requirement.

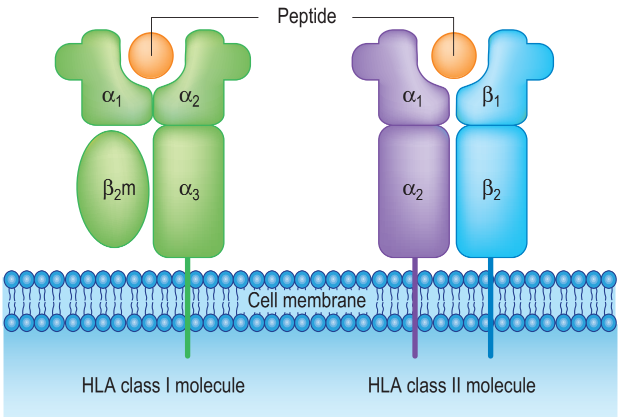

FIG 5.2 Human Leukocyte Antigen (HLA) Class I and II Domain Organization. Although HLA class I and class II proteins have a different chain structure, the organization of their domains is extremely similar. Both class I and II molecules are expressed on the cell surface, where they are accessible to T cells. Both have an outermost domain that contains a cleft where antigenic peptides are displayed. Two of the three class I α domains fold to create a domain with a peptide-binding cleft. The remaining α_3 domain helps support the peptide binding domain and anchors the molecular to the cell membrane. The class I molecule also contains an extrinsic β chain, β_2 microglobulin, which is encoded by a separate, invariant gene. β_2 microglobulin associates with the α_3 domain to support the antigen-binding domain created by the α_1 and α_2 domains. Class II molecules share a similar overall structure but are the product of two genes of variable sequence, each of which contains one α and one β domain.

Classic HLA Class I Molecules

The classic HLA-A, HLA-B, and HLA-C class I molecules consist of an α and a β chains. The α chain masses 45 kilodalton (kDa) and is 362-366 amino acids long. It is encoded by the respective class I genes within the MHC. The β chain, β_2 microglobulin (12 kDa), is encoded by its respective gene on chromosome 15. The α chain has three ≈90 amino acid extracellular domains encoded by exons 2, 3, and 4, respectively, a transmembrane segment (≈ 25 amino acids) encoded by exon 5 and a C-terminal cytoplasmic end (≈30 amino acids) encoded by exons 6 and 7. β_2 microglobulin, which is invariant, comprises the fourth domain (Fig. 5.2). The first two α domains (α_1 and α_2) are the most distal to the cell membrane. They combine to form a domain with a peptide-binding groove, or cleft, that is flanked by a surface that interacts with a TCR or a NK cell killer immunoglobulin-like receptor (KIR). The ends of the peptide-binding cleft are closed and fix the peptide's orientation. The sides of the peptide-binding cleft are composed of α helices, and the floor is composed of symmetric strands of β pleated sheet (Fig. 5.3). The α_3 domain and β_2 microglobulin are both members of the immunoglobulin superfamily (IgSF). Together they create a structure that supports the peptide-binding domain and, with the transmembrane domain of the α chain, attaches the molecule to the cell surface. Class I HLA molecules are ubiquitously expressed in all nucleated cells and in platelets. Expression of class I molecules is significantly reduced on red blood cells (RBCs) and absent on sperm cells.

HLA class I molecules bind peptides derived from the processed proteins of a pathogen or other self/nonself peptides (Chapter 6). These peptides average nine amino acids in length. Two or more of the amino acid side chains are used to anchor the peptide to pockets on the surface of the HLA class I molecule, with the NH_2 terminus to the "left" of the HLA-binding groove (see Fig. 5.3). Individual HLA class I alleles are generally distinguished by their own distinct pattern of peptide binding, as illustrated for selected HLA-B molecules in Table 5.1.[5] Among class I molecules, one or a few amino acid changes may considerably alter the binding properties of a binding pocket. In a healthy nonendocytosing cell, HLA molecules are filled with a variety of peptides from self molecules. The bound peptides are selected according to the binding motif of the particular allele. Even during viral infection or upon pathogen phagocytosis, the number of nonself peptides may not be high. Together, the MHC class I and its peptide create a complex ligand that serves as the target of the TCR on the T-cell surface. The expression of class I molecules is upregulated by the interferons (IFNs) IFN-α, IFN-β, and IFN-γ, granulocyte macrophage–colony-stimulating factor (GM-CSF) and certain other cytokines (Chapter 9). Class I expression is governed by a regulatory element that is located ≈160 nucleotides upstream from the initiation site of the class I gene. This site binds a number of regulatory factors, including those induced by IFNs.

Intact HLA-A, HLA-B, or HLA-C molecules are also ligands for KIR (Chapter 17).[6,7] KIR genes are located on chromosome 19. Their independent segregation from HLA genes located on chromosome 6 produces a wide diversity in the number and type of inherited HLA–KIR combinations. These combinations eventually influence immune competency and adaptability. KIRs do not interact with the whole top area of the HLA molecule that is normally recognized by the TCR. Instead, they interact with one end of the top of the molecule. All HLA-C alleles are

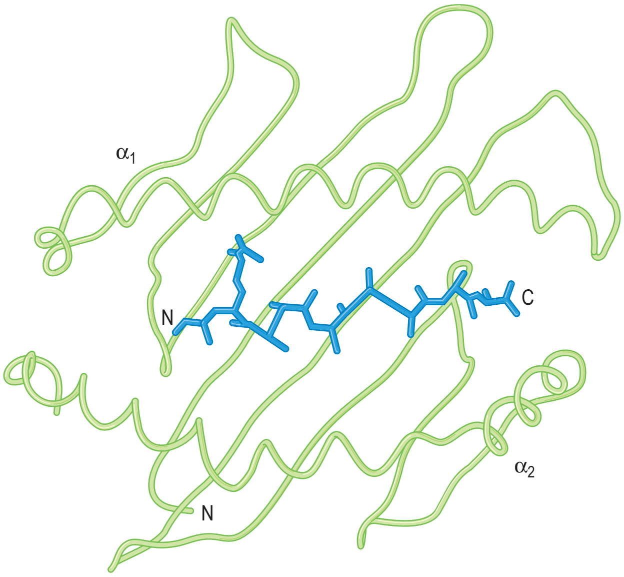

FIG 5.3 **The Three-Dimensional Structure of Human Leukocyte Antigen (HLA)-B27.** The α-helical margins of the peptide-binding cleft contain the bound peptide RRIKAITLK, which is oriented with its amino terminus to the left. There are extensive contacts at the ends of the cleft between peptide main-chain atoms and conserved HLA side chains. The peptide amino and carboxyl termini are tethered to the cleft by hydrogen bonds and charge interactions. The peptide reciprocally stabilizes the three-dimensional fold of HLA-B27. The positively charged side chain of arginine in the P2 position of the peptide inserts into the B pocket, which contains a complementary negatively charged glutamic acid at its base. The resulting salt bridge is the dominant anchor for the peptide. Side chains P4, P6, and P8 make minor contributions to the interaction of the peptide with the HLA-B27 molecule. The central region of the peptide is left free to interact with a T-cell receptor. [Modified from Madden DR, Gorga JC, Strominger JL, Wiley DC. The three-dimensional structure of HLA-B27 at 2.1 A resolution suggests a general mechanism for tight peptide binding to MHC. Cell 1992;70:1035.]

able to interact with their C1 (lysine) or C2 (asparagine) epitope (position 80 of HLA β chain). However, not all HLA-A and HLA-B alleles interact with KIRs. Only the few HLA-As and some HLA-B alleles that carry the Bw4 epitope can do so.

Upon interacting with their HLA ligands, the inhibitory KIR dampens NK-cell reactivity. In the presence of normal class I expression, NK cells will be inhibited from killing and the cell can function normally. However, if a cell loses classic class I expression, the NK cells are then controlled by their activating receptors that interact with their ligands (largely unknown) and perform their cell-killing function. This makes for a complicated dance involving both inhibitory and activating signals.

MICA and MICB

Within the class I region are *MICA* and *MICB* (HLA class I-related polypeptide sequence A and B). The products of these genes are more distantly related members of the class I family that neither associate with β_2 microglobulins nor bind peptides.[8] These molecules are expressed as “danger signals” by virus-infected or otherwise stressed cells. MICA and MICB are ligands for the activating NKG2D molecule (*KLRK1*), another member of the killer cell lectin-like receptor complex,[9] and appear on memory-effector T cells or NK cells, providing a signal to help activate their effector cytolytic response.

Single-letter amino acid codes are used. X denotes any amino acid; R, arginine; K, lysine; Y, tyrosine; L, leucine; P, proline, etc.

Nonclassic HLA-E, HLA-F, and HLA-G

The HLA nonclassic molecules E, F, and G are less polymorphic and have different functions and more limited tissue distribution compared with their classic HLA class I counterparts.[10]

HLA-E primarily presents self peptides to the TCR of CD8 T cells. The diversity of these self peptides is limited and includes the leader peptide of classic HLA class I molecules. The binding of HLA-E to inhibitory receptors, such as CD94/NKG2A, is an important part of the surveillance mechanism for missing self. In tumor cells, loss of class I expression results in a survival advantage for the particular tumor cell. In the absence of class I expression, HLA-E molecules will no longer be able to form a complex with the intracellular leader peptides of class I. As a result, HLA-E molecules are not expressed on the cell surface, and the inhibitory signals to the NK cells are removed. This licenses NK cells to kill the tumor target. Thus by selectively expressing self peptides derived from classic HLA class I molecules (leader sequences), HLA-E has evolved to be at the interface of innate and adaptive immunities.

HLA-F has a small binding cleft that does not contain peptide, and its functions are not well understood. It has limited polymorphism. It mainly resides intracellularly and rarely reaches the cell surface.

HLA-G has limited tissue distribution and is primarily expressed by placental trophoblast cells, the thymus, the cornea, and some erythroid and endothelial precursor cells. HLA-G has a peptide groove, binds a nonamer peptide, and is recognized as an MHC–peptide complex ligand by the leukocyte Ig-like inhibitory receptors (LIR-1 and LIR-2) and KIR receptors. In melanoma, HLA-G expression can be used by the tumor cells to avoid immunosurveillance by flooding the local microenvironment with soluble HLA-G and compromising the function of immune cells. The expression of HLA-G in chorionic villi suggests a role in the maintenance of pregnancy. The mechanism appears to involve production of soluble forms of HLA-G. They appear to have an inhibitory role on the immune cells of the mother. Uniquely among HLA molecules, HLA-G exists in different isoforms. Of these, four are expressed on the cell membrane, and three others exist as soluble forms. The functional significance of these isoforms is not known.

Classic Class II HLA Molecules

Classic class II HLA molecules are selectively expressed in cells of the immune system, similar to B cells, activated T cells, macrophages, dendritic cells (DCs), and activated T cells. The overall structure of class II HLA molecules is very similar to that of class I HLA molecules. The HLA class II molecules are also heterodimers that consist of two transmembrane glycoprotein α (34 kDa) and β (29 kDa) chains. Unlike class I, however, both the α and β chains are encoded by genes within the MHC. Each of the two chains is composed of two extracellular domains. *DR, DQ,* or *DP A1* include α_1 and α_2 domains that are encoded by exons 2 and 3 of the gene. *DR, DQ,* or *DP B1* include β_1 and β_2 domains that are encoded by exons 2 and 3 of the gene. The α_1 and β_1 domains form the binding groove of the class II HLA molecule and are highly variable. The single exception is the α_1 domain of DR, which not polymorphic. The α_2 and β_2 domains proximal to the membrane are members of the IgSF and have limited polymorphisms (see Fig. 5.2). Unlike class I, where the peptide-binding domain is encoded by α_1 and α_2 domains in the same gene, trans-arrangement of α and β chains derived from the two different haplotypes of the same or even different isotypes permit combinatorial polymorphism in class II.

Although the structure of the peptide-binding cleft in class II is homologous to that of class I, there are several distinct differences that have major functional consequences. Among the most important of these differences are those in length and cleft structure. The majority of peptides interacting with class II molecules have a length of >13 amino acids, whereas class I prefers peptides of nine amino acids. This is permitted in class II because, unlike class I, the binding cleft is open at the ends and the ends of the peptide can extend on both sides of the HLA molecule.

The peptide is bound to the class II molecule through the side chains of the peptide amino acids, which interact with five different polymorphic pockets within the cleft. Loading of the HLA class II molecules with peptides takes place primarily within the endosomes, where the HLA molecule interacts with endocytosed and phagocytosed extracellular antigens (Chapter 6). To prevent binding of intracellular peptides in the class II pocket, it first interacts with a protein called *invariant chain* (Ii) while the MHC molecule traffics through the endoplasmic reticulum (ER). The invariant chain is a trimer, and each of its subunits binds noncovalently with an HLA class II molecule. The MHC–invariant chain complex also interacts with another chaperone protein called *calnexin*. Upon release of calnexin, the class II molecule moves either directly into the late endosomal MHC class II compartment (MIIC) or is cycled to the cell surface, where it is then internalized into the MIIC. Once in the endosomal environment, invariant chain is degraded by proteases, including cathepsin S and L. It then leaves a fragment of peptide known as the class II–associated invariant chain peptide (CLIP). Upon dissociation of the CLIP peptide from the class II binding cleft within the endosome, the relevant exogenous peptide is associated with the class II molecule, as assisted by HLA-DM, prior to transport of the stable HLA class II–peptide complex to the cell surface.

Nonclassic HLA-DM and HLA-DO

The nonpolymorphic nonclassic class II molecules HLA-DM and HLA-DO are exclusively expressed in endosomes, and they regulate peptide binding to the classic HLA class II molecules. HLA-DM, a peptide editor, plays a central role in peptide loading of MHC class II molecules.[11] HLA-DO interacts with HLA-DM, but its expression is more restricted.

Proteosome Elements Within the Class II Region

The products of four genes in the class II region are involved with processing and loading peptides onto class I molecules (see Fig. 5.1). PSMB8 and PSMB9 are proteasome subunits generating peptides from the breaking down of proteins. TAP1 and TAP2 transport the peptides from the cytoplasm to the ER. The presence of these genes, which are related to the functioning of HLA class I molecules, in the midst of genes encoding the HLA class II molecules, is probably the reason we observe strong LD within the MHC. It appears that allelic forms of genes in the class I region require the presence of allelic forms in the class II region, indicating functional interdependencies developed throughout the evolutionary process and therefore the need for being transmitted together from generation to generation.

Principles of Peptide Presentation

The mechanism by which HLA class I and class II molecules present peptides became clear when the structures of these two molecules were determined. A simplified diagram of the domain structure of MHC class I and class II proteins is depicted in Fig. 5.2. A more intricate ribbon structure of the actual class I molecule interacting with the TCR is presented in Chapter 4. For both class I and class II, the peptide-binding structure takes the shape of a β pleated floor with two α helix walls. The peptide lies within the groove created by these structures (see Fig. 5.3; Fig. 5.4).

Each HLA molecule, whether class I or class II, binds a single peptide; but the same HLA molecule has a significant degree of promiscuity and can bind thousands of different peptides. Each of the binding grooves is composed of individual polymorphic pockets that dictate the binding of different peptides. Although the mode of TCR docking on HLA molecules is globally conserved, the shapes and chemical properties of the interacting surfaces found in these complexes are so diverse that no fixed pattern of contact has been recognized even between conserved TCR residues and conserved side chains of the HLA α helices.[12] Indeed, of the amino acid side chains not bound to the HLA, only two or three are typically bound to the clonotypic TCR. This limited contact yields considerable TCR plasticity, which has the important evolutionary implication of freeing the HLA molecule and the peptide–HLA complex from the strict stereochemical constraints that are usually imposed in receptor–ligand interactions. The consequence of TCR plasticity and this unusual receptor–ligand interaction has been the evolutionary development of a uniquely large number of different genes that encode various HLA structures, each of which is able to bind and present a different range of peptides to the same clonotypic TCR.

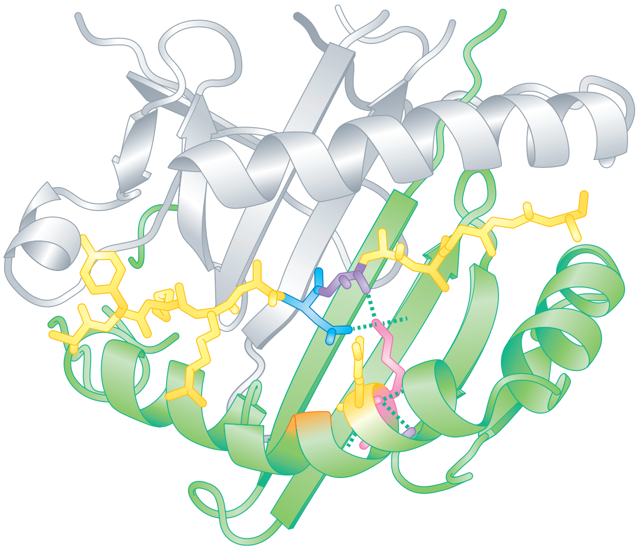

FIG 5.4 Structure of a Human Leukocyte Antigen (HLA) Class–II Peptide Complex. The structure was prepared using PyMol from published coordinates. The HLA molecule is largely shown as a ribbon, while the peptide is a stick diagram. The peptide-binding groove is delimited by α helices. The upper helix is encoded by the α chain, and the lower helix by the β chain. β pleated sheets form the saddle-like floor. Side chains are depicted on the β chain at positions 70 and 71, a region involved in specifying the side chain pocket P4. This pocket binds the fourth side chain of the peptide contained within the HLA molecule. The side chains shown are respectively glutamine and lysine, which form part of the "shared epitope" structure associated with susceptibility to rheumatoid arthritis. The lysine is shown forming hydrogen bonds with the peptide antigen.

KEY CONCEPTS

Structure of the Human Leukocyte Antigen (HLA) Molecules

- HLA class I molecules are involved in both innate and adaptive immunity.
  - For innate immunity, natural killer (NK) cell functions are influenced by the binding of killer immunoglobulin-like receptor (KIR) to class I genes.
  - For adaptive immunity, they enable T cells to identify antigenic peptides.
- Class I and class II HLA molecules have similar structures that enable them to bind peptides and present them to T-cell receptors (TCRs).
- Peptide binding to the HLA molecule is influenced by allele-specific pockets within the binding cleft of the HLA molecule, which interact with the amino acid side chains of the peptide antigen.
  - The HLA–peptide complex is recognized by the TCR.

Selection by Self Peptides in the Thymus

Peptides derived from external antigens, including pathogens, are typically absent during the formation of the T-cell repertoire in the thymus (Chapter 8). Thus self peptide–HLA complexes are used as surrogates for selecting, or training, individual T cells to recognize nonself pathogen peptides.[13] For T cells, "immunological self" is the set of self peptides and self MHC molecules that select the TCR repertoire in the thymus. This process of selection occurs primarily in two steps. The first step is a positive selection process, whereby only those cells with TCRs interacting with the self peptide–HLA complex survive. T cells with receptors that do not recognize any self peptide–HLA complex are eliminated. The second step is a negative selection process, whereby among the selected T cells with self recognition, those with high affinity interactions with the self peptides–HLA complex are eliminated allowing the rest with lower affinity interactions to survive and be released in the periphery. These self peptides constitute the T-cell recognition component of an individual's adaptive immune system. This patterning of TCR recognition on self peptides presented by self MHC molecules is critical to the development of autoimmunity and allorecognition.

Evolutionary Considerations Driving the Separate Functions of Class I and Class II

One basic task of the T cell is to protect the body from two major types of pathogens: *viruses,* which would commandeer the replicative machinery of a cell, and *bacteria,* which replicate autonomously and often extracellularly. These two types of pathogens present very different challenges to the immune system. To terminate viral infection, a cell harboring a virus has to be killed by a cytotoxic CD8 T cell, whereas a bacterium can be eliminated by being phagocytized by a macrophage that has been selectively activated by a CD4 T helper (Th) cell. The need to determine whether the presence of a pathogen peptide should elicit a killer-cell response or a Th-cell response is presumed to be the evolutionary drive that resulted in the creation of two specialized forms of HLA molecules, class I and class II (see Fig. 5.2).[12,14]

The specialized antigen processing and presentation intracellular machinery used to load class I molecules offers a means for the cell to reflect at the cell surface the molecular profile of antigens within the cell. This allows class I to sample for the presence of an intracellular viral infection. Recognition of the HLA class I–peptide complex is through the TCR of a CD8 T cell, which primarily reacts to the detection of an inappropriate intracellular antigen (*i.e.,* a virus) by cytotoxic activity. Class II peptide loading occurs in coordination with phagocytosis and lysosomes. Class II thus offers a means by which the immune system can be informed of the presence of extracellular antigens, such as bacteria. The recognition of the HLA class II–peptide complex is through the TCR of a CD4 T cell, which leads to the activation of Th cells and then to activation of an immune response.

Among the evolutionary strategies used for viral survival, some virally encoded genes decrease the expression of the HLA class I surveillance system, which would otherwise alert the immune system to the presence of an infected cell (Chapters 17 and 25).[15] This attempt to escape surveillance by downregulation of HLA class I is countered by the extensive interaction of class I molecules with various NK receptors expressed on NK cells or T-cell subsets. These interactions provide a mechanism for detecting decreases in HLA class I expression, which is termed recognition of "missing self."[16] There are two principal types of NK receptor used to detect missing self, members of the IgSF, such as KIRs, which bind directly to intact class I MHC molecules, and members of the C-type lectin family, such as CD94/NKG2C, which recognize the leader of class I molecules that selectively binds to HLA-E molecules. Considering that NK cells are cellular components of the innate immune response, this means that HLA class I molecules play a role in both adaptive and innate immune responses.

KEY CONCEPTS

Function of the Human Leukocyte Antigen (HLA) Molecules

- The HLA molecule is a receptor that binds a peptide. The peptide–HLA complex is a ligand that binds to the clonotypic T-cell receptor (TCR). The trimolecular Peptide–HLA–TCR complex triggers the activation and proliferation of the T cell in an adaptive immune response.
  - HLA class I A, B, and C molecules are expressed on the surface of virtually all nucleated cells.
  - HLA class II DQ, DR, and DP molecules are constitutively expressed on B cells, professional antigen-presenting cells (APCs), thymic epithelial cells, and activated T cells.
- The *immunological self* is the set of self peptides and self HLA molecules that select the TCR repertoire in the thymus and that constitute the T-cell recognition component of an individual's adaptive immune system.
- Nonself peptide–HLA complexes are recognized by T cells during an adaptive immune response, and they become activated to either initiate an immune response (CD4 helper T cells) or recognize a target (CD8 cytotoxic T cells).
- Through thymic selection, the TCR can adapt to recognize a very large variety of peptide–HLA structures.
  - Because of the plasticity of this recognition, genes encoding the HLA molecules are free to evolve a large number of genes encoding duplicated or alternative peptide-presenting molecules with specificity to bind different peptides.
  - The diversification of peptide-presenting structures fosters the development of different T-cell repertoires with completely different recognition properties. This thwarts the possibility that a pathogen will be able to evolve a way to bypass recognition.

GENERATION AND SELECTION OF POLYMORPHISMS: BIOLOGICAL CONSEQUENCES

The hallmark of the classic HLA molecules, both class I and class II, is their extensive polymorphism. HLA polymorphism observed in different human populations is far greater than any other polymorphism observed in any other part of the human genome. This is a direct reflection of their role in the immune response. Pathogens characterized by different proteins and peptides, either in different epidemics or endemic to regions, account for much of the evolutionary drive responsible for the large number of alternative gene forms and their regional diversity across the human race. An individual with an adaptive immune system based on HLA molecules that effectively bind peptides derived from common pathogens is much more likely to have an effective response against that common pathogen. This results in selection of individuals with a particular allele, encoded by an HLA gene.

Genetic polymorphism implies that alleles of a gene are present at a frequency greater than expected from random mutation as a result of selection for diversity. In the case of the HLA genes, there is no preponderant wild-type allele, which would be an example of *balancing selection.* Instead, virtually all alleles qualify as genetically polymorphic. These reflect prior successful selection events. HLA polymorphisms provide a major evolutionary survival benefit, since they equip the species with a large number of very specific, but alternative, HLA molecules that differ in their binding pockets, are most efficient in presenting different peptides, and selecting different T-cell repertoires. A polymorphism that offers survival advantage would eventually increase in frequency. This illustrates *frequency-dependent selection,* where the fitness of individuals bearing a particular allele increases, if they can manage an effective immune response to the particular pathogen. Moreover, selection also operates on the pathogen, encouraging peptide variation. Variation in peptides drawn from common pathogens and the introduction of novel pathogens with novel peptides result in pressure on the species to create variation in HLA molecules among individual members of that species. The remarkably different frequency of the HLA alleles in different ethnic subsets tells the history of the successful adaptation of our ancestors' adaptive immune systems to a new environment with different pathogens, as well as bottlenecks resulting from migration and perhaps survival during periods of massive epidemics.

The evolutionary consequence of the diversification of genes encoding HLA molecules is seen at two levels. The first is at the level of the *individual* and is characterized by the presence of different HLA class I and class II loci, each of which codes for one or two different peptide-presenting HLA molecules for each locus. The second is at the level of the *population* and is evidenced by the development of a very large number of alleles at each locus, with each allele coding for alternative polymorphic gene forms and thus for various peptide-presenting allotypes, each of which has the potential to bind a different set of peptides. Duplication of HLA genes involved in peptide presentation is a genetic strategy that increases the range of peptide-presenting structures available to the individual, thus enhancing the variety of presented peptides that can be recognized and bound.[8]

KEY CONCEPTS

The Biological Significance of Polymorphisms: Why so Many?

- Human leukocyte antigen (HLA) class I and class II genes are extremely polymorphic.
  - Each HLA allele encodes molecules with different peptide-binding properties that influence the particular peptides recognized by the T cells.
  - The sequence of the HLA gene thereby determines the peptide recognition features of the adaptive immune response.
- HLA allelic polymorphisms are maintained by frequency-dependent selection, where the fitness of an individual bearing a novel allele increases because it can respond more effectively to certain pathogens.
- The multiple loci and numerous alleles per locus serve both the fitness of an individual and the survival of the species.
  - The polymorphism of the HLA system reflects the environmental/pathogen challenges to which a particular population has been exposed over evolutionary time.

HLAS IN INFECTIONS, TRANSPLANTATION, AUTOIMMUNITY, AND CANCER

HLA in Infections

The first line of defense during infection by a pathogen is the triggering of innate immunity (Chapter 3). The infectious agent and the foreign peptides generated from that agent then initiate an immune response involving immune cells and signals that subsequently induce adaptive immunity.

During the course of an infection, specialized antigen-presenting cells (APCs; DCs and macrophages) are activated to take up antigen. Increasing synthesis of class II coupled with presentation of and pathogen's peptides by class II to the immune system of the host drives CD4 T cells that recognize the HLA class II–peptide complex and become activated. This event triggers adaptive immunity. Eventually CD8 T cells recognize target cells infected with the pathogen by interacting with the HLA class I–peptide complex on their cell surface and the targets are eliminated, thus containing the infection (Chapter 6).

In response, pathogens have evolved mechanisms to overcome the specific attack by the host's immune cells. The first of these mechanisms is "antigenic drift" or "antigen shift," whereby the pathogen, through minor (drift) or more substantive changes (shift), evades both humoral and cellular responses. These changes make the pathogen unrecognizable, as some of these new peptides do not form recognizable complexes with the HLA molecules of the host and therefore evade the T-cell responses. Another mechanism frequently adopted by viruses is to persist *in vivo* by not replicating until the immunity of the host is compromised. By not replicating, they avoid detection and exist in a dormant state (latency). It therefore becomes evident that the infectivity of a microorganism reflects the interplay between several complex processes. These include the ability of the pathogen to create new molecular forms unrecognizable by the host and thus evade detection. These efforts by the pathogen to avoid immunity are then counterbalanced by molecular polymorphisms between HLA molecules that enable recognition of new molecular forms of the pathogen.[17]

HLA in Transplantation

The large number of different HLA alleles greatly reduces the probability that two unrelated individuals will inherit an identical set of HLA alleles. Two basic mechanisms of responses in transplantation have been described. The first involves the "direct" recognition of the peptide–HLA complex of the donor tissue by the T cells of the recipient. This is possibly through structural similarities of the HLA molecules of the donor that allow the TCR of the recipient to interact with the peptide–HLA complex. The second involves the "indirect" presentation of donor's HLA antigens processed by the recipient's APCs, generating peptides presented by the recipient's HLA molecules to the recipient's T cells. This indirect mechanism operates the same way as the presentation of a foreign antigen, whereby the HLA molecule is now the foreign antigen processed by the antigen-processing mechanisms of the recipient.

By using appropriate immunosuppressive agents and therapies, T-cell activation by the donor's HLA molecules after clinical transplant can be controlled (Chapter 81). However, the major long-term problem is the presence of donor-specific antibodies that develop against mismatched HLA antigens. Controlling the antibody responses to mismatched HLA molecules has been very challenging, and there is a need for continuous monitoring of their development. An approach holding some promise for the future is the utilization of regulatory T cells (Tregs), which have important immunoregulatory role in all immune responses and can possibly induce transplant-specific tolerance (Chapter 18).

HLA in Autoimmunity

Selection on the self peptide presented by self HLA allotypes in the thymus can predispose to autoimmunity because the T-cell portion of the adaptive immune system is entirely selected on the self peptide. The inherent autoreactivity of the T-cell system can thus set the stage for the development of autoimmune diseases associated with the recognition of particular self peptides, or peptides from external antigens that mimic these self peptides and are effectively presented by self HLA.[18] Certain alleles encode HLA molecules that bind peptides from molecules expressed in sites favoring autoimmune recognition by T cells. These molecules become the target of the adaptive immune response. Together, features specific to certain sets of self peptides and to certain self HLA molecules can contribute to the progressive development of autoimmunity and, ultimately, autoimmune disease (Chapter 50).

HLA in Cancer

Immune evasion is a critical process in tumor biology. It is enabled by several mechanisms that include immune editing, downregulation of HLA expression, secretion of immunosuppressive mediators, and expression of proteins that modulate immune checkpoints. Most recently, somatic mutation of HLA genes was revealed to be a significantly frequent process in some tumor types. The strategies of immune evasion by cancer cells also include the silencing or aberrant expression of HLA class I and class II molecules, events that have often been associated with high-grade malignancy and metastatic potential in a variety of human cancers.[19]

In patients with solid tumors, HLA-G can contribute to a tumor-escape mechanism that favors cancer progression, and blocking strategies have been proposed to counteract it. Conversely, HLA-G can inhibit proliferation of malignant B cells as a result of the interaction between HLA-G and its receptor ILT2, which mediates negative signaling on B-cell proliferation. Thus treatment of some malignancies can benefit by blocking HLA-G, whereas in others HLA-G induction can counteract tumor progression.[20]

The concept of developing cancer-specific immunotherapies involving tumor-specific antigens presented by HLA molecules to T cells has been successfully tested in a number of tumors (Chapter 77), including testicular cancer and melanoma. These T-cell immunotherapies require adoptive transfer of T cells that have been expanded *ex vivo* and transferred back to the patient. Another approach is the use of retroviral vectors to transfer tumor-specific TCR genes into the patient's T cells before reinfusion.[21] Even though HLA molecules are involved in these processes, histocompatibility testing is not necessary in these therapies because the original T cells are derived from the patient. However, if the mechanism of immunotherapy involves neoantigens (epitopes of mutated proteins) from tumors presented by specific HLA alleles, such individualized therapy needs to take HLA alleles into account.

HLA AND DISEASE ASSOCIATIONS

Over the last several decades, a large number of studies have established strong associations between certain diseases and individuals carrying particular HLA alleles. In spite of extensive study, the mechanisms underlying HLA–disease associations remain unclear.

Hypotheses generated to explain these associations can be grouped into two general categories. The first category invokes linkage disequilibrium between a particular HLA allele that is associated with a given disease and another neighboring genomic element on the haplotype that is actually causative of the disease and does not involve HLA molecules directly. This can occur because the genes within the MHC are in extensive LD among themselves. Examples of this type of associations include hereditary hemochromatosis, where an apparent association with HLA-A alleles results from mutations in a nonclassic HLA class I gene,

KEY CONCEPTS

Human Leukocyte Antigen (HLA) in Infections, Transplantation, Autoimmunity, and Cancer

- HLA and infections by pathogens is an interplay of balancing acts, whereby the pathogens try to avoid the immune response and HLA alleles adapt to secure a robust immune response.
- Transplantation is an artificial system, and the transplant is perceived by the immune response to be a foreign element.
  - Induction of tolerance is the objective.
  - For the host to tolerate the graft, physicians attempt to engender immune nonresponsiveness to the transplant by manipulating the immune response pharmacologically.
  - The presence of donor-specific antibodies is a major problem in the field of transplantation because these antibodies are primarily responsible for chronic rejection reactions we observe.
- There are three features of the adaptive immune system that can set the stage for pathogenic autoimmunity.
  - First, the individual's adaptive immune system is determined by the set of self peptides and self HLA molecules that select the T-cell receptor (TCR) repertoire.
  - Second, the drive to genetic polymorphism that generates many different alternative forms of peptide-binding HLA molecules influences patterns of self and nonself reactivity.
  - Third, certain HLA allotypes bind particular self peptides from critical target antigenic molecules that can predispose to autoimmune responses and disease.
- Oncogenesis is associated with the modification of patterns of antigen presentation by the cancerous cells to immune cells and by modification of immune cell responses to the cancerous cells.
  - This enables the cancer to avoid immune surveillance and detection by the immune response.

HFE, which is in LD with *HLA-A*; and congenital adrenal hyperplasia resulting from an allele of the gene *CYP 21B,* which causes 21-hydroxylase deficiency and is located within the class III region of the MHC and thus in LD with *HLA-B*.

A second category implicates antigen presentation by the HLA allele. This category deals with diseases that have a strong immunological component. It has been hypothesized that inappropriate immune reactivity to some self antigens can reflect aberrant T-cell repertoire selection, immune cross-reactivity with foreign antigens, immune attack of "altered self" antigens, or differences in the expression levels of certain HLA alleles that secondarily influence the course of infections or cancer. The MHC cusp theory represents another hypothesis. In this case, the MHC codes for allele-specific ligands in the cusp region of the molecule, which interact with non-MHC receptors and activate various pathways. Aberrations in these pathways could cause MHC-associated diseases. According to this hypothesis, the cusp region has a peculiar three-dimensional shape that has been preserved on both class I and class II molecules through evolution, not dependent on antigen presentation, and is a hub for signal transduction ligands that interact with a variety of receptors and activate important biological functions. The MHC cusp theory posits that HLA molecules promote disease because of their auxiliary allele-specific, yet antigen presentation–independent, biological effect.[22]

Although many of these associations lie within the highly polymorphic HLA genes,[1] GWAS using SNP markers have established that not only HLA genes but also the MHC region as a whole harbors many SNPs associated with a large number of traits or diseases. Indeed, up to 90% of autoimmune disease variants have been located within the noncoding regions of the genome.[23] It is therefore possible that disease association elements may not only lie within the HLA genes but also be dispersed within the rest of the MHC. One possible genomic element that can be located within the noncoding regions of the MHC and yet have a significant regulatory role is microRNA (miRNA). A search for functional genomic elements within the noncoding regions of the MHC genes revealed 12 miRNAs, including hsa-miR-6891 (miR-6891), which is encoded by intron 4 of HLA-B.[24] Thus some, and perhaps many, diseases associated with specific MHC elements, whether HLA alleles or not, may involve noncoding RNAs (miRNAs or long noncoding RNAs) with important biological functions of a regulatory nature.

Below is a compilation of selected diseases with strong HLA allele associations in different populations. A more extensive list of diseases and reference materials can be found in other works.[25-27]

Ankylosing Spondylitis

One of the more extraordinary observations in the MHC field was made in 1973 when the frequency of HLA specificity HLA-B27 was found to be 95% in those with the disease ankylosing spondylitis (AS) (Chapter 57). This impressive observation implicated HLA-B*27 in the pathogenesis of AS and propelled the field of HLA and disease associations.[28] Different B27 alleles have different strengths of association with the disease, making genetic testing useful over and above serological testing. Even though the association of AS to B27 is among the strongest genetic associations with a common disease, the mechanism of action remains uncertain. AS has been hypothesized to be triggered by exposure to a common environmental pathogen. HLA-B*27:02 and B*27:05 demonstrate the highest degree of association. AS is characterized by arthritis affecting the spine and the pelvis. Twin studies have confirmed that susceptibility to AS is genetically determined. Family studies suggest that <50% of the overall genetic risk is caused by HLA-B27. HLA-B27 is found in 8–10% of the population, with only a minority of carriers progressing to development of the disease. It is likely that other genes, both within and outside the MHC, are involved. A number of GWAS have demonstrated that non-HLA genes are also associated with AS. These include the interleukin-23 receptor (IL-23R) and the protein-cleaving enzyme ER aminopeptidase 1 (ERAP1).

B27 testing can be an instructive component of the diagnostic work up of AS. Because of the chronic nature of the disease and its gradual debilitating nature, the value of B27 testing is that a presumptive diagnosis allows institution of treatment early in the disease when patients may have minimal symptoms.

Narcolepsy

Narcolepsy is a long-term neurological disorder characterized by irresistible daytime sleep attacks. People with narcolepsy suffer from episodes in which they fall asleep unexpectedly during the day. These "sleep attacks" can occur at any time and during any activity. Narcolepsy affects approximately 1 in 2000 people. Often those affected have low levels of the neurotransmitter *hypocretin* (also known as *orexin*). Hypocretin is a neuropeptide hormone that is responsible for controlling appetite and sleep patterns. Even though the cause of narcolepsy is unknown, the disease is believed to be of autoimmune nature.

Family studies have shown that genetic heritability plays a role in narcolepsy. However, twin studies show that only 25–30% of twins are concordant for the disease, again implicating environmental or other epigenetic events. The HLA-DQB1*06:02 allele on the DRB1*15:01–DQA1*01:02–DQB1*06:02 haplotype has been shown to be one of the most important predisposing genetic factors, with 85–95% of patients with narcolepsy carrying this haplotype.[29] Conversely DQB1*05:01 and DQB1*06:01 have a protective effect. The protective associations of these two DQB1 alleles with narcolepsy may provide an insight to the molecular mechanisms for the differential associations of DQB1*06:01 and DQB1*06:02, as the size of P4 pocket of DQB1*06:02 is larger than the DQB1*06:01. This difference possibly influences the binding of larger residues in the DQB1*06:02 allele, which may explain the opposite effect these two alleles have on narcolepsy. Homozygosity for HLA-DQB1*06:02 increases the risk for narcolepsy compared with heterozygosity, as does heterozygosity for HLA-DQB1*03:01/DQB1*06:02.

HLA testing for DQB1*06:02 in narcolepsy is a useful aid to diagnosis. However, as instructive as the association may be, it is not specific as there are many patients with narcolepsy without HLA-DQB1*06:02 and many individuals with HLA-DQB1*06:02 who do not have narcolepsy.

Type 1 Diabetes

Type 1 diabetes (T1D) is also known as *insulin-dependent diabetes mellitus* (IDDM; Chapter 71). This is a disease in which the body fails to maintain normal glucose levels because of the destruction of insulin-producing pancreatic islet cells. The disease is characterized by infiltration of immune cells (CD4 and CD8 T cells) into the islets of the pancreas and by autoantibody production. When >90% of an individual's β cells are destroyed, clinical symptoms ensue.

Twin studies have shown that the concordance rate for the disease is 30–50%. This suggests that other factors, including environmental triggers (*e.g.,* diet and viral infections) and epigenetic changes, may be involved. The major heritable risk of T1D comes from the HLA system (about 50%). More than 90% of Caucasian patients with T1D carry the haplotypes DRB1*03:01, DQA1*05:01, DQB1*02:01 or DRB1*04:01, DQA1*03:01, DQB1*03:02. Patients heterozygous for these haplotypes carry a greater susceptibility risk. The critical residues are thought to be position 52 on the DQα chain and position 57 on the DQβ chain. The presence of arginine of 52 at DQα and the absence of aspartate at DQβ are strongly associated with T1D. Conversely, in Caucasian populations, resistance to T1D is conferred by DQA1*01:02, DQB1*06:02. Besides the contribution of the HLA, GWAS have identified a number of other genomic regions associated with the development of T1D.[30]

HLA typing is useful as an aid to diagnosis of T1D. Considering that the islet destruction by the autoimmune processes is progressive, associated with the presence of autoantibodies, HLA typing of siblings of patients with T1D may be useful information in assessing risk for the nonsymptomatic siblings.

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is a chronic disease characterized by inflammation of the synovial lined joints leading to joint deformation and disabilities (Chapter 52). The presence of autoantibodies, such as rheumatoid factor and anticitrullinated protein antibodies (ACPAs), are largely responsible for the classification of RA as an autoimmune disease. It is a multifactorial disease that involves both environmental and genetic factors. RA in the general population has a prevalence of <1%. Studies with monozygotic twins show a 12–15% concordance rate for the disease, underlying both genetic heritability, but also other factors, such as environmental triggers or epigenetic components. Multiple genetic loci have been shown to contribute to the risk of developing RA. Of these, the HLA class II DRB1 is the most important and contributes 30–50% of the overall genetic susceptibility risk.

The HLA DRB1 alleles associated with RA share common sequences at positions 70–74 of the β chain.[31,32] This has led to the shared epitope hypothesis. Amino acids in these positions influence both peptide binding and contact between the HLA and the TCR. HLA-DRB1 alleles associated with RA have any of the following sequences: QKRAA, QRRAA, RKRAA, and RRRAA. In Fig. 5.4, the yellow-colored residue in the α-helical ribbon is glutamine, and the magenta residue is positively charged lysine. Hydrogen bonding to two side chains of the peptide is shown. The region around position 70 is involved in the formation of a peptide side chain–binding pocket that binds the fourth amino acid side chain contained within the HLA molecule. The presence of a negatively charged residue at position 71 or 74 removes susceptibility for RA. The presence of two alleles of this group increases susceptibility and favors development of more severe disease.[33]

In addition to the MHC, GWAS have led to the identification of over 100 loci associated with RA. Among these is the protein tyrosine phosphatase, nonreceptor type-22 (*PTPN22*) gene, which codes for an inhibitor of T-cell activation. The majority of these additional loci are expression quantitative trait loci (eQTLs), in which genetic variants regulate the level of transcription.

Multiple Sclerosis

Multiple sclerosis (MS) is a complex neurodegenerative disease in which myelin sheath degradation is caused by the immune system (Chapter 66). On the basis of family and twin studies, the disease has been shown to have a large genetic component. HLA-DRB1*15:01, DQA1*01:02, DQB1*06:02 is a disease susceptibility haplotype and accounts for up to 35% of the risk for developing the disease. The primary association is with the DRB1 locus, and homozygosity is associated with increased risk. A number of GWAS have identified more than 100 additional candidate genomic regions conferring risk, including cell adhesion, leukocyte activation, apoptosis, Janus kinase (JAK)–signal transducer and activator of transcription (STAT) signaling, nuclear factor (NF)-κB activation, and T-cell activation and proliferation.[34] The exact mechanism by which HLA genes increase susceptibility to MS is as yet unknown. Although HLA typing is not of any diagnostic value for MS, genetic testing is still of value in providing insights into the mechanism of the disease.

Celiac Disease

Celiac disease (CD) is an autoimmune disorder of the small intestine caused by a combination of genetic and environmental factors (Chapter 75). The disease is characterized by diarrhea and weight loss, among other symptoms. The strong genetic component has been confirmed with monozygotic twins demonstrating 90% concordance.[35] A significant portion of the genetic predisposition (about 40% of genetic risk) comes from HLA genes. GWAS also implicate additional genomic regions. The disease-triggering environmental factor comes from a component of wheat gluten, the protein gliadin (family of closely related proline- and glutamine-rich proteins). CD is a lifelong condition, with the only effective treatment being a gluten-free diet.

The implicated HLA molecules are the class II antigens DQ2 and DQ8. The DQ2 molecule mostly associated with CD is encoded by the HLA-DQA1*05:01–DQB1*02:01 alleles, with a small proportion encoded by the DQA1*02:01–DQB1*02:02 genotype. The DQ8 molecule associated with CD is DQA1*03–DQB1*03:02. Approximately 90% of patients with CD express the HLA-DQ2 molecules, with the remaining 10% mostly expressing the HLA-DQ8 molecule. Deaminated by transglutaminase, negatively charged gluten peptides bind strongly to HLA-DQ2 and -DQ8 to present an HLA–gluten peptide complex that activates CD4 T cells. The immune response also includes the development of antibodies against gluten and autoantibodies to endogenous tissue transglutaminase.

Genetic testing for HLA-DQ as a complement to histology can help confirm the diagnosis in patients not known to be positive for tissue transglutaminase antibody.

DRUG HYPERSENSITIVITY AND PHARMACOGENOMICS

Severe cutaneous adverse reactions to drugs include syndromes, such as Stevens-Johnson syndrome/toxic epidermal necrolysis and drug reaction with eosinophilia and systemic symptoms or drug-induced hypersensitivity syndrome[36] (Chapter 48). Although their incidence is very low, they are severe, life-threatening adverse drug reactions with mortality rates as high as 5–12.5%. The associations reported between drug hypersensitivity and specific HLA alleles has been a recent finding and has led to the possibility that hypersensitivity reactions may be predictable and preventable. Drugs associated with immunologically mediated drug-induced hypersensitivity include the anticonvulsant carbamazepine and the antiretroviral agents nevirapine and abacavir. Regulatory agencies, such as the US Food and Drug Administration (FDA), have issued relevant and informative pharmacogenomics guidelines: (http://www.fda.gov/Drugs/ScienceResearch/ResearchAreas/Pharmacogenetics/ucm083378.htm).

Carbamazepine

Carbamazepine is an aromatic amine anticonvulsant, used for the treatment of epilepsy and other seizure disorders, trigeminal neuralgia, and bipolar disorder. Approximately 10% of patients develop mild cutaneous adverse reactions. Carbamazepine has been shown to be associated with the HLA class I allele HLA-B*15:02 or A*31:01.

Nevirapine

Nevirapine is a nonnucleoside reverse transcriptase inhibitor, widely prescribed for human immunodeficiency virus 1 (HIV-1) infection. Hypersensitivity HLA class I and II associations have been described for DRB1*01:01, B*35:05, Cw8, and B*14:02.

Abacavir

Abacavir belongs to the family of nucleoside reverse transcriptase inhibitors and is used for the treatment of HIV-1 infection. Two recent abacavir studies have shown that 100% of patients who develop abacavir drug hypersensitivity carry the HLA-B*57:01 allele. This predictive value supports the use of HLA-B*57:01 typing of patients prior to initiating treatment with abacavir, even though not all of HLA-B57:01-positive patients develop hypersensitivity.

KEY CONCEPTS

Human Leukocyte Antigen (HLA) and Disease Associations

- HLA molecules are associated with many diseases.
  - HLA alleles frequently confer a higher risk for a number of immune related diseases than other genomic factors.
  - Most associations reflect situations where the HLA molecules are directly involved in the disease process.
  - Some associations reflect linkage disequilibrium with other non-HLA genes that are directly involved and responsible for the disease phenotype.
  - In some cases, the HLA molecule, the associated peptide, and the T-cell receptor (TCR) are sufficient for the development of disease.
  - In others, the HLA molecule may be necessary, but not sufficient for the development of the disease.
- Twin studies have demonstrated that genetics is not the only component of many of HLA-associated diseases and that environmental of metagenomic modifications are also likely involved in the disease process.

METHODS OF DETECTING HLA POLYMORPHISMS: HLA TYPING

Since the discovery of the HLA genes over 50 years ago, there has been a concerted effort to properly categorize and characterize these very polymorphic genes. Our understanding of the complexity and polymorphic nature of the HLA genes has been substantially improved as the technologies for characterizing these genes have improved (Fig. 5.5).

Initial serological and cellular testing in the 1960s (antibody and mixed lymphocyte culture [MLC]), supplemented by two-dimensional electrophoresis and restriction fragment length polymorphism (RFLP) analysis in the 1970s to the 1980s, made us aware of the high degree of polymorphism that was not properly revealed by the technologies used earlier. The development of the polymerase chain reaction (PCR) in the mid-1980s revolutionized our understanding of these genes at the molecular level. From PCR, methods utilizing sequence-specific oligonucleotide probes (SSOPs, or SSO) and sequence-specific primers (SSPs) provided the means for more directly evaluating the highly variable sequence motifs within the HLA genes. Subsequently, Sanger sequence-based typing (SBT) in the 1990s significantly advanced tissue typing and transplantation genetics by providing an unprecedented molecular view of HLA polymorphism in the context of exonic variation. Most recently, NGS appears to have revolutionized the field by addressing the HLA typing complexity in a very definitive way. NGS provides entire HLA gene characterization and haploid sequence determination.[37]

To meet the growing demand, clinical HLA typing over the past decade has transitioned from a combination of serological and DNA-based methods to more direct, faster, more affordable, and more informative DNA-based techniques. Even though serological typing may continue to have some clinical or research-based testing in determining the expression of the HLA molecule at the cell surface (a function that DNA-based testing cannot always verify), direct DNA-based typing techniques have all but replaced serological methods in routine HLA typing.

DNA-Based Typing Techniques: SSO, SSP, and SBT

The techniques primarily in use today in clinical immunogenetics laboratories are SSO, SSP, and SBT. The genomic regions analyzed

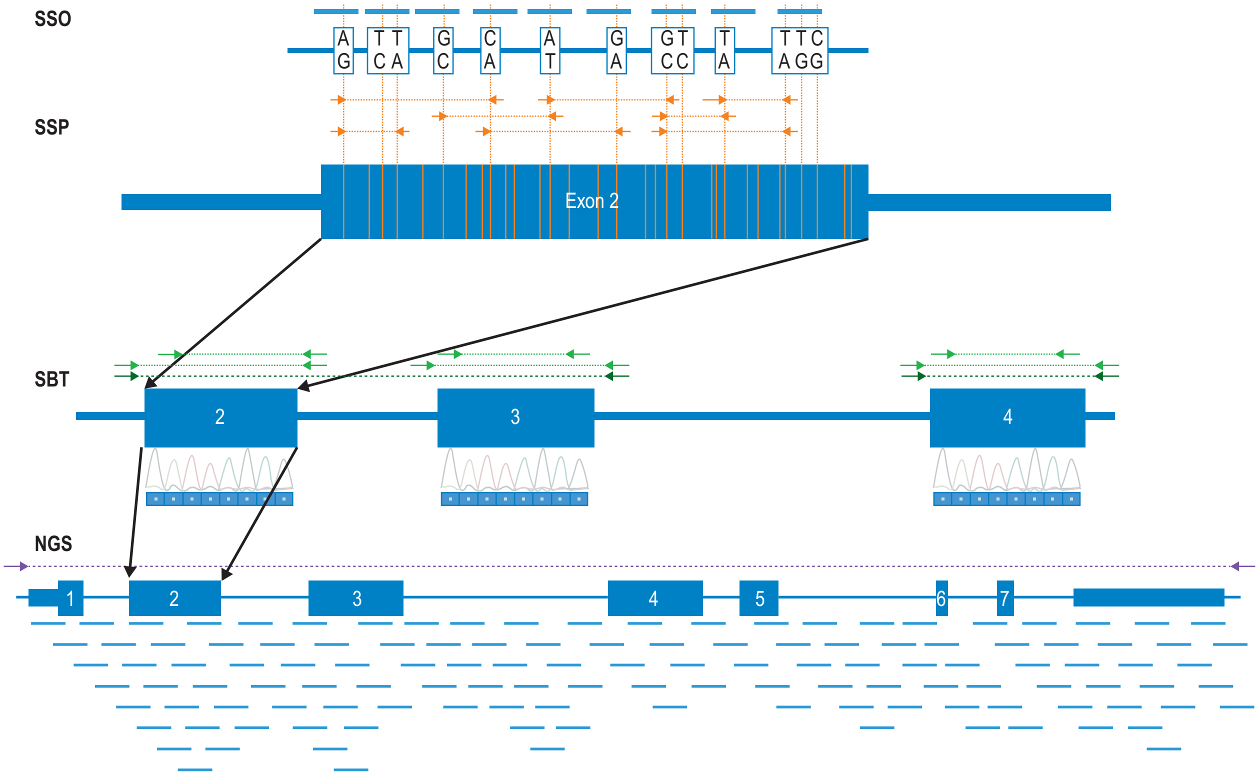

FIG 5.5 **Examples of Molecular Human Leukocyte Antigen (HLA) Typing Techniques and Their Methods of Interrogating the HLA Genes.** For any given HLA gene (dark blue rectangles), SSOs of ≈20 bp (light blue lines) can provide single-nucleotide resolution of haplotype differences (polymorphic differences, red lines in exon 2). This requires a complex panel of oligonucleotide probes to discern differences between HLA alleles. This probe set is static and therefore cannot adjust to novel alleles. SSPs (orange arrows) can provide haplotype-specific or allele-specific resolution of nucleotide differences and additionally provide some level of phasing between polymorphic sites. As with SSOs, these oligonucleotide sets are complex and static, limiting their flexibility. SBT provides whole-exon information on the polymorphic content of the HLA allele (amplification primers [dark green] and sequencing primers [light green arrows]) but cannot discern phasing, as this method generally does not rely on allele-specific primers for amplification as a first step. Next-generation sequencing (NGS) provides whole-gene amplification (amplification primers, purple arrows) and detection of polymorphic content for any HLA allele (known or unknown) and provides significant phasing between polymorphic sites that are within the read lengths of the system being used (usually between 200 and 1000 bp). This is accomplished through the alignment of thousands of short overlapping reads that are combined to form a single consensus sequence (blue lines).

are usually exon 2 and 3 of class I and exon 2 of class II genes. However, this rather limited genomic characterization generates many typing ambiguities.

SSO interrogates polymorphic differences using panels of individual DNA oligo probes that differentially hybridize to the target of interest. The probe either perfectly matches or mismatches the target's polymorphic sites. The hybridization pattern of the oligos is compared with an expected pattern, based on the sequence database of HLA alleles, and is interpreted as an HLA type.

SSP uses panels of specific primer sets that overlap polymorphic sites. Perfectly matched primers produce an amplification product, whereas mismatched primers do not. The pattern of amplification from multiple primer sets determines the HLA allele.

In **SBT**, specific gene regions, usually exons, are amplified and sequenced through a process of polymerase-based extension of specific-sequencing primers using fluorescently labeled nucleotides, indicating allelic differences base by base. Whether SSO, SSP, or SBT; the genomic regions analyzed are usually exon 2 and 3 of class I and exon 2 of class II genes. The result of this rather limited genomic characterization is the generation of many typing ambiguities.

Next-Generation Sequencing

Protocols utilizing NGS technology are on the rise because they provide the means for the complete characterization of these genes and the elimination of ambiguities in a cost-effective manner.[38] Regardless of the platform (Illumina MiSeq; ThermoFischer Ion Torrent; Pacific Biosciences, Oxford Nanopore), these systems resolve a number of technological barriers and limitations that continue to hamper existing molecular techniques, such as inflexibility in typing practices, discovery of novel alleles, and the inability to easily resolve phase ambiguities. Although

HLA typing by NGS has been introduced only recently, it is likely that this new method will transform the way HLA typing is performed in the coming years.

KEY CONCEPTS

The Resolution of the Human Leukocyte Antigen (HLA) Typing Problem

- Currently HLA typing is performed primarily through DNA-based methodologies.
- It appears that the dominant methodology will soon be the single molecule DNA sequencing (next-generation sequencing [NSG]) and most likely with platforms sequencing the length of the whole gene, whether class I or class II.

HLA NOMENCLATURE

The HLA genes/alleles are very polymorphic (about 15,000 have been named, and close to 30,000 sequence entries have not been named yet), and their numbers are expected to further increase, approaching hundreds of thousands, possibly millions. This has led to the development of comprehensive systems for their naming.

The WHO Nomenclature Committee for factors of the HLA system undertook the first systematic approach for the naming of HLA alleles in 1968. The HLA naming convention has undergone a substantial number of iterations because the earlier naming conventions were unable to address the growing numbers and complexity of alleles (*i.e.,* A*02 and B*15 have more than 100 alleles). The most recent nomenclature was introduced in 2010 to address the growing numbers of new alleles being discovered and to reduce naming complexity and confusion. The changes added colons (:) into the allele names to act as delimiters of the separate fields (field separator). Thus each HLA allele name has a unique number corresponding to up to four sets of digits separated by colons.

The first field following the asterisk in the allele name (XX:xx:xx:xx) describes the allele family and generally corresponds to the serological assignment carried by the allele. HLA typing defined only at the first field is often referred to as "low-resolution typing." The second field following the first colon (xx:XX:xx:xx) is assigned sequentially as new alleles are determined (*e.g.,* 01, 02, 03….101, etc.). Together, these two fields (XX:XX) indicate one or more nucleotide substitutions that change the HLA protein coding sequence and are often referred to as "high-resolution typing." Indeed, the Harmonization of Histocompatibility Typing Terms Working Group recently defined a high-resolution typing result "as a set of alleles that encode the same protein sequence for the region of the HLA molecule called the antigen-binding site and that exclude alleles that are not expressed as cell-surface proteins."[39] The third field (xx:xx:XX:xx) is for designating synonymous nucleotide substitutions within the coding sequence that do not change the amino acids of the protein, and the fourth field (xx:xx:xx:XX) identifies sequence polymorphisms in introns, or in the 5' and 3' untranslated regions (Fig. 5.6).

All alleles receive a name that includes at least the first two fields. At the end of the allele name, specific characters have been added (N = null; L = low expression; S = secreted; C = cytoplasm; A = aberrant; Q = questionable) to designate unique characteristics for an allele, such as whether a protein is not expressed (*i.e.,* HLA-A*24:09N) or whether the expression of the protein is unclear (*i.e.,* HLA-A*32:11Q).[40] For ambiguous allele strings, the codes "P" and "G" were introduced. A group of alleles having nucleotide sequences that encode the same protein sequence for the peptide binding domains (exon 2 and 3 for HLA class I and exon 2 only for HLA class II alleles) will be designated by an upper case "P," which follows the two-field allele designation of the lowest-numbered allele in the group. For example, HLA-A*01:01:01:01, HLA-A*01:01:01:03, or HLA-A*01:37 could be named HLA-A*01:01P.

HLA prefix
Gene
Field 1; allele group
Field 2; specific HLA protein
Field 3; used to show a synonymous DNA substitution within the coding region
Field 4; used to show differences in a noncoding region

FIG 5.6 Human Leukocyte Antigen (HLA) Nomenclature. [Courtesy of Steven G. E. Marsh, Anthony Nolan Research Institute, London, United Kingdom.]

A group of alleles that have identical nucleotide sequences across the exons encoding the peptide binding domains (exons 2 and 3 for HLA class I and exon 2 for HLA class II) were named after the first allele in the sequence and given the code "G" as a suffix. The upper case "G" follows the first three fields of the allele designation. For example, HLA-A*01:01:01:01, HLA-A*01:01:01:03, or HLA-A*01:37 could be named HLA-A*01:01:01G. More details regarding HLA nomenclature can be found on the website: http://hla.alleles.org.

To manage and to have access to the sequences of the ever-growing number of alleles, the IMGT/HLA Database project was initiated in 1997 as part of a European collaboration. The database is an invaluable resource, as it provides detailed DNA sequences and protein sequences for all known HLA alleles. It is also interactive and incorporates tools for data retrieval and analysis so that the user can select what segments of the gene/molecule to examine and make comparisons among different alleles. It can also be used for new data submission.

ON THE HORIZON

- Advanced technologies for the sequencing and detailed characterization of human leukocyte antigens (HLAs) and of the whole major histocompatibility complex (MHC) should allow a clearer elucidation of the functional interrelationships of the different genes within the MHC and the genomic elements responsible for many MHC-associated diseases.
- Computational approaches for the accurate definition of peptide-binding properties of individual HLA alleles, whether class I or class II, will influence our ability to control the tri-molecular complex of HLA–peptide–TCR and therefore control some processes, such as responses to infectious diseases, autoimmunity, transplantation, vaccine design, and cancer.
- Immunotherapies for cancer involving neoantigens will require individualized approaches when HLA alleles play a critical role.
- Understanding the genomic organization of the MHC, the most complex genomic region in the human genome, will most likely reveal and teach us important lessons relevant to the organization and operation of the rest of the genome as well.

FUTURE LEARNING AND RESOURCES

This chapter provides only a limited sketch of this fascinating, but complex, topic. The reader is referred to the *HLA Facts Book* for a more detailed and very accessible presentation, although slightly out of date. There are also a number of websites with extremely useful information. Four stand out in terms of their utility and the curated quality of the information. *(i)* The IMGT/HLA Database contains all MHC sequences and has a variety of sequence alignments of different alleles as well as specialized sequence searches (http://www.ebi.ac.uk/imgt/hla/index.html and http://hla.alleles.org). *(ii)* The NCBI maintains dbMHC, which includes several components of the international histocompatibility working group (IHWG) that are of interest. Among these is the anthropology database, which contains HLA class I and class II allele and haplotype frequencies in various human populations (http://www.ncbi.nlm.nih.gov/projects/mhc/). *(iii)* Information about the genes and the genetic organization of the MHC is contained in several sites, but perhaps the most comprehensive and comprehensible is that using the Entrez search engine (http://www.ncbi.nlm.nih.gov). *(iv)* A comprehensive database of MHC ligands and peptide motifs is located at http://www.syfpeithi.de.

Please check your eBook at https://expertconsult.inkling.com/ for self-assessment questions. See inside cover for registration details.

MULTIPLE-CHOICE QUESTIONS

1. Genome-wide association studies (GWAS) reveal a large number of single nucleotide polymorphisms (SNPs) within the MHC to be associated with many diseases. This finding could have resulted from:
   - **A.** Extensive linkage disequilibrium within the major histocompatibility complex (MHC)
   - **B.** Numerous genomic elements within the MHC may contribute independently to different diseases
   - **C.** Many genes work together for certain physiological functionalities, and in particular diseases there may be multiple loci affected simultaneously
   - **D.** All of the above

2. Human leukocyte antigen (HLA) genes are very polymorphic because:
   - **A.** They need to interact with a wide range of environmental and intracellular molecular entities to which they elicit an appropriate immune response.
   - **B.** They need to interact with the T-cell receptor (TCR), which is also polymorphic.
   - **C.** It is necessary for thymic selection.
   - **D.** Through evolution they have mutated, but their functionality is not affected.
   - **E.** All of the above.

3. Single-molecule DNA sequencing or next-generation sequencing (NSG) is the right technology for the characterization of the HLA polymorphisms because:
   - **A.** It allows the cost-efficient and complete sequencing of the HLA genes
   - **B.** It provides sequencing of haploid DNA (single DNA molecule), and by doing so the polymorphisms are on phase
   - **C.** Eliminates essentially all ambiguities generated when other legacy methods are used
   - **D.** All of the above
   - **E.** None of the above

4. The reported associations of diseases with HLAs can result from:
   - **A.** Linkage disequilibrium with another nearby locus that is actually responsible for the disease
   - **B.** The HLA is involved in the disease process directly
   - **C.** The HLA is necessary but not sufficient for the disease
   - **D.** All of the above
   - **E.** None of the above

5. HLA molecules are involved in many immune-related responses and processes; which one(s) are true?
   - **A.** HLA class I genes encode products involved in both innate and adaptive immunity.
   - **B.** HLA class II are involved in adaptive immunity.
   - **C.** HLA class I bind peptides originating primarily from outside the cell.
   - **D.** HLA class II bind peptides anchored with their amino and carboxyl ends in the binding groove of the HLA molecule.
   - **E.** CD8 reacts with the domain proximal to the membrane of a HLA class II β chain.

Overview of T-Cell Recognition: Making Pathogens Visible to the Immune System

Andrea J. Sant

ANTIGENS

Antibodies and T-Cell Receptors Recognize Antigens

By the late nineteenth century, "antibodies" were the hypothesized to be molecular entities that mediated specific immune memory and could neutralize toxins and whose presence resulted in the formation of precipitates when mixed with the molecular species that induced their formation. In almost all cases, evidence for the presence of such antibodies required the prior exposure of responding animals to the very substances (or ones closely related, as in the case of toxoids) with which the antibodies reacted. This *specific* relationship of inducing agent and antibody led to the concept of an *antigen*—the molecular entity that could induce the formation of antibodies specific for it and that could be recovered in the blood of exposed animals. By developing the concept of the specific *receptor,* with a specificity analogous to the lock-and-key model of enzymes, Paul Ehrlich could explain the specificity of antibodies in molecular terms of a reciprocal interaction between a receptor and its binding partner (*ligand*).[1] Thus an "antigen" is any molecule that, in whole or in part, binds specifically to the antigen-binding domain of an "antigen receptor" (antibody or T-cell receptor [TCR]) (Fig. 6.1).

Ehrlich proposed several tantalizing, but unsatisfying, explanations for the other critical property of antigens—that they induce the formation of their own antibodies. This view of antigen is that of the vaccinologist, who wants to induce effective immunity to an organism expressing that antigen, or of a clinician, who is wondering why a patient does or does not respond to a particular allergen, self antigen, or tumor antigen. More than a century later, the explanation for the antigenicity of antigens remains an important and poorly understood issue—why humans fail to respond adequately to some pathogen or tumor antigens and how vaccines can be improved; why humans respond to their own self antigens (autoantigens) or antigens present in tissue grafts (alloantigens); and how autoimmune and tissue graft-related diseases (graft-versus-host disease [GvHD] and graft rejection) can be prevented or treated. The cellular mechanisms governing how and when humans respond to antigens remains at the cutting edges of both laboratory science and clinical medicine and are discussed later in this chapter. At the core of this central issue is the defining feature of the immune system—the distinction between "self" and "nonself." The host must remain tolerant to its own macromolecules and yet have the capacity to respond to its nonself. The molecular components of the immune system, including cells that display TCRs (T cells) and B-cell receptors (BCRs; antibodies expressed by B cells), undergo developmental events that promote self-tolerance—elimination of reactivity to self proteins, leaving cells with the potential to respond to a diverse set of antigens that may be expressed on pathogens or other "foreign"molecules.

Antigens can belong to many different chemical classes and can derive from viral or bacterial proteins, lipids, carbohydrates, or combinations of these, such as lipoproteins or glycoproteins. Antigens can also be small chemical compounds, termed *haptens* (Fig. 6.2), made synthetically in the laboratory, such as nitrophenyl (NP), or be a natural compound introduced into the host, such as urushiol, the toxin found in poison ivy, which becomes modified and antigenic when introduced into the host (Fig. 6.3). Haptens generally require linkage to a larger host protein or foreign protein to become immunogenic.

Innate Receptors Recognize Pathogen-Associated Molecular Patterns or Danger Signal Ligands

As a result of advances in the domain of innate immunity, it has become challenging, but all the more important, to distinguish between antigens and the many ligands for innate immune receptors (Chapter 3). Innate receptor ligands are often described as exhibiting patterns or motifs characteristic of a microbial class or physiological condition and the host proteins that recognize them as "pattern recognition receptors."[2] Many of these innate ligands facilitate the host immune system's recognition of a pathogen. Included in these innate ligands are Toll-like receptors (TLRs), which recognize such ligands as bacterial lipopolysaccharide (endotoxin), or viral single- or double-stranded RNA. Included among the innate activators are cytosolic DNA sensors and nucleotide-binding oligomerization domain (NOD)–like receptors (NLRs), which recognize bacterial wall peptidoglycans and intracellular metabolites induced by cellular damage.

The conceptual difference between antigens and innate receptor ligands lies in the diversity of ligands and the receptors that can engage them. The innate immune response recognizes predictable ligands through binding of a limited set of receptors that recognize these pathogen-derived molecules. The result of this recognition is often a rapid production of cytokines or induction of cell-surface proteins, including host human leukocyte antigen (HLA) proteins and costimulatory proteins that help activate the adaptive immune system. In contrast, the adaptive immune response collectively recognizes a wide variety of antigens through a tremendously diverse, but clonally distributed, set of BCRs and TCRs. The function of the specific antigen receptors in the adaptive immune responses and the cells that bear them is to promote activation and proliferation of the antigen-specific cells, leaving the host with memory B cells or T cells that are in higher abundance and often in a poised state after the first encounter.

FIG 6.1 Hapten, Carriers, and Two Kinds of Antigens. The antigen-binding site of an antibody binds an antigen through the latter's epitope: this is the biochemical sense of antigen used in ELISA, flow-cytometry and western blot analysis. Haptens are self-conjugating antigen moieties that can modify epitopes and provide new binding specificities. Haptens and many antigens by themselves are not immunogens, the second sense of "antigen". Immunogens (complete antigens) are processed by antigen presenting cells to reveal T-cell epitopes presented by MHC molecules. MHC, Major histocompatibility complex.

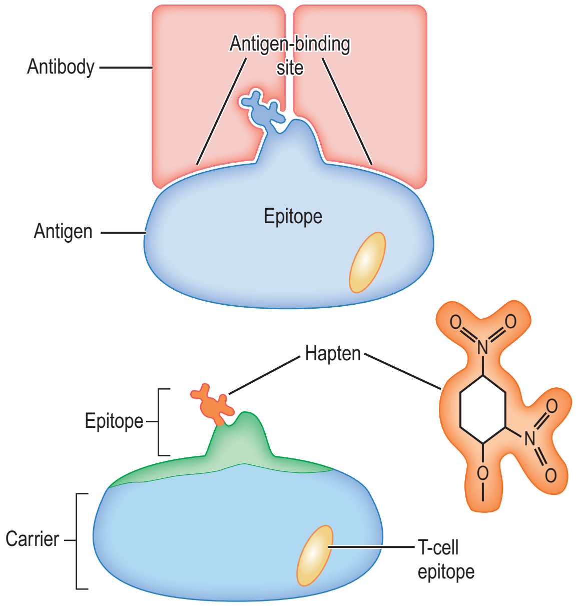

FIG 6.2 Haptens can modify the epitope of the antigen that is recognized by immunoglobulin, while the T-cell epitope remains unchanged.

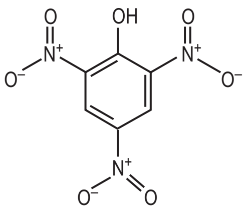
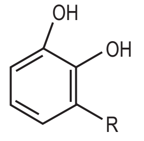
Trinitrophenol (Picric acid)	Urushiol (poison ivy) R=aliphatic chain	Penicillin
		




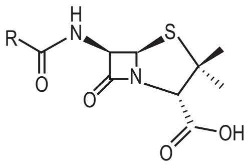


FIG 6.3 Examples of small chemical haptens that can be recognized by antigen specific immunoglobulins in the host, which are produced B cells.

This memory state allows for a more rapid response to a later confrontation with the same or related antigen or pathogen. This is the basis of induced immunological memory, which is the goal of many vaccines.

THE NATURE OF ANTIGEN RECOGNITION BY IMMUNOGLOBULIN AND T-CELL RECEPTOR DIFFERS

The receptors for B cells and T cells share similarities in development, structural organization, and function (Chapter 4). Both are derived from gene rearrangement events during development, and both combine variable and constant regions within their protein structure. Both are heterodimers that can be expressed at the cell surface of their respective lymphocytes and convey signals via partner chains within the transmembrane and intracytoplasmic segments that ultimately promote activation and proliferation of the responding lymphocyte. Despite these similarities, the nature of recognition by B cells and T cells is quite distinct. Immunoglobulins (Igs) tend to recognize solvent-exposed regions on a conformationally intact molecule (*e.g.,* a viral glycoprotein or a bacterial toxin). In contrast, TCRs typically recognize peptide fragments of protein antigens presented by host cell-surface molecules. In the case of TCRαβ, major histocompatibility complex (MHC) class I or II molecules are the presenters and lead to *MHC-restricted recognition* of antigen.

Antigens for B Cells

Vaccines can be used to target toxin binding and neutralization. For example, when ingested, *Vibrio cholerae* produces the secreted cholera toxin (CT) that can cause life-threatening diarrhea.[3,4] Both inactivated or attenuated forms of *V. cholerae* and recombinant forms of the cholera toxin B subunit protein have been used as vaccines. When introduced orally, these vaccines can elicit antibodies that neutralize the activity of the toxin within the gut. In contrast, protective antibodies elicited by viruses and virus-derived vaccines most often act by preventing binding and entry of the virus into host cells. Typically, vaccination strategies for these types of pathogens, such as human immunodeficiency virus (HIV) or influenza virus, employ semipurified or recombinant

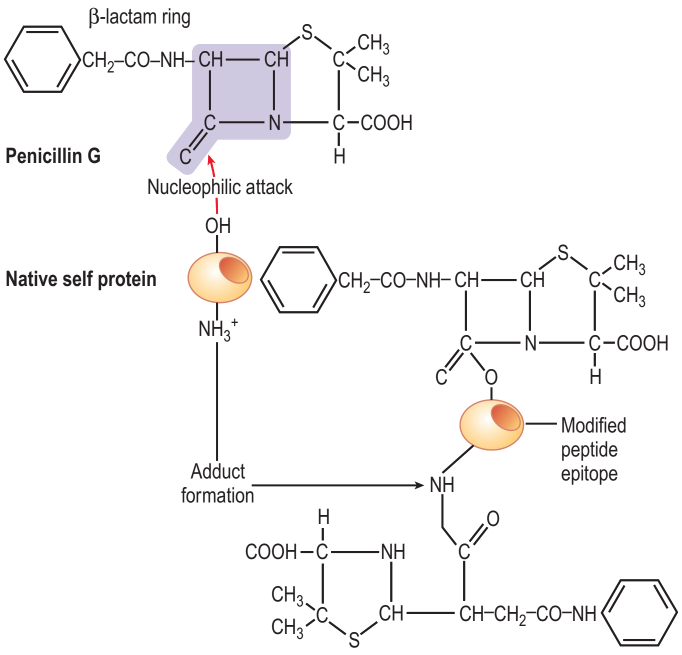

FIG 6.4 Penicillin Creates Neoantigens by Forming Covalent Adducts With Self Proteins. Penicillin allergies involve both antibodies against penicillin and with T-cell responses to penicillin-modified self proteins. The same chemical reaction that allows penicillin to inhibit peptidoglycan formation in bacteria leads to adduct formation of cellular proteins. Nucleophilic attack by penicillin G (upper left) on the β-lactam ring (shaded) opens the ring and creates an adduct (lower left) with serines and lysines. The lactam adducts can be presented to B cells as modified self proteins or processed for presentation by major histocompatibility complex (MHC) molecules to T cells as lactam-conjugated self peptides.

proteins that elicit neutralizing antibodies in the host against surface displayed proteins on the virus.[5-8] Antigens recognized by B cells can also be damaging to the host, as in the case of allergens such as penicillin and the chemical urushiol found in poison ivy (see Fig. 6.4).

KEY CONCEPTS

Antigens for B Cells

- Immunogens contain:
  - Epitopes that bind to the antigen-binding sites of antibodies
  - Class II epitopes for T helper cells
- Haptens can have almost any chemical nature.
- The amino acids that comprise epitopes on native proteins can be scattered throughout the primary sequence, but juxtaposed and found on the surface of the folded molecule.

Coupling of B-Cell and T-Cell Epitopes Permits Highly Focused Adaptive Responses

Encapsulated bacteria often express lipids or carbohydrate moieties on their cell surfaces that can be targeted by vaccines because they can promote pathogen clearance or neutralization. These polysaccharides by themselves are not immunogenic (*e.g.,* able to elicit an immune response) and therefore are often chemically conjugated to a complex protein.[9,10] Coupling promotes T-cell help and thus production of high-affinity antibodies (Fig. 6.1).

Coupling of a pathogen-derived carbohydrate to another foreign protein forms the basis of conjugate vaccines, used to elicit neutralizing antibody responses to bacteria (Chapter 90). Because related bacterial strains can display distinct polysaccharide structures that can be recognized by the B cells in the host (*serotypes*), some conjugate vaccines couple multiple distinct polysaccharides to a single carrier protein. A classic example is Prevnar® 13, which is composed of polysaccharides from 13 different serotypes of *Streptococcus pneumoniae* that are conjugated to a highly immunogenic inactivated diphtheria toxin protein. The conjugate vaccine offers distinct epitopes for the responding B-cell and CD4 T-cell helpers (see Fig. 6.1). The clonally distributed B-cell Ig receptor binds to the polysaccharides, whereas the protein carrier provides peptides to be presented on the surface of the priming dendritic cell (DC) and the antigen-reactive B cell. This allows focused help by the antigen-specific CD4 T cell.

For viral glycoproteins, B cells and CD4 T cells often recognize distinct sites on the same protein, with the B cell focusing on the surface regions of the intact protein structure and the T cell recognizing peptides produced after internalization and degradation.

Superantigens

Superantigens (SAgs) are microbial proteins that have the capacity to bind both class II MHC molecules and the TCR, thereby activating T cells via TCR signaling.[11,12] Included among the SAgs are bacterial toxins derived from *Staphylococcus aureus* and *Streptococcus pyogenes,* some gram-negative bacteria, *Mycoplasma arthritidis,* and *Yersinia pseudotuberculosis*, as well as proteins made by endogenous retroviruses. These SAgs are abbreviated as a three- or four-letter acronym that relates to the organism from which they are derived. These include *S. aureus* enterotoxin A or B ("SEA" or "SEB", respectively), *S. pyogenes* enterotoxin A or C ("SPE-A or SPE-C", respectively), and *Y. pseudotuberculosis* A (YPM-A").

KEY CONCEPTS

Properties of Superantigens

Defining Properties

- Presented and recognized as an unprocessed, native protein
- Contact T-cell receptor (TCR) and major histocompatibility complex (MHC) class II molecules outside the traditional antigen-binding groove

Specific Properties

- Selectively stimulate T cells expressing certain TCR Vβ chains
- TCR recognition not MHC allele-restricted
- Stimulate both CD4 and CD8 T cells in an MHC class II-dependent manner

SAgs bind class II MHC molecules (Chapter 5) on APCs as intact macromolecules. Although most bind outside of the peptide-antigen binding groove[13] some SAgs, such as the *S. aureus* toxic shock protein, can contact the bound peptides. Although class II binding by SAgs is largely independent of allelic polymorphism, it often displays a preference for particular class II isotypes. For example, HLA-DR tends to be preferred over HLA-DP and HLA-DQ in the binding of SAgs to human T cells. Key to the biological activity of SAgs is the ability to dock simultaneously with the HLA class II molecule expressed by APCs and the TCRs expressed by host T cells. TCR recognition of SAgs typically involves a characteristic and large subset of the various TCR Vβ families, since binding occurs outside of the TCR peptide-binding groove. Consequently, the binding of SAgs to class II and TCRs can recruit as many as 20% of the total TCR repertoire, leading to polyclonal activation of T cells. Subsequent production of proinflammatory cytokines by the activated T cells can lead to a profound systemic inflammatory syndrome. Most notable among these is toxic shock syndrome, caused by *S. aureus* (toxic shock syndrome toxin [TSST]) and streptococcal toxic shock syndrome (STSS), caused by *S. pyogenes.* Bacterial SAgs have also been implicated in the pathogenesis of acute rheumatic fever and Kawasaki disease.

ANTIGEN-PRESENTING CELLS

Cells That Present Antigens to B Cells: Follicular Dendritic Cells[14]

In absolute terms, B cells do not need another cell to present antigen to them. They express antigen Ig receptors (BCRs) that can interact with intact proteins expressed by pathogenic organisms or within protein vaccines. Physiologically, B cells typically recognize their antigen as a multivalent array displayed by other cell types.[15] The most potent and sustained B-cell responses involve BCR recognition of antigen in a cellular context in conjunction with provision of cognate CD4 T-cell help (*vide infra*). However, a polyvalent antigen, such as that displayed as highly repetitive structures expressed on encapsulated bacteria, can elicit B-cell antibody responses in the absence of specific T-cell help. These antigens are designated T-independent antigens, or "TI" antigens. Although they do not require specific CD4 T-helper (Th) cells, their responses can be enhanced by cytokines produced by other cell types.

Pathogen or vaccine-encoded proteins that enter the host and access secondary lymphoid tissue (*e.g.,* spleen or lymph nodes) are presented on the surface of specialized cell types via high-affinity binding to cell-surface molecules, such as complement receptors or Ig Fc receptors. Antigens accessing the lymphoid tissue can initially access and be bound via these receptors on subcapsular macrophages. Ultimately antigen accesses follicular dendritic cells (FDCs). FDCs bind opsonized antigen via complement receptors (CR1 and CR2) and thus can display the intact antigen directly to B cells. FDCs can maintain this antigen store throughout the extended course of the immune responses, as Ig affinity maturation takes place within the germinal center. It is thought that binding of opsonized antigen by FDCs leads to recycling of the antigen complex into nondegradative, internal, endosomal compartments. This allows intermittent display of the antigen at the surface as the B-cell Ig receptor repertoire matures into highly selected B cells. These highly selected B cells can differentiate into long-lived memory B cells and into plasma cells that secrete high-affinity antibodies.

Cells That Present Antigens to T Cells

T cells recognize antigen in the form of peptide fragments presented by host MHC proteins, which are termed *H-2* in the mouse and *HLA* in humans (Chapter 5). APCs mediate this process of T-cell recognition. Antigen accesses the draining lymph node or spleen, either directly, by drainage from a peripheral site or after being carried by tissue resident APCs. Peripherally distributed APCs (*e.g.,* DCs) act as sentinels in tissue sites of infection (*e.g.,* skin or lung). Here, DCs pick up and carry pathogen-derived antigens to the draining lymph node, where recognition by and priming of naïve T cells can take place. Resident DCs in the lymph node can also internalize antigen from the lymph drainage or from other antigen-bearing cells. In the secondary lymphoid tissue, there are limited sites in which the contact between circulating naïve T cells and APCs take place. These sites are dictated by cytokines, chemokines, and a network of stromal cells that collectively controls cellular trafficking and localization. In addition to the restrictions imposed by APCs and T cells locating one another, naïve T cells have a high threshold for activation. Active APCs require a high density of antigenic peptide–MHC ligands, and they must express accessory ligands that "costimulate" the T cells that engage their TCR.

The most important type of APCs for priming CD4 and CD8 T cells are DCs that gain access to the antigen and express costimulatory proteins that promote T-cell activation, such as B7 (CD80) and CD40. These costimulatory proteins are upregulated upon encounter with pathogen-derived pattern recognition receptors. After priming, other types of "professional" APCs can be recognized by T-cells, including B cells and macrophages, where delivery of help for antibody responses or pathogen elimination can occur, respectively. For CD4 T cells, T-cell interactions are typically limited to cell types that express MHC class II molecules, which are 0only expressed on a subset of cells. B cells, macrophages, and some epithelial and endothelial cells can express class II molecules, particularly after activation or in inflammatory cytokine milieus. In some experimental systems, more atypical APCs, such as mast cells and basophils, have been found to upregulate class II molecules and thus be targets of CD4 T cell recognition. CD8 T cells can recognize a wide variety of host cells because of the almost ubiquitous expression of MHC class I molecules. Almost all nucleated cells are thus potential targets for CD8 T-cell recognition, a function that is critical for elimination of infected cells at many distal sites by cytolytic CD8 T cells.

MHC-RESTRICTED RECOGNITION OF ANTIGEN

TCR, the antigen-specific receptor on T cells, recognizes a physical complex between host MHC proteins and small peptide fragments derived from protein antigens (Chapter 5). The interaction between the peptide and the MHC is highly specific. Because the genetically polymorphic regions of host MHC proteins are the decisive features in the MHC that determine which peptides are presented, this event is termed *MHC-restricted presentation of antigen* (Fig. 6.5).

Class I MHC

MHC class I proteins consist of a genetically polymorphic MHC-encoded heavy chain and a nonpolymorphic 12-kD light chain (β_2M). MHC class I molecules *present* peptide antigens to CD8 T cells, whose most common protective function is cytolysis of pathogen-infected cells or transformed tumor cells. Each molecule contains a series of pockets, controlled by genetically polymorphic amino acid residues, which allow high-affinity binding of the peptide's side chains. The binding cleft is flanked by hydrogen bonding residues at the periphery of the pocket so that the cleft is *closed* at its end. This peripheral closure of the binding pocket limits the size of peptides that can be bound and presented to CD8 T cells to 8–10 amino acids (Fig. 6.6, Top). Class I molecules are synthesized and expressed on all nucleated cells. Thus the

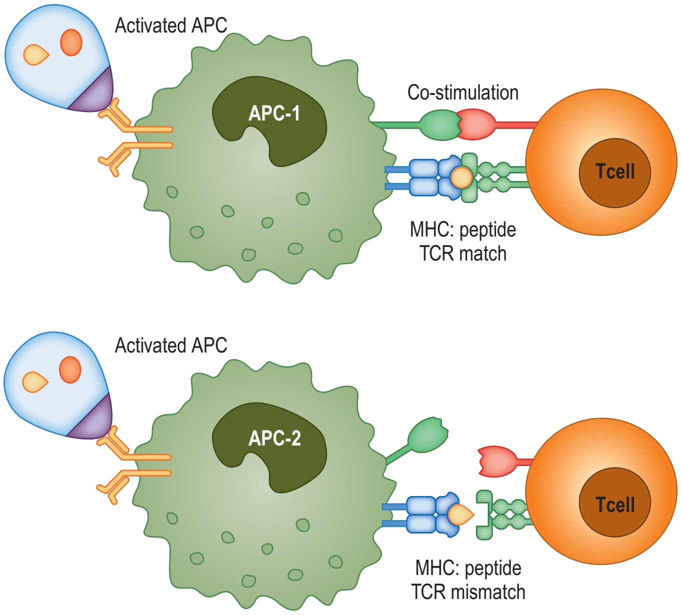

FIG 6.5 Major Histocompatibility Complex (MHC) Restriction Carries Out a Critical Function. Naive T cells (purple) respond to cognate epitopes only when presented in association with an MHC molecule on the surface of an antigen-presenting cell (APC). APCs can be activated by antigen uptake, cytokines, or pathogen-derived molecules, and this makes them more effective at activation T cells. Experimentally observed MHC restriction reflects the need for the APC to bear the correct MHC that matches the T cell (top). In the absence of a matched MHC, the T cell will be unable to respond to the peptide (bottom).

repertoire of presented peptides is widely available throughout the body for scanning by circulating CD8 T cells.

Class II MHC

MHC class II proteins consist of a heterodimer of MHC-encoded, genetically polymorphic α and β chains. Peptide binding is controlled by a series of 4–5 *pockets* into which the amino acid side chain of peptides selectively dock. Allele-dependent amino acid diversity within these pockets permits varied binding of peptide fragments across individuals. Coupled with a network of hydrogen-bonding residues between the main chain of the peptide and the α helices of the MHC class II α and β chains that stretches along the entire binding cleft, the interaction between peptide and MHC class II can be exceptionally stable. The class II binding cleft is open and thus can bind peptides ranging in length from 13 to 20 amino acids (see Fig. 6.6, Bottom).

Class II molecules are expressed on a restricted, but diverse, set of cells that includes B cells, macrophages, monocytes, DCs, and, in humans, activated T cells. Class II–bearing cells can activate CD4 T cells. CD4 Th cells promote expansion of B cells and their production of isotype-switched high-affinity antibodies. Interleukin-2 (IL-2)–secreting CD4 T cells facilitate CD8 T-cell expansion and generation of long-lived CD8 T memory. CD4 T cells can mediate protective immunity through secretion of cytokines, such as interferon-γ (IFN-γ), which leads to killing of intracellular pathogens. Finally, CD4 T cells can directly kill infected host cells or class II–positive tumors via perforin- or granzyme-mediated cytotoxicity.

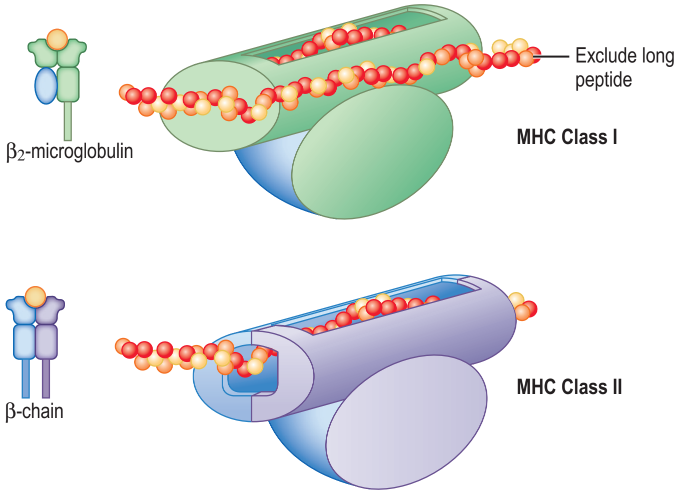

FIG 6.6 Peptide Binding by Major Histocompatibility Complex (MHC) Class I and II Molecules. MHC class I molecules (top) are typically "closed" at both ends. Peptides that are too long must be cleaved prior to entry into the binding site. The clefts of class II molecules (bottom) are "open" at the ends, and thus permit the binding of long peptides. Both molecules interact with peptides through both hydrogen bonding residues that are directed by nonpolymorphic residues in the MHC molecule and that are thus conserved among different complexes, and anchor-pocket interactions that typically employ polymorphic residues in the MHC molecule and thus vary for different MHC alleles and different peptides.

KEY CONCEPTS

Antigen Uptake for Presentation to CD4 T Cells

- B cells acquire antigen through uptake by the immunoglobulin receptor.
- C-type lectins expressed on the surface of many types of antigen-presenting cell (APC) receptors promote the binding and internalization of antigen by the APCs.
- Vaccines can be targeted to dendritic cells for CD4 T-cell priming by conjugation to C-type lectins and thus enhance antibody responses.

MHC Class II Antigen Presentation

MHC class II–restricted presentation of antigen to CD4 T cells is sensitive to inhibitors of endosomal proteolysis. Inhibitors include pharmacological reagents that neutralize endosomes, such as chloroquine or ammonium chloride, or specific protease inhibitors, such as leupeptin. These data have helped establish the paradigm that MHC class II molecules acquire peptides generated by endosomal proteolysis of internalized protein antigens. This process involves a number of cofactors and checkpoints that serve to regulate MHC class II molecule trafficking to endosomal/lysosomal compartments, acquisition of peptide, and trafficking to the cell surface. These pathways and mediators control the ability of class II molecules and their peptides to be recognized by CD4 T cells. Central features include the mechanisms that direct sorting and localization of class II molecules to the intracellular endosomal compartment(s) containing antigen, proteolytic enzymes that efficiently degrade antigen into peptides, and cofactors that promote rapid binding of the appropriate peptides[16-19] (Fig. 6.7).

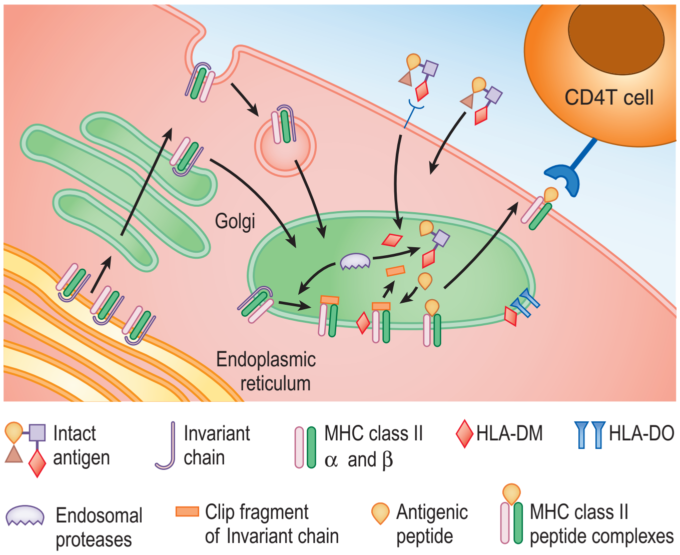

FIG 6.7 Major Histocompatibility Complex (MHC) Class II Presentation of Antigens to CD4 T Cells. Assembly of MHC class II molecules with invariant chain in the endoplasmic reticulum (ER) helps class II molecules fold correctly and blocks acquisition of peptide. After transport through the Golgi body, the class II invariant chain complex can be directly sorted into endosomal compartments or can gain access after a brief cell surface intermediate. Invariant chain is cleaved by endosomal proteases upon arrival into late endosomal compartments. Cleavage leaves the CLIP (class II–associated invariant chain peptide) fragment within the peptide binding pocket of the MHC class II dimer. Antigens can reach endosomal compartments through endocytosis, receptor-mediated uptake, or autophagy (not shown). Endosomal proteases cleave the protein antigens into small proteolytic fragments capable of binding to class II. The replacement of CLIP with an antigenic peptide is facilitated by human leukocyte antigen (HLA)-DM. HLA-DM also promotes binding of peptides with high affinity for the class II molecule. HLA-DO occupies the class II binding site on HLA-DM, preventing its binding to class II. Thus HLA-DO can adjust the active level of HLA-DM within endosomal compartments. After DM-editing of the highest-affinity peptides, a cohort of MHC class II molecules that has stable peptides bound is exported to the cell surface for presentation to CD4 T cells.

Invariant Chain

Invariant chain is a nonpolymorphic, non–MHC-encoded type II membrane glycoprotein protein that associates with class II during biosynthesis. It contributes several discrete functions to the biogenesis and function of MHC class II molecules.[20] Many of the functions of the invariant chain are conveyed by different segments or domains of this protein. Invariant chain also has several different isoforms resulting from alternative splicing and alternative start sites, with the most abundant being approximately 31 kD (mouse) or 33 kD (human).

Early during its biosynthesis in the endoplasmic reticulum (ER), invariant chain forms a trimer that nucleates assembly of three MHC class II dimers, forming a nonamer, which exits the ER. During assembly, a small segment of invariant chain termed *CLIP* (class II–associated invariant chain peptide) facilitates correct class II folding. CLIP occupies the peptide-binding pocket of the class II molecule. This prevents premature occupation of the peptide-binding pocket by self peptides, and it ensures the conformation integrity of the membrane distal, class II peptide binding domains. Successful assembly of invariant chain with MHC class II allows egress of the complex from the ER to later biosynthetic compartments. In this context, invariant chain acts as a molecular chaperone.

As they leave the ER, MHC class II and invariant chain are cotranslationally modified by the addition of complex carbohydrates into the Golgi complex. Either directly from the trans-Golgi network or after a short-lived cell-surface intermediate, they are then selectively sorted into the endosomal compartment of APCs. The amino terminal cytosolic tail of invariant chain plays a key role in the sorting event, which is mediated by the adaptor protein AP-2. Once in the endosomal compartments, invariant chain is degraded by defined sequential proteolytic events mediated by pH-dependent proteases, including aspartyl and cysteine proteases. The key proteases that cleaves invariant at CLIP's amino-terminus are somewhat cell-type specific. They include cathepsin S in peripheral APCs and cathepsin L in the thymus. Because the small CLIP fragment is sequestered within the class II binding pocket, it resists endosomal proteolysis. A rapid exchange reaction must take place between CLIP and the self or antigenic peptide. This process of peptide exchange is promoted by an additional critical protein cofactor termed *DM,* as discussed below.

APCs lacking invariant chain exhibit defects in antigen presentation and class II localization in endosomal compartments. The loss in efficiency of antigen presentation can vary, depending on the allele of class II and the peptide under study. For example, the murine I-A^b molecule expressed by the very commonly used C57BL/6 strain of mouse displays very inefficient egress from the ER, thus blunting all subsequent functions of export, intracellular sorting, and peptide acquisition. Other alleles of class II are able to assemble and exit the ER, although inefficiently. By alternative sorting mechanisms, they can access endosomal compartments. This allows them to access some, although not all, degraded antigens. Invariant chain dependent and independent peptide epitopes are distinct. Epitopes that do not need invariant chain for presentation by class II molecules are thought to represent peptides made available early in the endosomal compartment, perhaps accessing mature invariant chain–free class II from the cell surface via internalization.

KEY CONCEPTS

MHC Class II–Restricted Antigen Presentation

- Major histocompatibility complex (MHC) class II–peptide complexes form in late endosomes.
- Acidic pH in endosomes promotes:
  - Proteolysis of protein antigens
  - Alteration class II conformation to make it more receptive to peptide binding
  - Release of CLIP (class II–associated invariant chain peptide) from class II
  - Class II interactions with human leukocyte antigen (HLA)-DM.
- HLA-DM interaction with MHC class II molecules promotes:
  - Release of the CLIP fragment
  - Binding of antigenic peptide
- DM editing selects for high-affinity peptides to bind to class II and recruit CD4 T cells.

Class II Peptide Loading

The precise intracellular compartment where class II peptide loading occurs has been a subject of much investigation.[21] Endosomal vesicles "mature" over time, becoming more acidic as they progress toward an end-stage lysosome. MHC class II molecules change conformation with acidic pH, becoming more "peptide receptive." Also, as pH decreases, endosomal proteolytic enzymes generally become more active. Some resident endosomal proteases are synthesized as inactive enzymes, termed *zymogens,* which become activated either directly by pH-dependent conformational changes or by cleavage of other endosomal pH dependent proteases. In most APCs, late endosomal compartments are enriched in serine proteases (cathepsins A and G), aspartic proteases (cathepsins D and E), and cysteine cathepsins (cathepsins S and L). The low pH in late endosomes promotes antigen unfolding and access to reductases, such as the IFN-γ–inducible thiolreductase (GILT) that cleaves disulfide bonds. The combination of low pH and reduction of disulfide bonds thus facilitates protein unfolding, proteolytic digestion, and generation of antigenic peptide fragments.

Although MHC class II molecules traffic through many endosomal compartments, they are most highly enriched in late endosomes that have a pH of approximately 4–5. These heterogeneous intracellular compartments are termed *MIICs* (MHC class II compartments) or *MVBs* (multivesicular bodies) and can have either multilamellar or multivesicular organization, consisting of both a limiting membrane and internal membranes. In these compartments, class II molecules localize with the other critical components of the antigen presentation pathway. The precise organization of the class II–containing compartment likely varies with the APC studied (B cells, macrophages, or DCs) and can change upon signaling or antigen receptor engagement.

The exchange reaction of the invariant chain fragment for antigenic peptides represents an intriguing biochemical event that derives from many factors of MHC class II structure and biology. The first is the polymorphic nature of the peptide-binding pocket of the class II heterodimer. Much of the genetic variability in both α and β chains lies within the peptide-binding cleft of class II molecules. This highly localized genetic polymorphism is thought to allow alternate MHC molecules expressed in different individuals to capture distinct subsets of peptides from pathogenic organisms.

All allelic forms of class II thus must be able to accommodate the CLIP segment while they are associated with an intact invariant chain. This ensures conformational integrity of the class II molecule early in biosynthesis. Once invariant chain is proteolytically cleaved, the various allelic forms of class II are differentially able to sustain interactions with CLIP and acquire peptides. Class II molecules with high affinity for CLIP require an efficient mechanism to release CLIP. Class II molecules devoid of peptide have a tendency to aggregate and become degraded, particularly at the low pH of the endosome. Peptide binding to class II molecules, even at low pH where peptide acquisition is facilitated, is quite slow. These combined characteristics of class II structure and biochemistry led to the early speculation that there must be a mechanism to ensure the release of CLIP from all alleles of class II and rapid subsequent binding of antigenic peptide. The protein that facilitates this process is termed *HLA-DM* (in humans) or *H-2M* (in mice).

HLA-DM and Peptide Exchange

HLA-DM (DM) is the critical mediator in the release of CLIP from class II and its replacement with peptide.[22-26] HLA-DM α and β heterodimers are encoded within the HLA gene complex. Instead of associating with invariant chain, HLA-DM gains access to endosomal compartments via a tyrosine-based motif in its cytosolic tail that allows rapid internalization into endosomal compartments after a brief cell-surface intermediate. The release of CLIP from MHC class II molecules (the dissociation reaction) and the acquisition of antigenic peptide (the binding reaction) are greatly enhanced by the presence of DM. Both dissociation and binding are greatly affected by acidic pH. At acidic pH, interactions between DM and class II are initiated along their lateral faces on the side of class II that bears the amino terminal segment of peptide.

DM prefers class II molecules that are open and have unstable interactions with peptide. DM is thought to bind and stabilize this open intermediate of class II–peptide complexes that is promoted by low pH. This accelerates peptide release. This same open conformation is apparently also readily able to capture peptide, promoting a rapid exchange of CLIP for antigenic peptides. When a stable interaction between class II and antigenic peptide forms and the antigenic peptide is fully docked within the MHC class II molecule, DM is released from class II molecules. MHC class II–peptide complexes can then escape to the cell surface for recruitment of CD4 T cells. Accordingly, DM acts as a catalyst of peptide exchange for class II, binding to a transition state until the final product (MHC-class II–peptide) is formed.

Selection of Immunodominant Peptides

Of the many potential peptides that can bind to class II molecules and recruit CD4 T cells when introduced into the host as single peptides, only a subset of these epitopes recruit CD4 T cells when the host encounters an intact antigen or pathogen. For example, in a 50-kDa protein that has more than 80 potential 15–18mer peptides, the CD4 T cells may focus on just 3–5 peptide epitopes. These peptides are termed *immunodominant.* Another subset of peptides is capable of recruiting CD4 T cells in the host when introduced as single peptides. These are termed *cryptic* because they are sequestered from the immune responses to complex protein antigens. Other peptides can neither bind to the host class II nor recruit CD4 T cells.

Early models to explain the selectivity of CD4 T-cell responses suggested that intracellular antigen proteolysis would play a prominent role in selection of epitopes because intact antigens, but not peptides, require internalization and degradation. By this model, the position of the peptide within the three-dimensional structure of antigenic proteins might limit access to proteolytic enzymes and thus availability to bind to class II molecules. Conversely excessive degradation, leading to destruction of the peptide epitopes by endosomal proteases, could lead to diminished yield of some peptides for class II binding and presentation. These differential proteolytic events could thus restrict the potential presented repertoire to a limited number of peptides of the appropriate size (typically 12–25 amino acids). Although it is likely that in some cases such differential antigen processing might impact the yield of available peptide, accumulated data now suggest that selective presentation of potential antigenic peptides in association with MHC class II molecules is primarily as a result of intracellular DM editing.

Studies in both intact APCs and *in vitro* with purified recombinant class II and HLA-DM proteins suggest that DM selectively releases some peptides from class II molecules. Generally, these peptides possess low affinity for the class II molecule. Only those peptides that are stably bound to class II molecules will sustain interactions with MHC class II and survive endosomal DM editing. These MHC class II complexes will be successfully exported to the cell surface, displayed at high density on the APC and recruit CD4 T cells during an immune response. These *DM-selected* peptides are thus the targets of the focused CD4 T-cell response.

The relationship between *DM sensitivity* and the affinity of the peptide–class II complex is not absolute. However, it is generally a good predictive feature of immunodominant peptides. In some cases, the size and diversity of the CD4 T-cell repertoire can also determine the abundance of responding CD4 after encounter with pathogens or vaccines, but the qualitative ability of a peptide to successfully or ineffectively recruit CD4 T cells can be generally attributed to how stably the peptide binds to host HLA-class II molecules and thus DM editing. Importantly, modification of this parameter by increasing the affinity of peptide binding to class II can enhance the immunogenicity of peptides, and thus can be used to enhance immunogenicity of vaccine candidates.

HLA-DO

A final critical component of the MHC class II presentation pathway is HLA-DO (DO) in humans (H-2O in mice). The expression can be regulated independently of invariant chain and HLA-DM. DO is unevenly distributed in MHC class II–positive cells. Factors influencing expression include cell lineage and state of activation. The differential expression of DO has important biological consequences because it inhibits the activity of DM. The expression of DO in APCs can thus diminish CLIP release from class II, peptide loading of MHC class II and DM editing of the final repertoire of class II presented peptides. HLA-DM binds to DO in the same regions that it does the classic antigen-presenting class II molecule, but with a higher affinity and independently of peptide binding. HLA-DO can thus be considered to be a high-affinity *substrate mimic* for HLA-DM. DO initiates its interaction with DM within the ER, and the two protein dimers are transported together into endosomal/lysosomal compartments. *In vivo,* DO essentially titrates the amount of DM that is available to catalyze peptide exchange and editing of the peptide repertoire. The ratio of DM to DO synthesis by an APC will thus determine the amount of DM that is available for CLIP release, peptide binding, and peptide editing.[22,23]

HLA-DO is expressed in resting B cells but downregulated in germinal center B cells. Some subsets of DCs, including Langerhans cells, express DO as do some activated DCs. When B cells have the opportunity to capture antigen and process and present the derived peptides, they appear to compete for the limited number of CD4 Th cells that are needed for isotype switching and Ig affinity maturation in antigen-specific B cells. Because the expression of DO within APCs attenuates the efficiency of antigen presentation for most epitopes, it allows only the highest affinity B cells to successfully recruit CD4 T-cell help. Once this affinity threshold has been met, DO is downregulated. Robust antigen presentation then sustains the CD4 T cell–dependent germinal center response.

Targeting of Antigen into the MHC Class II Processing Pathway

MHC class II molecules use several mechanisms to access self, tumor, or pathogen-derived proteins. In the case of extracellular antigens, proteins can access endosomal compartments through receptor-mediated uptake, fluid phase uptake, or via internalization of cell surface molecules. The major pathways utilized will vary with the type and the activation state of APCs. For DCs and macrophages, calcium-dependent C-type lectins play a major role in accessing exogenous protein antigens or pathogens.[27-29] These lectins recognize carbohydrate recognition domains (CRDs) specific for different sugar side structures on self or foreign proteins. Examples include O-linked or N-linked sugars on glycoproteins or O-linked sugars on glycolipid molecules. Among the C-type lectins are those that recognize mannose-bearing ligands (mannose receptor, SIGNR1, and langerin) and those that recognize complex sugars (dectin 1).

Receptors that have been implicated in antigen presentation include DEC205, expressed on lymphoid-resident DCs and DIR2 (also known as *Clec4*) and its human orthologue DCIR2. Clec9A is a C-type lectin receptor that preferentially induces CD4 T-follicular helper (Tfh) cells, which promote B-cell production of isotype-switched high-affinity antibodies. Combined with ligands for pattern recognition receptors or immunostimulatory agents, such as CD40-specific antibodies, antigens delivered through these cell surface proteins can activate CD4 T cells and induce protective immunity. Use of antibodies to these lectins, which allow precise targeting of specific subsets of APCs with antigen conjugates, has been exploited in vaccine design strategies to elicit the desired immune response to weakly immunogenic antigens, such as tumor antigens and HIV.

In B cells, MHC-restricted antigen presentation is largely limited to those antigens taken up through the specific binding of the somatically variable cell-surface Ig[30-32] (Fig. 6.8). Ig-mediated uptake of antigen is up to 10,000 times more efficient than fluid phase uptake. Antigen capture by B cells within lymph node and spleen follicles can involve direct access of soluble antigens (<70 kDa) delivered via afferent lymphatics to FDCs. For larger membrane-associated antigens, viral aggregates, or immune

FIG 6.8 Antigen Presentation by B Cells. Under physiological conditions, B cells acquire antigens through their B-cell receptor (BCR). They present processed peptide epitopes via major histocompatibility complex (MHC) class II molecules to CD4 T cells. CD4 T cell cytokine production and cell-surface interactions between B cells and T cells (*e.g.,* CD40 and CD40L) are nonspecific. In contrast, the interaction between peptide-specific CD4 T cells and antigen-specific B cells facilitates antigen-specific clonal B-cell expansion and immunoglobulin (Ig) production.

complexes, subcapsulary macrophages can bind and capture antigenic material and transfer it across the subcapsulary sinus. For antigen presentation, B cells must *extract* the antigen from the presenting APC surface. This extraction of cell-associated antigen may involve localized protease secretion and/or myosin mediated pulling forces that allow invagination of antigen-containing membranes. Ig-mediated uptake of antigen enhances the ability of B cells to acquire low concentrations of antigen, providing a way to discriminate B cells with high affinity versus low affinity for antigen, and it also directly signals to the B cells. Signal transduction through the BCR is typically initiated by cross-linking of Ig from multivalent antigens (Chapter 4). Rearrangement of endosomal compartments following signal transduction promotes antigen processing and efficient recognition of the antigen-derived peptides by CD4 T cells.

After uptake, the antigen–Ig complex is delivered to late endosomal compartments where the more mild proteolytic compartments prevent terminal degradation of the antigen. MHC class II synthesis and transport to these compartments allows for peptide–class II epitope display. The capture of antigen by the Ig receptor is an essential feature of the ability of the B cell to obtain CD4 T-cell help. Note that to recruit CD4 help, the antigen recognized by the B cell must be physically attached, by either covalent or strong noncovalent interactions, to the antigen that will elicit CD4 T-cell help. The cognate-nature B cell–CD4 T cell help, which requires linkage of CD4 T-cell and B-cell epitopes, is key to vaccine strategies. It underlies the creation of conjugate vaccines used to elicit antibodies that will recognize carbohydrate ligands expressed by bacteria. Carbohydrate moieties coupled to protein carriers contain the recognition structure for the B-cell response (the carbohydrate) and a source of CD4 T-cell help (the protein carrier). The requisite linkage of CD4 T-cell and B-cell epitopes can limit antibody responses to complex viruses, whose protein components can become dissociated from each other during virus replication and ensuing cell death.

Autophagy, or *self eating,* provides a major pathway for viral or self proteins to access MHC class II molecules in APCs.[17,33] It is a catabolic process by which cytosolic, organelle-associated and nuclear materials are delivered to endosomal and lysosomal compartments. Autophagy provides key metabolites that allow cell survival under conditions of stress. It also allows access of self- and pathogen-derived intracellular cellular proteins into the class II–containing compartments. Indeed, 20–30% of peptides presented by class II molecules are derived from cytosolic or nuclear proteins. Autophagy has also been shown to be active in thymic APCs, thus broadening the array of self peptides that can mediate deletion of potentially autoreactive cells during development.

Three routes by which autophagy in APCs can lead to import of cellular proteins into the endosomal pathway of presentation include microautophagy, macroautophagy, and chaperone-mediated autophagy. All of these ultimately lead to degradation of host proteins in the lysosome. Macroautophagy, which is the best understood, involves formation of large, double-membrane vesicles containing cytosolic components or cytosolic organelles into *autophagosomes.* The autophagosomes fuse with endosomes and lysosomes, delivering their content for degradation and cellular reuse. These cytoplasmic proteins can be used as a source of peptides presented by class II molecules. Immunofluorescence studies have documented delivery of autophagosomes to the lysosomal compartments that contains both conventional class II and DM proteins.

Viral infection can activate and increase autophagy, thus increasing the potential the ability of MHC class II molecules to sample cytosolic viral proteins for presentation of their derived peptides. Viral antigens, such as Epstein-Barr virus (EBV)–nuclear antigen 1 and the *Mycobacterium tuberculosis* antigen Ag85B, have been shown to be presented via this pathway, allowing immune detection. Interestingly, a number of viruses have been shown to antagonize specific components involved in autophagy and thus evade immune surveillance.

KEY CONCEPTS

Antigen Presentation by Major Histocompatibility Complex (MHC) Class I Molecules

- Proteolysis for MHC class I–restricted presentation is typically the function of the proteasome, which is found in the cytosol.
- Peptides are imported through the endoplasmic reticulum (ER) membrane by the TAP (for transporter associated with antigen processing) transmembrane channel.
- Peptide binding to class I within the ER is orchestrated by a large multiprotein complex termed the *peptide-loading complex.*
- Tapasin serves as an adaptor between TAP and MHC class I molecules, and it edits the peptide repertoire presented by MHC class I for recruitment of CD8 T cells.

MHC Class I–Restricted Antigen Presentation

The classical pathway of MHC class I–restricted antigen presentation involves antigens derived from endogenously synthesized internal materials. By displaying the peptides made inside the cell, MHC class I proteins allow circulating CD8 T cells to survey host cells for expression of aberrant, mutant self proteins that may be selectively expressed in cancer or for viral protein–derived peptides in infected cells. Infected or cancerous host cells can then be eliminated by the CD8 T cells.

The Proteasome

Proteins made within APC gain access to the host MHC class I following cytosolic proteolysis by the *proteasome.*[16,34,35] The proteasome participates in protein catabolism within all cells. This multimeric protein complex has a 20S catalytic core composed of four stacked heptameric rings, which, together, determine access and the protease specificity of degradation. Proteases include a chymotrypsin specificity that cleaves after hydrophobic residues, a trypsin-like activity that cleaves after basic residues and a caspase-like activity that cleaves after acidic amino acid residues. A 19S regulator forms a lid on the proteasome and promotes recognition and binding of polyubiquitinated proteins, as well as unfolding and translocation of protein substrates.

The composition of the proteasome and its biochemical activity can vary, depending on cell type and conditions. The ubiquitously expressed proteasome is termed the *constitutive* form. In response to IFN-γ in some cell types, there is an exchange of the constitutive β subunits for homologous βi (for induced) subunits to create the *immunoproteasome,* which is expressed by many cells. The specificity of the β_1 proteasomal subunit can lead to diminished cleavage of peptides with acidic residues and enrichment for peptides with hydrophobic P9 pocket residues. These changes fit the preferences of most class I molecules and suggest coevolution of MHC class I and the proteasome. The proteasome and immunoproteasome appear to primarily differ in their preferences for proteolytic cleavage rather than absolute specificity. Recent studies, however, have suggested that some tumor cell recognition epitopes are selectively destroyed by the immunoproteasome. A third form of the proteasome, the *thymoproteasome,* has alternative forms of the β_5 subunit, β_{5t}. The *thymoproteasome* is selectively expressed in the thymus and permits the use of alternative peptides for *positive selection* of CD8 T cells during development (Chapter 8). This leads to a broader CD8 TCR repertoire with diminished reactivity to self peptides expressed in the periphery.

Import of Antigenic Peptides Into the Endoplasmic Reticulum and Final Trimming

After antigenic or self peptides are generated by the proteasome in the cytosol, they are imported into the ER for potential binding to newly synthesized MHC class I molecules. This transport activity, which must cross the ER membrane, is mediated by a protein heterodimer termed *TAP* (for transporter associated with antigen processing). The TAP heterodimer consists of TAP1 and TAP2, each with 6 transmembrane domains, which within the ER form a transmembrane channel. The adenosine triphosphate (ATP) binding domains are on the cytosolic side of the endoplasmic membrane, where peptide binding is initiated. ATP binding and hydrolysis provides the energy needed for conformational changes that drive channel function and the import of the peptides into the lumen of the ER. TAP is selective for peptide length and sequence in its ability to bind and import peptides. The carboxy-terminal amino acid residues are enriched for generally favored residues for MHC class I binding. These are generally hydrophobic for mice and, consistent with the less restricted peptide binding preferences of human class I, both acidic and hydrophobic for humans.

Import of peptides by TAP appears to enrich for peptides of suitable length (8–10mers) for MHC class I binding. Cytosolic peptides that gain access to the ER via TAP can also be trimmed, if needed. Within the ER, an amino peptidase, termed *ERAAP* (ER associated amino peptidase), can trim the peptide length from its amino terminal residues, permitting the peptide to bind firmly within the confines of the peptide-binding pocket.[36] Peptides lacking anchor residues that allow stable binding to class I are terminally degraded by EERAP.

The Peptide Loading Complex

Upon arrival to the lumen of the ER, peptides gain the opportunity to bind newly synthesized class I. As with class II, spontaneous acquisition of peptides by MHC class I molecules is inefficient and requires cofactors that both enhance the local concentration of the peptide and promote class I *peptide receptivity.* The cellular proteins that promote these events for class I are collectively referred to as the *PLC* (for peptide loading complex), which is a highly organized structure within the ER (Fig. 6.9).

Tapasin, an adapter protein, plays a key role in peptide loading. Tapasin helps MHC class I molecules associate with TAP and brings newly imported peptides into close proximity. Tapasin recruits the ERp57, a thiol oxidoreductase, which assists in the folding of class I by mediating disulfide bond formation. It also recruits the chaperone protein calreticulin to the PLC. Finally, tapasin interactions with MHC class I molecules appears to promote peptide acquisition via its maintenance of class I in a peptide-receptive state, serving the same role for class 1 as HLA-DM for class II. Also similar to DM is the ability of tapasin interactions with MHC class I molecules to *edit* or select the repertoire of bound peptides. The PLC thus promotes correct folding and disulfide bond formation for MHC class I molecules, and all of the intermolecular interactions needed for their assembly with peptide.

FIG 6.9 Major Histocompatibility Complex (MHC) Class I–Restricted Presentation. Internally synthesized proteins, destined for presentation by MHC class I molecules, are degraded by the large proteolytic complex in the cytosol termed the *proteasome.* Peptides that are generally of the appropriate size and sequence for binding to class I molecules are imported from the cytosol by the TAP (for transporter associated with antigen processing) transmembrane channel, catalyzed by adenosine triphosphate (ATP). Once in the endoplasmic reticulum (ER), the peptides can be trimmed to the correct size by an amino peptidase (ERAP). Class I molecule folding is facilitated by chaperones such as calreticulin and ER localized reductases (ERAP) that help class I molecule adopt a transport competent form. Tapasin bridges TAP and class I molecules and helps edit the peptide repertoire bound so that higher-affinity peptides are selected. After peptide binding, the class I–peptide complex is exported through the Golgi body and to the cell surface for recognition by CD8 T cells. There is a second pathway of class I presentation that can be used for externally derived antigens, such as pathogens and tumor cells. This pathway, termed *cross-presentation,* is not shown here but is discussed in the text.

Once assembled with a stable peptide and adopting a stable conformation, the MHC class I–peptide complex is competent to be transported from the ER, through the Golgi complex to the plasma membrane. Overall, the proteasome, TAP, the PLC, and ERAAP cooperate to efficiently load internally synthesized antigens of the correct size and optimal binding affinity onto host class I molecules and to display them at the cell surface for recognition by circulating CD8 T cells.

Cross-Presentation of Antigens for Recognition by CD8 T Cells

T cells are *primed* in lymphoid tissues by specialized APCs that belong to the DC lineage. Under physiological conditions, this process of T-cell priming is restricted to DCs in secondary lymphoid tissues because of their specialized location, access to antigen, and functionality.

Antigen-bearing DCs have several properties that are not shared by most host cells within the lymph node, properties that are essential for activation of antigen-specific T cells. First, subsets of DCs are positioned at sites of host and potential antigen encounter, for example, skin, mucosae, and lungs. Here, they are able to receive molecular signals from pathogens that both activate the DCs and promote internalization and processing of antigens. These pathogen-derived signals initiate DC mobilization, exit from the tissue, and transit to secondary lymphoid organs. Other subsets of DCs are *resident* cells within the lymph node and encounter antigens delivered either via the lymphatics or by other cell types that transit from the site of antigen encounter to the lymphoid tissue.

DCs gain access to secondary lymphoid tissue through expression of chemokine receptors and become localized to regions that allow encounter with recirculating T cells that enter the lymphoid tissue to survey potential antigen-bearing cells. DCs also express key costimulatory molecules, such as CD80 and CD86, and cytokines, such as IL-12, which are essential to prime naïve T cells for expansion and differentiation into the effector cells (Chapter 12).

The intracellular events associated with antigen acquisition and presentation by DCs is easy to envision for CD4 T cells because the antigens that need to access class II molecules can become internalized into the key endosomal compartments. For MHC class I–restricted antigen presentation, particularly for responses to pathogens that do not infect DCs or become systemic, and for responses to tumors that are sequestered in distant sites in the body, this *exogenous presentation* poses a challenge because the site of peptide binding to class I is in the ER, generally not thought to be readily accessible to internalized proteins.

In the last decades, an auxiliary pathway of antigen presentation, termed *cross-presentation,* has been discovered. This antigen presentation event for CD8 T-cell priming to exogenous antigens involves uptake and class I–restricted presentation of cell-associated antigens from tumors or virus-infected cells, and those associated with intracellular bacteria pathogens, such as listeria or fungal pathogens whose proteins are not synthesized within the APC. Cross-presentation also serves to prime CD8 T cells reactive with pathogen-derived proteins and aggregates released by infected cells in distal sites, such as the respiratory tract.[37,38]

Internalization of cell- or pathogen-associated antigens into endosomal/lysosomal compartments through phagocytosis or receptor-mediated uptake initiates cross-presentation and ultimately leads cell-surface presentation of the pathogen-derived peptides in association with class I molecules, leading to CD8 T-cell activation, cell division, and differentiation. These primed CD8 T cells ultimately become programmed to deliver their effector function, most commonly cytolysis, on either pathogen-infected cells or transformed cells, eliminating them from the host.

The intervening, intracellular events involved in cross-presentation are the subject of active research. Early studies pointed to the possibility that this presentation occurs in only a subset of DCs, now known to be distinguished by markers, such as CD8α^+ in mice and BDCA3$^+$ cells in humans. Ablation of DCs *in vivo* eliminates cross-presentation of pathogen-associated antigens, emphasizing the need for this cell type for efficient cross-priming.

There are a number of studies that suggest that cross-presentation is dependent on TAP and the proteasome because in many cases, presentation of the epitope is sensitive to inhibitors of these proteins. Because of the shared cellular cofactors involved in peptide generation and loading, it is envisioned that the same peptides would be presented by the endogenous and the cross-presentation route. This conclusion would seem to be most beneficial to effective surveillance and protection through recognition of the target cell synthesizing the viral or tumor antigen. This cytosolic cross-presenting route requires that internalized or phagocytosed proteins from pathogen-infected or transformed cells gain access to the cytosol. A mechanism that allows transport of an intact or partially unfolded/degraded protein from the lumen of lysosomal compartments into the cytosol is therefore needed. Export has been speculated to involve a transmembrane channel or a direct extraction mechanism. Proteins, such as those involved in ER-associated degradation (ERAD), have been implicated by many studies, as has the Sec61 translocon. Cross-presentation has also been shown to require an endosomal, pH-dependent reductase (GILT), suggesting that protein unfolding may be needed for antigenic protein transfer.

After crossing the lysosomal membrane, the cytosolically localized proteins can now enter the classical or *endogenous* pathway of class I–restricted presentation: proteolysis by the proteasome, import of the derived peptides into the ER via TAP, and peptide binding being facilitated/edited by the components of PLC. The peptide class I complex would then be exported from the ER to the cell surface via the typical default secretory pathway (Fig. 6.9).

The *vacuolar pathway* provides as an alternative means for cross-presentation. In this pathway, the internalized pathogen or tumor-derived proteins remain in the endosomal compartments, where they are degraded by lysosomal proteases. Class I molecules at the cell surface then encounter the antigens during internalization and recycling. Some evidence also suggests that components of the ER-associated PLC may localize to the endosomal compartments and intersect with MHC class I, allowing assembly of the complex within these compartments by a similar mechanism as in the ER. Under what conditions, within what cells *in vivo,* and with what antigens these two potential pathways of exogenous presentation are operational remain to be defined.

Both pathways of cross-presentation require that the internalized antigen be protected from rapid and terminal degradation. Alkalization of the compartment diminishes recruitment of enzymes responsible for acidification of lysosomal compartments, such as nicotinamide adenine dinucleotide phosphate (NADPH) oxidase 2 (NOX-2). Most of the lysosomal enzymes are pH dependent and require acidic pH for optimal activity. Strategies to modify this acidification, either by genetic means or by pharmacological approaches, have been shown to promote cross-presentation.

THE MHC-PRESENTED PEPTIDOME

Isolation and sequencing of host peptides constitutively bound and presented by MHC molecules has yielded significant new insight regarding the diversity, abundance, and source of peptides that are normally displayed.[39,40] The key technical advance was the development and use of tandem mass spectroscopy to sequence very low abundance peptides.[41] In this approach, MHC class I or class II molecules of interest are isolated by antibody affinity chromatography. The bound peptides are then eluted, and the low-molecular-weight material, including peptides, are separated from antibody and class I and then subjected to sequencing.

From these studies, it is now estimated that as many as 10,000 different self peptides are in association with a given class II molecule on the cell surface. For human APCs that can express 6–10 different class II species (HLA-DR, HLA-DQ, and HLA-DP in multiple allelic forms), this diversity of different peptide–class II complexes displayed by APCs was unexpected.

Several key features of MHC biology and biochemistry were revealed by this new technology. First, peptides derived from alternative alleles of MHC proteins yield nonoverlapping sets of peptides. This permits assignment of peptide binding preferences or motifs to different allelic and isotypic forms of MHC molecules (in humans, HLA-A, HLA-B, and HLA-C for class I, and HLA-DR, HLA-DQ, and HLA-DP for class II). This advance has enabled development and refinement of algorithms that predict pathogen-associated epitopes as well as the definition of preferred peptide-binding characteristics for MHC proteins that are associated with susceptibility to autoimmune disease or infection. Sequencing of the peptidome presented by MHC class II molecules also modified our view of class II presented peptides, indicating that the bound peptides extend far beyond the exogenous pathway of antigen access. Many peptide epitopes presented by class II molecules are now known to be derived from cytosolic, nuclear, and membrane-associated proteins synthesized within the APC.

The discovery that antigenic peptides from vaccines, pathogens, or transformed cells represent just a few of the hundreds to thousands of self peptides presented on the surface of APCs supports the current view that the TCR must be capable of acute discriminatory power and behaves more as a signaling protein than a ligand-binding protein. With clarification of the diverse nature of the peptides used for central tolerance induction, tumor-specific antigens and peptides have been identified that can be used for specific immunotherapy. And, methodology to allow sequencing of peptides from just a few million cells from the respiratory tract has led to the identification of respiratory viral peptides presented by the HLA, offering new strategies for vaccine design.

KEY CONCEPTS

Viral Antagonists of Antigen Presentation

- Many viruses, particularly those that lead to chronic infections, encode multiple proteins that antagonize MHC-restricted antigen presentation.
  - Most viral evasion proteins inhibit MHC class I pathways needed for CD8 T-cell recognition.
  - Some human immunodeficiency virus (HIV)–encoded proteins antagonize class II–restricted presentation, as well.
- Viral antagonists typically target the proteins most critical for presentation, including the TAP (for transporter associated with antigen processing) transporter, tapasin, and the MHC molecule itself.

Cryptic Viral or Tumor-Associated Peptides Presented by MHC Class I Molecules

The *transcriptome* consists of the known translated sequence from a viral or endogenous self antigen. An increasing number of tumor- and viral-derived peptides have been identified that are not represented by the transcriptome. These cryptic peptides are derived from many different molecular mechanisms,[40,42] including alternate reading frames, translation of introns, antisense transcript encoded peptides, 5’ untranslated regions, and long noncoding RNAs. In many cases, cytotoxic CD8 T cells have been identified that recognize these peptides. For example, nearly 25% of epitopes from Simian immunodeficiency virus in rhesus macaques appear to be derived from translation of alternative reading frames. Perhaps most surprising is the discovery that the proteasome can ligate distal peptides together through a transpeptidation event, creating new epitopes from noncontiguous segments.

Besides the interest in understanding the precise mechanism responsible for generation of these epitopes is the practical implication of these events. Epitope identification often involves derivation and testing of overlapping peptide libraries from the pathogen or tumor-derived proteins that are based on known protein databases. The cryptic epitopes will not be represented in these libraries, and accordingly, epitopes recognized by many potential effector CD8 T cells will fail to be identified. Thus future vaccine strategies will need to take into account the probability that some of the existing and potentially protective host CD8 T cells may be dedicated to unpredicted peptides from pathogens or transformation.

CLINICAL RELEVANCE

Features of MHC Restricted Presentation that are Important for Clinical and Translational Studies

- Many viral- and tumor-derived peptides for CD8 T-cell recognition are derived from noncoding sequences, alternative reading frames, and antisense coding segments.
- Vaccine strategies must take into account the need for linked recognition of B-cell and CD4 T-cell epitopes and also the selectivity of CD4 T-cell responses that focus only on peptides that bind with very high affinity on the class II molecule.
- Self tolerance within the thymus is selective for peptides that survive tapasin editing for class I presentation and DM editing for class II presentation.
- Autoantigenic peptides that escape self tolerance induction in the thymus often have very low affinity interactions with MHC class II molecules. This can make them difficult to identify or study with MHC–peptide tetramers.
- Chronic viral infection frequently leads to downregulation of the expression of MHC class I–peptide complexes. This leads to escape from immune detection and destruction of infected cells by CD8 T cells.

Pathogen Evasion Strategies

Viral and bacterial pathogens employ extensive evasion strategies that to avoid immune recognition[43-45] (Chapters 24–26). A number of viral proteins, particularly those involved in chronic viral infections, interfere with components of the antigen presentation pathway. Many prevent peptide access to MHC class I molecules, which results in both immune evasion and greatly diminished cell-surface expression of class I molecules.

For example, herpes simplex virus (HSV)– and EBV-encoded proteins both interfere with the binding of peptide to the ER localized TAP transporter. This blocks peptide transport to class I molecules from the site of generation in the cytosol to the ER. The requisite ATP-dependent conformation change of TAP, needed for peptide translocation from the cytosol to the ER, is also a target of viral antagonists. ATP activity is blocked by human cytomegalovirus (hCMV) US6 and EBV-derived BNLF2a. The importance of tapasin in protective CD8 T-cell immunity is evident by the ability of hCMV US3 to bind directly to it and prevent tapasin-dependent loading of antigenic peptides. There are also numerous viral proteins that directly target MHC class I for ER retention, such as adenovirus E3-E19, or degradation directly from the site of synthesis in the ER. Finally, degradation of MHC class I molecules that have successfully emerged to the cell-surface expression is promoted by viral proteins that mediate polyubiquitination and targeting for lysosomal degradation (Kaposi sarcoma–associated herpes viruses Kk3/MIR1 and Kk5/

MIR2 and EBV BILF1). Together, these and other mechanisms prevent detection by CD4 and CD8 T cells and the ensuing protective immune response.

Tumor Escape From Immune Surveillance

Tumor progression is often associated with alterations in the expression and/or function of the MHC class I molecules.[46] Loss of DNA binding factors needed for promoter activation can lead to altered class I transcription. Loss of β2m gene expression can lead to a global defect in class I protein expression at the cell surface. Downregulation of the components of the constitutive and immune-proteasome have been identified in a number of cancers. Low levels of TAP transporter components and the ER aminopeptides (ERAAP) have been seen in others. Loss or diminution of class I presentation of peptides is often associated with disease progression, metastasis, and a detrimental clinical outcome in part as a result of evasion of immune detection and impaired elimination of the transformed cells.

Potential Role of "Peptide Editing" of Presented Peptides on Self Tolerance and Autoimmunity

HLA-DM *edits* the repertoire of peptides presented by HLA-class II molecules at the cell surface. These are the only peptides that are available to interact with circulating CD4 T cells. Tapasin appears to have a similar function for MHC class I peptide binding, enriching for presentation of peptides that bind with high affinity with the MHC class I molecule. This selective peptide display by MHC molecules has important implications for self tolerance and autoimmunity. Tolerance to self arises as a consequence of deletion of developing T cells whose TCR recognizes self peptides presented by host MHC molecules within the thymus (Chapter 8). This is termed *central tolerance.* Accordingly, central tolerance can only be operative if a self peptide is displayed at the cell surface of APCs in the thymus. The bone marrow-derived MHC class II and MHC class I positive APCs responsible for deletion of self-reactive cells express the HLA-DM and tapasin proteins and thus will only express peptides that bind with high affinity to MHC class II molecules. Therefore the host is selectively tolerant only to host peptides that survive this intracellular editing during biosynthesis of the MHC proteins. Self peptides that are removed from MHC molecules during endosomal DM editing or ER-associated tapasin editing are essentially invisible to developing T cells. T cells that have escaped deletion in the thymus will seed the peripheral pool of circulating T cells. The mature CD4 and CD8 T cell repertoire therefore maintains reactivity to some self peptides. Events in the periphery that modify presentation of this subset of lower affinity peptides for MHC molecules will thus allow their display at the cell surface potentially leading to recognition by host CD8 or CD4 T cells and thus initiation or propagation of autoreactivity.

SUMMARY

The intracellular events involved in MHC class I and class II restricted antigen presentation have many commonalities, although they are different in the details. Both can be considered three-chain proteins, where the bound peptide is the third chain. Binding of peptide is needed for conformational integrity of the protein, and accordingly, self or antigenic peptides must be present throughout biosynthesis. Both have a primary site of peptide acquisition: For class I molecules, it is early in biosynthesis within the ER, and for class II, it is within acidic endosomal compartments accessed later during biosynthesis of the MHC protein. Within each of these compartments resides a set of proteins that participate in and direct peptide loading. Both class I and class II molecules acquire peptides inefficiently, and accordingly both require critical protein cofactors that prepare the MHC protein to capture peptide. The presentation events are also similar in that they allow only a subset of the potential self or pathogens peptides to be presented. Peptide editing of the repertoire of peptides presented by MHC proteins is primarily based on the ability to stably interact with the MHC protein.

ON THE HORIZON

- New means to regulate class II antigen presentation could come from a better understanding of the mechanisms by which HLA-DO regulates HLA-DM or from the elucidation of new mechanisms by which viral or bacterial products antagonize the MHC class II presentation pathway.
- New means to regulate class I antigen presentation could come from a better understanding of the mechanisms used to regulate proteasome generated cytosolic peptides and their transport by TAP (for transporter associated with antigen processing) to MHC class I molecules and from a better understanding of cross-presentation.
- A better understanding of the similarities and differences in antigen presentation by the various APC subsets could lead to new vaccination methods.
- A better understanding of the role of cryptic peptides in CD8 T-cell selection events could lead to the manipulation of CD8 T-cell responses to tumors, viruses, and autoantigens.

Because of MHC polymorphism, the peptides selected for protection, self tolerance, and autoimmunity will vary from one individual to the next. Many pathogens have developed specific proteins that degrade or interfere with the essential functions of the protein cofactors that regulate MHC-restricted antigen presentation. These viral evasions strategies allow the infected host cell to avoid immune recognition and destruction by CD8 and CD4 T cells. Interference with antigen presentation also leads to the escape of host cells from tumor-specific surveillance and allow progressive growth and metastases.

We now understand many of the key players in MHC-restricted presentation of antigen to CD4 and CD8 T cells. In the future this understanding will be used for vaccine design strategies, and in personalized medicine aimed at enhancing immunosurveillance and protection mediated by the adaptive immune response.

MULTIPLE-CHOICE QUESTIONS

1. How does the expression of human leukocyte antigen (HLA)-DO most commonly modify the peptide repertoire presented by major histocompatibility complex (MHC) class II molecules?
   A. It enhances presentation of most peptide epitopes.
   B. It targets MHC class II presentation to the correct endosomal compartment.
   C. It inhibits peptide editing by HLA-DM.
   D. It promotes release of the class II–associated invariant chain peptide (CLIP) fragment from MHC class II molecules.

2. How do the proteasome and immunoproteasome differ?
   A. They differ primarily in their subcellular localization.
   B. They differ with regard to targeting of ubiquitinated ligands.
   C. They differ in the number of subunits they contain.
   D. They differ in the sequence and structure of the β subunit.

3. How does cross-presentation differ from the classical pathway of class I–restricted antigen presentation?
   A. It involves exogenous antigens gaining access to MHC class I molecules.
   B. It utilizes the TAP (transporter associated with antigen processing) transporter.
   C. It involves degradation by the proteasome.
   D. It uses only one subset of class I molecules for presentation.

4. What is the function of invariant chain in MHC class II biology?
   A. It prevents class II acquisition of peptides made in the endoplasmic reticulum.
   B. It targets class II molecules to endosomal compartments.
   C. It helps degrade antigens internalized through the immunoglobulin receptor.
   D. A and B

B-Cell Development and Differentiation

Harry W. Schroeder, Jr., Andreas Radbruch, Claudia Berek

B lymphocytes arise from multipotent hematopoietic stem cells that successively populate the embryonic paraaortic splanchnopleure, the fetal liver, and then bone marrow. Stem-cell daughter cells give rise to lymphoid-primed multipotent progenitors (LMPPs), which, in turn, can give rise to either myeloid or lymphoid cells.[1,2] LMPPs then produce common lymphoid progenitors (CLPs), which can generate T cells, B cells, natural killer (NK) cells, and dendritic cells (DCs). Final B-cell differentiation requires the exposure of CLP daughter cells to specialized microenvironments, such as those found in the fetal liver and bone marrow. These two tissues are the primary B-lymphoid organs. In humans, the shift from fetal liver to bone marrow begins in the middle of fetal life and ends just prior to birth. B cells continue to be produced in bone marrow throughout the life of the individual, although the rate of production decreases with age.

KEY CONCEPTS

B-Cell Development in the Primary Lymphoid Organs

- Commitment to the B-cell lineage reflects differential activation of transcription factors that progressively lock the cell into the B-cell pathway.
- B-cell development is typically viewed as a linear, stepwise process that is focused on the assembly and testing of immunoglobulin function, first in the fetal liver and bone marrow and then in the periphery:
  - Failure to assemble a functional receptor leads to cell death.
  - Expression of a functional receptor subjects the B cell to antigen selection.
  - B cells with inappropriate specificities tend to be eliminated.
  - B cells responding appropriately to external antigen can develop either into immunoglobulin-secreting plasma cells or into memory cells.
- At the clinical level, B-cell development can be monitored by examining the pattern of expression of characteristic surface proteins.

An intact and functional B-cell receptor (BCR) complex, which consists of membrane-bound immunoglobulin (mIg), the Igα and Igβ coreceptors, and ancillary signal transduction components, must be present for the developing B cell to survive (Chapter 4). The composition of the BCR is subject to intense selection. In the primary organs, hazardous self-reactive BCRs, as well as nonfunctional ones, can be culled by changing the light (L) chain (receptor editing), by cell anergy,[3] or by apoptosis of the host cell. Survivors of this initial selection process are released into blood and thence to the spleen, lymph nodes, and other secondary lymphoid tissues and organs, where selection for specificity continues (Chapter 2).

B-cell differentiation (Fig. 7.1) is commonly presented as a linear process defined by the regulated expression of specific sets of transcription factors, immunoglobulin (Ig), and cell-surface molecules. Given the central role of the BCR (Chapter 4), initial developmental steps are classically defined by the status of the rearranging Ig loci. With the development of monoclonal antibody (mAb) technology, analysis of cell-surface markers, such as CD10, CD19, CD20, CD21, CD24, CD34, and CD38 (Fig. 7.2), has facilitated definition of both early and late stages of development, especially in those cases where Ig cannot be used to distinguish between cell types.[4] Of these, CD19, a signal transduction molecule expressed throughout B-cell development up to, but not including, the mature plasma cell stage[5] warrants special mention as the single best clinical marker for B-cell identity.

In practice, B-cell development is a more complex process than the simple, linear pathways depicted in Figs. 7.1 and 7.2. For example, proB cells typically derive from a CLP, but they can also develop from a bipotent B/macrophage precursor. Thus B-lineage subsets identified by one fractionation scheme may consist of mixtures of subsets identified by others. The practitioner would therefore be wise to clarify the fractionation scheme used by the reference laboratory when comparing patient findings to the literature.

Initial commitment to the B-cell lineage requires activation of a series of transcriptional and signal transduction pathways. At the nuclear level, the transcription factors PU.1, Ikaros, ID-1, E2A, EBF, and PAX5 play major roles in committing progenitor cells to the B-cell lineage.[6] After lineage commitment has been established, however, it is generally accepted that the composition of the BCR controls further development.

Each B-cell progenitor has the potential to produce a large number of offspring. Some will develop into mature B cells, and even less into long-lived memory B cells or plasma cells. Others, indeed the majority, will perish.[7] Most of the defined steps in this process of development represent population bottlenecks: developmental checkpoints wherein the developing B cell is tested to make sure that its BCR will be beneficial.[8] In the periphery, exposure to antigen is associated with class switching and hypermutation of the variable domains of the antigen receptor. A few select survivors earn long lives as part of a cadre of memory B cells. These veterans are charged with the responsibility to rapidly engage antigen to which they have been previously exposed, providing experienced protection against repeated assault.

FIG 7.2 **B-Cell Subsets in Peripheral Blood.** Peripheral blood B-cell subsets can be identified by differential staining for immunoglobulin M (IgM), IgD, CD10, CD19, CD24, CD27, and CD38 and by the use of the rhodamine dye R123, which is extruded by the ABCB1 transporter expressed in naïve, mature B cells and, to a lesser extent, T3 transitional B cells.[36] B cells that are CD20$^+$ CD27$^+$CD43$^+$CD70$^-$ are currently the best candidates for the human B-1-cell counterparts,[4] but this is subject to change. In addition to these subsets found in blood, germinal center B cells found in the spleen, and lymph nodes are characterized as IgD$^-$CD38^{++} CD10$^+$ CD27$^{+/-}$; marginal zone (MZ) B cells are typically CD27$^+$CD21^{++}CD23$^{+/-}$CD1c$^+$IgD$^-$; and long-lived plasma cells found in bone marrow, the spleen, and tonsils are CD138$^+$CD20$^-$CD38^{++}.

Specialized microenvironments also play a role in peripheral B-cell development (Chapter 2), each of which enables the B cell to properly engage different types of antigens or venues of attack. In the marginal zone (MZ), mature splenic MZ B cells await bacterial pathogens. In the lymphoid follicles, B cells reactive with a given antigen collaborate with follicular T helper (Tfh) cells and DCs to maximize the immune response (Chapter 6). In the germinal centers (GCs), B cells use class switching and somatic mutation to modify and optimize the function and affinity of their Igs. And, underneath mucosal surfaces, B cells are primed to express IgA (Chapter 20).

B-CELL DEVELOPMENT BEGINS IN THE PRIMARY LYMPHOID ORGANS

Generation of a Functioning Antigen Receptor Is Key to the Viability of a B Cell

Ig rearrangement is hierarchical. In proB cells, heavy (H) chain $D_H \rightarrow J_H$ joining precedes $V_H \rightarrow DJ_H$ rearrangement (Chapter 4), followed by light (L) $V_L \rightarrow \rightarrow J_L$ joining in late-stage preB cells.

Production of a properly functioning B-cell receptor (BCR) is essential for development beyond the preB cell stage. For example, loss-of-function (LOF) mutations in RAG-1/2 and DNA-dependent protein kinase (DNA-PKcs, Ku 70/80) preclude B-cell as well T-cell development (Chapter 35). Each proB cell faces the probability that only one of three possible splices will place the V_H and J_H in the same reading frame. The opportunity to try rearrangement on the second chromosome gives failing proB cells a second opportunity. Together, this provides the cell with five chances out of nine for initial survival ($\frac{1}{3} + [\frac{1}{3} \times \frac{2}{3}] = \frac{5}{9}$). This calculation reflects the fact that after failure of the first rearrangement for $\frac{2}{3}$ of the cells, these remaining cells will each have a 1 in 3 chance of a functional rearrangement of the second chromosome. In-frame, functional VDJ_H rearrangement allows the proB cell to produce μ H chains, most of which are retained in the endoplasmic reticulum (ER). The appearance of cytoplasmic μ H chains marks initiation of the preB cell stage. These early preB cells tend to be large in size.

VpreB and λ14.1 [λ5], which together form the surrogate light chain (ψLC), and Igα and Igβ (Chapter 4) are constitutively expressed by proB cells. The first H chain quality control checkpoint tests for the ability of the μ H chain to associate with surrogate light chain to form a preB-cell receptor. In addition to checking to see if the scaffolding (frameworks) of the L chain can associate correctly with the scaffolding of the H chain, VpreB encodes a sensing site that can test the H chain antigen-binding site. Thus the surrogate light chain functions as the first, and invariant, antigen to screen for antigen-binding characteristics.

Successful formation of a stable preBCR is followed by the termination of further H chain rearrangement (*allelic exclusion*), which is followed by four to six cycles of cell division, a process associated with a progressive decrease in cell size. Late preB daughter cells reactivate recombinase activating gene 1 (RAG1) and RAG2 and begin to undergo $V_L \rightarrow J_L$ rearrangement. Successful production of a complete κ or λ light chain permits expression of conventional IgM on the cell surface (sIgM), which identifies the *immature* B cell. Immature B cells expressing self-reactive IgM antibodies may undergo repeated rounds of light chain rearrangement to lessen the self specificity of the antibody, a process termed *receptor editing.*

Immature B cells that have successfully produced an acceptable IgM BCR extend transcription of the H chain locus to include the Cδ exons downstream of Cμ. Alternative splicing permits coproduction of IgM and IgD. These now newly *mature* IgM^+IgD^+ B cells enter blood and migrate to the periphery, where they form the majority of the B-cell pool in the spleen and the other secondary lymphoid organs. The IgM and IgD on each of these cells share the same variable domains.

Tyrosine Kinases Play Key Roles in B-Cell Development

Signaling through the BCR is required for continued development. Bruton tyrosine kinase is an important component of the phospholipase Cγ (PCLγ) pathway, which is used in BCR signaling. Deficiency of BTK function results in the arrest of human B-cell development at the preB cell stage[9] and is the genetic basis of X-linked agammaglobulinemia (XLA) (Chapter 34).

BLNK is a SRC homology 2 (SH2) domain–containing signal transduction adaptor. When phosphorylated by SYK, BLNK serves as a scaffold for the assembly of cell activation targets that include GRB2, VAV, NCK, and phospholipase C-[γ] (PLCγ). LOF mutations in BLNK can result in the loss of preB and mature B cells and thus agammaglobulinemia.

FLT3 (FLK2) is a receptor tyrosine kinase belonging to the same family as c-FMS, the receptor for colony stimulating factor-1 (CSF-1). FLT3 ligand, which has homology to CSF-1, is a potent costimulator of early proB cells. In mice, targeted disruption of *flt3* leads to a selective deficiency of primitive B-cell progenitors.

Cell Surface Antigens Associated With B-Cell Development

B-cell development is associated with the expression of a cascade of surface proteins, each of which plays a key role in the fate of the cell (see Fig. 7.1; Table 7.1). The timing of the appearance of each of these proteins can be used to further analyze the process of B-cell development.

CD34 is a highly glycosylated type I transmembrane glycoprotein that binds to CD62L (L-selectin) and CD62E (E-selectin) and thus likely aids in cell trafficking (Chapter 11). It is expressed on a small population (1–4%) of bone marrow cells that includes hematopoietic stem cells (HSCs). Minimal hematopoietic defects have been documented in mice deficient in CD34. However, such observations must be viewed with caution when extrapolated to humans because CD34 is not expressed on HSCs in mice.

CD10, also known as *neprilysin, neutroendopeptidase,* and the *common acute lymphocytic leukemia antigen* (CALLA), is a type II membrane glycoprotein metalloprotease. CD10 has a short *N*-terminal cytoplasmic tail, a signal peptide transmembrane domain, and an extracellular *C*-terminal domain that includes six *N*-linked glycosylation sites. The extracellular domain contains 12 cysteines whose disulfide bonds help stabilize its zinc-binding pentapeptide motif, which is involved in its zinc-dependent metalloprotease catalytic activity. By virtue of its protease activity, it is thought to downregulate cellular responses to peptide hormones and cytokines. Inhibition of CD10 activity on bone marrow stromal cells enhances B-cell maturation. CD10 (CALLA) is used as a marker for preB acute lymphocytic leukemias (ALLs) and for certain lymphomas.

CD19 is a cell-surface glycoprotein of the immunoglobulin superfamily (IgSF) that is exclusively expressed throughout B-cell development from the proB-cell stage up to the plasma cell stage (see Fig. 7.1).[10] CD19 exists in a complex with CD21 (complement receptor 2: CDR2), CD81 (TAPA-1), and Leu 13. With the help of CD21, CD19 can bind the complement C3 cleavage product C3d. The simultaneous binding of sIgM and CD19 to a C3d-antigen complex enables CD19 and the BCR to

TABLE 7.1 Cell-Surface Proteins Active in Early B-Cell Development

Gene	Class or Alternative Name	Associated or Targeted Genes or Molecules	B-Cell Developmental Phenotype in Humans or *Mice* Associated With Disrupted Function of the Indicated Gene
B-Cell Receptor Complex			
μ chain	Immunoglobulin superfamily (IgSF)	κ,λ L chains, ψL chain, CD79 a,b (Igα,β)	AGM1: agammaglobulinemia and no B cells. *Arrest at preB-cell stage*
Immunoglobulin λ-like polypeptide 1; IGLL1 (λ14.1, λ5)	IgSF	VpreB, μ H chain	AGM2: agammaglobulinemia and reduced B-cell numbers. *Arrest at preB-cell stage*
VPREB1 (VpreB)	IgSF	λ14.1, μ H chain	*Arrest at preB-cell stage*
CD79a,b (Igα,β)	IgSF, cytoplasmic immunoreceptor tyrosine-based activation motifs (ITAMs)	H chain, LYN, FYN, BLK, SYK	AGM3 (CD79A); AGM6 (CD79B): Agammaglobulinemia and arrest at proB-cell stage. *Arrest at proB-cell stage*
Other Cell-Surface Proteins			
CD10	Type II metalloproteinase	Hydrolyzes peptide hormones, cytokines	*Not expressed in murine B-cell progenitors*
CD19	IgSF	mIgM, PI-3 kinase, VAV, LYN?, FYN?	CVID3: panhypogammaglobulinemia, normal numbers of $CD20^{+}$ B cells in blood
CD20	Four transmembrane domain surface molecule	B-cell Ca^{2+} channel subunit; indirectly interacts with LYN, FYN, LCK	CVID5: low IgG, normal IgM, variable IgA *20–30% reduction in B-cell numbers*
CD21	Complement control protein	iC3b, C3dg, C3d, CD19, CD81, Leu 13, CD23	CVID7: Low IgG, reduced IgA, low normal IgM. *Diminished T cell–dependent immune responses, decreased germinal center formation, reductions in affinity maturation*
CD24	Glycosyl-phosphatidylinositol (GPI)–linked sialoglycoprotein	Ligand for P-selectin (CD62P)	A57V polymorphism associated with increased risk of multiple sclerosis. *Deletion in mice leads to reductions in late preB-cell and immature B-cell populations*
CD34	Type I transmembrane glycoprotein	Ligand for L-selectin (CD62L) and E-selectin (CD62E)	*Not expressed in murine B-cell progenitors*
CD38	Type II transmembrane glycoprotein adenosine diphosphate (ADP)-ribosyl cyclase, cyclic ADP-ribose hydroxylase	ADP ribosylates proteins	*Diminished T cell–dependent immune responses, augmented responses to T cell–independent type 2 polysaccharide antigens*

interact and thereby provides a link between innate and adaptive immune responses (Chapter 3). CD19-BCR interactions permit the cell to reduce the number of antigen receptors that need to be stimulated to activate the cell. Coactivation also reduces the threshold required for B-cell proliferation in response to a given antigen.

The cytoplasmic domain of CD19 contains nine conserved tyrosine residues that, when phosphorylated, allow CD19 to associate with PI-3 kinase and the tyrosine kinase VAV. Patients deficient in CD19 have normal numbers of $CD20^{+}$ B cells in blood but have panhypogammaglobulinemia and are susceptible to sinopulmonary infections (Chapter 34).

CD20 contains four transmembrane domains and cytoplasmic *C*- and *N*-termini. It is a member of the CD20/FcεRIβ superfamily of leukocyte surface antigens. Differential phosphorylation yields three forms of CD20 (33, 35, and 37 kilodaltons [kDa]). Activated B cells have increased fractions of the 35- and 37-kDa forms of the antigen. CD20 appears to function as a B-cell Ca^{2+} channel subunit that regulates cell cycle progression. It can interact directly with major histocompatibility complex (MHC) class I and II molecules, as well as members of another family of four transmembrane domain proteins, known as the TM4SF (*e.g.*, CD43, CD81, and CD82). It also appears to interact indirectly with LYN, FYN, and LCK. A patient born of consanguineous parents and with a CD20 deficiency present with normal numbers of B cells, reduced circulating memory B cells, low IgG with normal IgM and IgA, and reduced somatic hypermutation (SHM). Rituximab, a common monoclonal biological approved for medical use in 1997, is directed against CD20. It is commonly used to treat certain autoimmune diseases and lymphoid cancers (Chapter 89).

CD21 (complement receptor 2 [CR2]) is a cell-surface protein that contains a small cytoplasmic domain and an extracellular domain consisting of a series of short consensus repeats termed *complement control protein* (CCP) domains. These extracellular domains can bind three different products of complement C3 cleavage, iC3b, C3dg, and C3d. When binding these products, CD21 acts as the ligand-binding subunit for the CD19–CD21–CD81 complex, tying the innate immune system to the adaptive immune response. Mice that lack CD21 exhibit diminished T-dependent B-cell responses. However, serum IgM and IgG are in the normal range. A patient lacking CD21 presents with low IgG, low normal IgM, normal IgA, and normal responses to protein vaccination, but impaired responses to polysaccharide vaccines.

CD24 is a glycosyl-phosphatidylinositol (GPI)-linked sialoprotein that serves as a ligand for P-selectin (CD62P). It is expressed on progenitor, immature, and mature B cells. Its expression decreases in activated B cells and is lost entirely in plasma cells. Monoclonal antibodies (mAbs) against CD24 inhibit human B-cell differentiation into plasma cells. In mice, CD24 is also known as heat-stable antigen (HSA). Mice made deficient in CD24 show a leaky block in B-cell development with a reduction in late preB-cell and immature B-cell populations. However, peripheral B-cell numbers are normal, and no impairment of immune function has been demonstrated.

CD38 is a bifunctional enzyme that can synthesize cyclic adenosine diphosphate–ribose (cADPR) from nicotinamide adenine dinucleotide (NAD$^+$) and also hydrolyze cADPR to ADP-ribose. It is presumed that the enzyme exists to ADP-ribosylate target molecules. CD38 is expressed on preB cells, activated B cells, and early plasma cells, but not on immature or mature B cells or on mature plasma cells. Antibodies to CD38 can inhibit B lymphopoiesis, induce B-cell proliferation, and protect B cells from apoptosis. CD38 knock-out mice exhibit marked deficiencies in antibody responses to T cell–dependent protein antigens and augmented antibody responses to T-cell–independent type 2 polysaccharide antigens.

Transcription Factors Controlling B-Cell Differentiation

Ultimately, B-cell development is a function of differential gene expression. Deficiencies in the function of the transcription factors that regulate lymphoid-specific gene expression can thus be expected to result in abnormal B-cell development (Fig. 7.3; Table 7.2).[11]

PU.1 belongs to the ETS family of loop–helix–loop (winged helix) transcription factors, which bind purine-rich DNA sequences. In B cells, PU.1 regulates a number of critical genes, including CD79a (Igα), J chain, μ chain, κ chain, λ chain, RAG1, and terminal deoxynucleotidyl transferase (TdT), the enzyme responsible for *N* addition (Chapter 4). ETS family members are relatively weak transcriptional activators and typically require the presence of other factors to activate or repress their target genes. PU.1 is no exception. It cooperates with PIP (LSIRF, IRF4), c-JUN, and c-FOS. PU.1-deficient mice demonstrate defective generation of monocyte, granulocyte, and lymphocyte progenitors, indicating a role in the generation of MPPs as well as LMPPs. PIP-deficient mice lack GCs in peripheral lymphoid organs and exhibit defects in B-cell activation.

Ikaros and Aiolos belong to the same zinc finger transcription factor family. Although both are expressed during lymphoid development, Ikaros is expressed in stem cells and mature lymphocytes, whereas Aiolos is only expressed after commitment to the B-cell lineage. Ikaros transcripts are subject to alternate splicing. It can generate several isoforms, each of which differs in its DNA-binding pattern, tendency to dimerize, and nuclear localization. Among the genes bound by Ikaros are TdT, λ14.1 (λ5), VpreB, and LCK. Ikaros-deficient mice lack B cells. Aiolos-deficient mice exhibit elevated levels of IgG and IgE. As they age, these mice tend to develop autoantibodies and B-cell lymphomas.

The *E2A* locus encodes two basic helix–loop–helix transcription factors that represent two alternately spliced products, E12 and E47. Targets for E2A include RAG-1 and TdT. Although the functions of E12 and E47 overlap, E47 appears to play the greater role in driving TdT and RAG-1, whereas E12 is a better activator of EBF and PAX5 and thus helps commit developing cells to the B-cell lineage. In mice, disruptions in the *E2A* gene are marked by an arrest of B-cell development prior to the first transcription of *RAG-1*.

ID-1 has a helix–loop–helix domain, but lacks a DNA-binding domain. Thus it can function as a dominant negative factor, inhibiting the function of helix–loop–helix transcription factors, such as E2A. ID-1 is expressed only in proB cells. *ID-1* transgenic mice have a phenotype similar to *E2A* knock-out mice, suggesting that Id-1 can regulate E2A function.

EBF, or early B-cell factor, is a helix–loop–helix–like transcription factor. It is expressed at all stages of differentiation except plasma cells. In mice, it has been shown to be critical in the progression of B cells past the early proB-cell stage. The developmental block in B-cell differentiation is similar to that seen in E2A mutants, suggesting that these transcription factors act cooperatively and regulate a common set of genes.

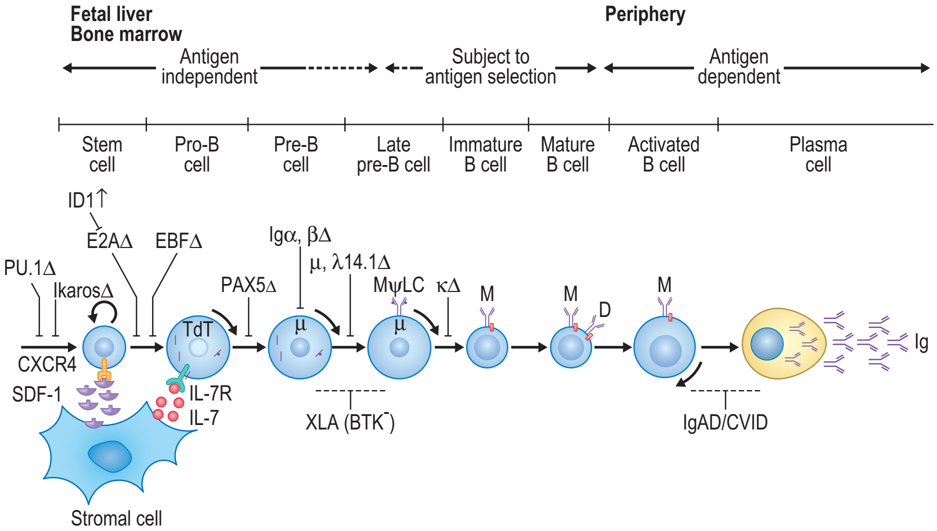

FIG 7.3 Genes Involved in Early B-Cell Development. The stage of development at which abnormal function of selected set of transcription factors, cytokines, chemokines, and signal transduction elements can influence B-cell development is illustrated. A Greek delta (Δ) or a dash (–) indicates a loss of function of the gene in question. An upward arrow (↑) indicates an increase in the function of the gene in question.

TABLE 7.2 Nuclear and Cytoplasmic Factors Active in Early B-Cell Development

Gene	Class or Alternative Name	Associated or Targeted Genes or Molecules	B Cell Developmental Phenotype in Humans or *Mice** Associated With Disrupted Function of the Indicated Gene
Transcription Factors			
PU.1	Loop–helix–loop (winged helix)	CD79a (Igα), μ H chain	Arrest prior to the proB-cell stage*
Ikaros	Zinc finger	RAG1, TdT, IL2R, VpreB, LCK	CVID13: progressive loss of B cells and serum immunoglobulins Arrest prior to the proB-cell stage*
Aiolos	Zinc finger	RAG1, TdT, IL2R	Aging mice develop symptoms of systemic lupus erythematosus*
E2A	Basic helix–loop–helix (BHLH)	RAG1, IgH, Igκ, TdT, EBF, PAX5	AGM8: Agammaglobulinemia, reduced numbers of $CD19^+$ B cells that lacked B-cell receptors (BCRs) Arrest prior to the proB-cell stage*
EBF	EBF/Olf helix–loop–helix (HLH) –like	CD79a (Igα), λ14.1, VpreB, PAX5	Arrest prior to the proB-cell stage*
PAX5	Paired-domain	CD19, λ14.1, VpreB, BLK kinase, J chain, V_H promoters, Vκ promoters	Susceptibility to B-cell acute lymphoblastic leukemia 3 Arrest at proB-cell stage*
The Recombinase Complex			
RAG1, RAG2	Recombinase	Recombination signal sequences of immunoglobulin gene segments	Autosomal recessive severe combined immunodeficiency (SCID) Arrest at proB-cell stage*
TdT	Nontemplated DNA polymerase	Coding ends of rearranging immunoglobulin gene segments	Absence of N nucleotides, diminished production of pathogenic anti-DNA autoantibodies, loss of heterosubtypic immunity against influenza virus*
DNA-PK	DNA repair complex	Multimeric complex consisting of DNA-PKcs, Ku70, Ku80, which repairs double-stranded DNA breaks	SCID Arrest at proB-cell stage, original mouse SCID mutation identified as a loss-of-function mutation in DNA-PKcs*
Protein Tyrosine Kinases			
FLK2/FLT3	Class III receptor tyrosine kinase	GRB2, SHC	Activating mutations contribute to acute myeloid leukemia Selective deficiency of primitive B-cell progenitors*
BLNK	SH2 adaptor protein	SYK, GRB2, VAV, NCK, Phospholipase Cγ (PLCγ)	AGM4: Normal numbers of proB cells, absent preB and B cells. Arrest at proB-cell stage*
BTK	BTK/TEC protein tyrosine kinase	Phospholipase Cγ (PLCγ), SAB	XLA: X-linked agammaglobulinemia - arrest at preB cell stage Xid: Impaired responses to T-cell–independent antigens*

*Indicates B cell development phenotype in mice.

PAX5 is a paired-box, or domain, transcription factor that, among the progeny of HSCs, is expressed exclusively in cells of the B-cell lineage. PAX5 has both a positive and a negative effect on B-cell differentiation. In mice, B-cell precursors require Pax5 to progress beyond the proB-cell stage. The presence of Pax5 also prevents early B-lineage progenitors from transiting into other hematopoietic pathways. Downregulation of PAX5 allows upregulation of BLIMP1 and plasma-cell differentiation. PAX5 downregulation in plasma cells permits expression of genes typically expressed in macrophages and neutrophils.

MicroRNAs and B-Cell Development

MicroRNAs (miRNAs) are a class of small, noncoding RNAs that downregulate target genes at a posttranscriptional level.[12] These RNAs are derived from longer transcripts by the sequential action of RNA polymerase II, the nuclear nuclease Drosha, and the cytosolic nuclease Dicer. Mature miRNAs are incorporated into the multiprotein RNA-induced silencing complex (RISC), which represses target messenger RNAs (mRNAs) by either inducing mRNA cleavage or mRNA degradation or by blocking mRNA translation. Critical miRNAs include miR-150, miR-155, and miR-17-92. Several of these miRNAs play a role in both early and late B-cell development. Abnormal function of these miRNAs can contribute to oncogenesis and immune dysfunction.

Modulation of B-Cell Development by Chemokines, Cytokines, and Hormones

Stromal cells provide the microenvironment for B-cell development and differentiation (see Fig. 7.3). For example, the chemokine CXCL12, also known as preB-cell growth-stimulating factor and as stromal cell-derived factor-1 (PBSF/SCF-1), promotes proB-cell proliferation. Mice with a targeted disruption of this gene exhibit impaired B-lymphopoiesis in fetal liver and bone marrow and fail to undergo bone marrow myelopoiesis.[13] The mechanism by which CXCL12 regulates early B-cell development remains unclear.

Although in mice interleukin-7 (IL-7) plays an essential role in B-lineage differentiation, in humans, it has a minimal proliferative effect on human B-cell progenitors. Nevertheless, IL-7 enhances CD19 expression, which plays an important role in BCR signal transduction (Chapter 4). IL-7 treatment of human proB cells also leads to a reduction in the expression of RAG-1, RAG-2, and TdT. Thus IL-7 can modulate the process of Ig gene segment rearrangement in human.

Interferons-α and -β (IFN-α/β) are potent inhibitors of IL-7-induced growth of B-lineage cells in mice.[14] The inhibition is mediated by cell death (apoptosis). One potential source of IFN-α/β is bone marrow macrophages. Another macrophage-derived cytokine, IL-1, can also act as a dose-dependent positive or negative modulator of B lymphopoiesis.

Systemic hormones also regulate lymphopoiesis.[15] A role for sex steroids is suggested by the reduction in preB cells during pregnancy. Estradiol can also alter later stages of B-cell development, promoting expansion of the marginal zone (MZ) compartment. Prolactin appears to enhance production of both MZ and follicular B cells. Mice with a LOF mutation in the *Pit-1* transcription factor gene do not produce growth hormone, prolactin, or thyroid-stimulating hormone. These dwarf mice exhibit a defect in B-cell development that is correctable by the thyroid hormone thyroxine.[16]

KEY CONCEPTS

B-Cell Development in the Periphery

- T cell–independent activation of naïve B cells results in terminal differentiation into short-lived plasma cells.
- T cell–dependent activation of B cells:
  - Induces germinal center formation, permitting somatic hypermutation and class-switch recombination (CSR)
  - Results in differentiation into high-affinity memory B cells (reactive memory) and plasma cells secreting high-affinity antibodies (protective memory)
  - Generates long-term humoral immune protection
- The longevity of plasma cells is supported by highly specialized survival niches in bone marrow.
- T-follicular helper (Tfh) cells control late B-cell differentiation by cell-bound ligands and secreted cytokines.
- Activated B cells control T-cell development by presentation of antigen and costimulation.

B-CELL DEVELOPMENT IN THE PERIPHERY

The life span of mature B cells expressing surface IgM and IgD appears entirely dependent on antigen selection. After leaving bone marrow, unstimulated cells live for only a few days. Deletion of the transmembrane/intracellular domains of the BCR leads to loss of mature B cells, which indicates that signaling through the BCR is essential for their survival. As originally postulated by Burnet's "clonal selection" theory, B cells are rescued from apoptosis by their response to a cognate antigen. The reaction to antigen leads to activation, which can then be followed by diversification.

The nature of the activation process is critical. T cell–independent stimulation of B cells induces differentiation into short-lived plasma cells with limited class switching. T-dependent stimulation adds additional layers of diversification, including SHM of the variable domains, which permits affinity maturation, class switching to the entire array of classes available (Chapter 4), and differentiation into the long-lived memory B-cell pool or into the long-lived plasma-cell population.

BAFF and APRIL Can Play Key Roles in the Development of Mature B Cells

B cells leave bone marrow while still undergoing initial maturation, demonstrating progressively higher levels of IgD expression with a commensurate lowering of IgM. The splenic environment plays a key role in this maturation process. Immigrant splenic maturing B cells pass through two transitional stages, known as transitional stages 1 (T1) and 2 (T2). Only a minority of these cells successfully make the transition, as this differentiation step is a crucial checkpoint for controlling self-reactivity. Passage through this checkpoint requires the interaction of soluble B cell–activating factor (BAFF) of the tumor necrosis factor (TNF) family, with its receptor, BAFF-R, which is expressed primarily on B cells.[17] Death signals triggered through interaction of the BCR with self antigen can be counterbalanced by stimulation of BAFF-R, which enhances expression of survival factors, such as Bcl-2, and at the same time downregulates proapoptotic factors.

BAFF and a second TNF family member APRIL (a proliferation-inducing ligand) are essential factors for B-cell development and also for their long-term maintenance.[18] With the development of plasma cells, BAFF-R is downregulated while the receptors transmembrane activator and calcium-modulator and cyclophilin ligand (CAML) interactor (TACI) and B-cell maturation antigen (BCMA) are upregulated. In contrast to BAFF-R, these members of the TNF-R family can bind both BAFF and APRIL. APRIL can induce isotype switching in naïve human B cells. More importantly, it is a crucial survival factor supporting the longevity of plasma cells.

B CELLS AND THE RESPONSE TO ANTIGEN

T Cell–Independent Antigens

Unlike T cells, which require presentation of antigen by other cells, B cells can respond directly to an antigen as long as antigen is able to cross-link the BCR. Such antigens, especially those that by nature cannot be recognized by T cells (*e.g.*, DNA or polysaccharides), can induce a B-cell response independent of T-cell help. Depending on the cytokine milieu, B cells may even class switch (Chapter 4; and see below), although the range of available classes appears to be restricted. B cells that are activated by antigen alone do not take part in a germinal center (GC) reaction (see below).

T Cell–Dependent Antigens

Activated B cells express both MHC class I and class II molecules on their cell surface (Chapter 5). They can thus present both intracellular and extracellular antigens to CD4 T-helper (Th) and CD8 T cytotoxic lymphocytes (Chapter 6). Their role as antigen-presenting cells (APCs) is enhanced when they present peptides from the same antigen they have taken up with their antibodies. Cognate recognition of the same antigen by both a B cell and a T cell permits each of these cells to reciprocally activate the other.

T cell–activated B cells express the costimulatory molecules CD80 and CD86. These cell-surface molecules are required for activation of T cells via CD28, and for inactivation by CD152 (cytotoxic T-lymphocyte antigen-4 [CTLA-4]). Since B cells do not express IL-12, they do not induce expression of IFN-γ in the activated T cells but rather favor the differentiation of activated T cells into IL-4, -5, -10, and - 13 expressing Th2 cells and IL-21 secreting T-follicular helper (Tfh) cells.[19] These cytokines can support the CD40-induced expansion of memory B cells (IL-4), CD40-induced class-switch recombination (CSR) to IgG4 or IgE (IL-4), and differentiation of antigen-activated B cells into high-affinity plasma cells (IL-21).

ORGANIZATION OF PERIPHERAL LYMPHOID TISSUES

B lymphocytes enter the secondary lymphoid organs through defined ways. Each organ exhibits a preferred route of entry.[20] For example, most lymphocytes enter the spleen through the bloodstream, whereas lymphocytes enter lymph nodes and the Peyer patches through high endothelial venules. DCs, macrophages,

Marginal zone B cells bring antigen to the follicle

FIG 7.4 **T-Cell and B-Cell Compartments in the Murine Spleen.** T-cell compartments surround the central arterioles (periarticular lymphocyte sheath [PALS]). B cells are found in the adjacent follicles, where they are embedded in a network of follicular dendritic cells (FDCs). Marginal zone (MZ) B cells are located outside of the marginal sinuses, which mark the border of the white pulp and the red pulp.

and other highly specialized cells transport antigens from peripheral sites of entry into the secondary lymphoid organs. Within these organs, circulating lymphocytes survey available antigens (Chapter 6).

During ontogeny, the primary and secondary lymphoid organs are built up in an organized way.[21] This compartmentalization of the immune structures is essential for an efficient and controlled immune response. The establishment of the different immune compartments involves multiple factors. Among these, cytokines of the tumor necrosis factor superfamily (TNFSF), such as TNFα, lymphotoxin α (LTα), LTβ, and their receptors TNFR1 and LTβR, play important roles (Chapter 2). Chemokines also play an essential function in the organized development of the secondary lymphoid organs and the specific localization of immune cells (Chapter 10).[20]

In the secondary lymphoid organs, T cells and B cells are segregated into clearly defined areas, the T-cell zone and the B-cell follicle (Fig. 7.4). B cells are embedded into a network of highly specialized stromal cells, the follicular dendritic cells (FDCs). In contrast to other types of DCs, FDCs do not process antigen. Instead, FDCs have abundant complement receptors and Ig Fc receptors that allow accumulation of antigen in the form of immune complexes within the B follicle. Antigen presentation by FDCs is crucial for B-cell maintenance and for their activation and differentiation (see below).[22]

The Spleen

In the white pulp of the spleen, one can distinguish between a periarticular lymphatic sheath (PALS) of T cells and adjacent B-cell follicles.[23] In the murine spleen, the MZ is separated from the white pulp by the marginal sinus, the site of entry for lymphocytes, macrophages, and DCs into the splenic tissue. A specialized layer of metallophilic macrophages are thought to control the entry of antigen into the white pulp.[22] In the human spleen, one can distinguish an inner and an outer MZ. The latter is surrounded by a perifollicular area, where blood vessels terminate and thus facilitate the entrance of lymphocytes. Macrophages lining the ending of the capillaries help control the entry of antigen into the splenic tissue.

The splenic MZ provides a home for rapid B-cell responses. The ability of MZ B cells to rapidly respond to encapsulated bacteria by differentiating into antigen-specific plasma cells helps keep such infections under control. The MZ takes time to develop and is not present in young infants. It becomes fully populated with MZ B cells only after the age of 2 years. In the physiological absence of these B cells, a poor response to bloodborne infections is commonly observed.[24]

B-1 Cells

In addition to the MZ and conventional (B-2) subsets, differential expression of the cell-surface molecules IgD, CD5, CD11b/CD18, CD23, and CD45 in mice have allowed the identification of two additional peripheral B-cell subsets, B-1a, and B-1b.[25] “Conventional” B cells (B-2 cells) express high levels of IgM and IgD, whereas “CD5” B cells (B-1 cells) express minimal surface IgD. B-1 cells express little CD45 and virtually no CD23. They all express CD5 mRNA, although some display CD5 on their cell surface (B-1a) and some do not (B-1b).

B-1 cells seem to develop from distinct progenitors that represent a majority of B cells in fetal life. Accordingly, in mouse fetal liver, all B cells, and in fetal spleen, 40–60% of B cells are B-1 cells. Later in development, B-1 cells comprise <10% of the splenic IgM$^+$ B cells but are abundant in the peritoneal cavity.

Natural antibodies (NAbs) are IgM antibodies produced by B-1 cells. They are always found in serum and tend to have specificity for bacterial antigens as well as autoantigens. In general, they are polyreactive but of low affinity. Self-reactivity appears to play a major role in tissue homeostasis. NAbs also appear to provide an important and immediate defense against many infectious organisms.

The frequent presence of CD5 on chronic lymphocytic leukemia (CLL) B cells and their tendency to produce poly- and self-reactive antibodies led many to conclude that CLL was a leukemia of the human homologue of B-1 cells. When it became clear that CD5 was not a definitive marker for B-1 cells in humans, considerable effort was expended searching for this elusive subset. NAbs are present in human serum, but definition of the human B-1 subset remains controversial. Currently B cells that are CD2 $0^+CD27^+CD43^+CD70^-$ appear to be the best candidates.[4]

GERMINAL CENTERS

T cell–dependent activation of follicular B cells can induce the formation of a GC, which is the microenvironment where affinity maturation of the humoral immune response takes place. The interplay of hypermutation followed by antigen selection is the basis of affinity maturation. In the germinal center, B cells that express antibodies of high affinity are selected to develop into memory and long-living plasma cells.[26]

GCs develop only after T cell–dependent activation of B cells. Their full function is dependent on the interaction between CD40 expressed on B cells and CD40L (CD154) expressed on activated T cells. Patients with LOF mutations in CD40L have high serum levels of IgM and suffer from recurrent infections (hyper-IgM syndrome, Chapter 34).[27]

In a primary immune response, it takes about a week for the complex GC structure to develop. In the spleen, a few days after activation of antigen-specific B cells and T cells, small clusters of proliferating B cells are observed at the border of the T-cell zone and the primary B-cell follicle. The rapidly expanding B-cell clone seems to push the naïve B cells toward the edge of the primary follicle. The naïve B cells form a mantle zone around the newly developing GCs, and the primary follicle changes into a secondary follicle. Subsequently, the network of FDCs becomes filled with proliferating, antigen-activated B cells. An influx of antigen-activated Tfh cells is also observed. Tfh cells express the chemokine receptor CXCR5, which enable them to enter the B-cell follicle. During the GC reaction, expression of the chemokine CXCL13 by FDCs attracts both antigen-activated B and Tfh cells.[19]

In the second week after immunization, the GC matures into a classic structure that contains a dark zone and a light zone. At this stage of GC development, proliferation is restricted to the dark zone. Amidst the network of FDCs, the B cells differentiate into plasma cells and memory cells. In a fully developed GC, dividing cells are termed *centroblasts,* whereas differentiating cells within the FDC network are termed *centrocytes.*

In the dark zone, proliferating B cells activate a mechanism of SHM (Chapter 4).[28] This is a highly specific process that is targeted toward the gene segments that encode the antigen-binding domain of the antibody molecule. Hypermutation introduces single nucleotide changes into the rearranged variable genes of the Ig molecules. Thus within the dark zone, a clone of variants expressing antigen receptors with various affinities for the antigen is generated from a single B-cell progenitor. By chance, a few of these mutations result in a receptor with higher affinity for antigen. B cells expressing such receptors are favored for activation and proliferation, particularly late in an immune response when availability of antigen is limiting.

FDCs present antigen to B cells, but only those with high-affinity receptors are able to internalize the antigen via their BCR. Processing of the internalized antigen and presentation of peptides to Tfh cells are prerequisites for B-cell differentiation into memory and plasma cells.[19] Thus only the few B cells with high-affinity receptors get adequate help. IL-21 provided by the Tfh cells is crucial in this differentiation phase, and since it controls the fate of the GC B cell, it is essential for affinity maturation of the immune response.

B-CELL FUNCTIONS IN ADDITION TO ANTIBODY PRODUCTION

Mature B cells are not homogeneous. Functionally and developmentally distinct subsets exist. In the spleen, follicular B cells have a key role in the adaptive immune response, whereas MZ B cells are major players at the interface between the immediate innate immune response and the delayed adaptive response.[29]

B cells play an important function in the activation of T cells. Similar to DCs (Chapter 6), B cells can internalize antigen, process it, and the present antigen peptides to the T-cell receptor (TCR). In cancer, B cells can secrete tumor-associated autoantibodies and inflammatory cytokines and alter patterns of antigen presentation to T cells. Thus they can modulate T-cell and innate immune responses to the tumor. Through antigen–antibody complexes, B cells have the potential to influence immune cells that express Fc receptors, which include granulocytes and NK cells. In autoimmune diseases and also in response to inflammation, B cells can have an immune suppressive function. Regulatory B cells (Bregs) appear to exert their activity via the release of suppressive cytokines, such as IL-10, IL-35, and tumor growth factor-β (TGF-β).[30]

MOLECULAR MECHANISM OF SOMATIC HYPERMUTATION AND CLASS-SWITCH RECOMBINATION

Ig SHM and CSR are essential mechanisms for the generation of a high-affinity, adaptive humoral immune response. They allow the generation of effector plasma cells secreting high-affinity IgG, IgA, and IgE antibodies.

Somatic Hypermutation

Hypermutation occurs only during a narrow window in B-cell development. The mechanism is induced during B-cell proliferation within the microenvironment of the GC. With a high rate of about 10^{-3}/base pair/generation, single nucleotide exchanges are introduced in a stepwise manner into the rearranged V-region and its 3’ and 5’ flanking sequences. Mutations are randomly introduced, although there is a preference for transitions (cytidine → thymidine or adenosine → guanine) over transversions. Analysis of the pattern of somatic mutations has revealed that the sequence of the complementarity-determining regions (CDRs; Chapter 4), the loops that form the antigen-binding site, have been selected to form mutation hot spots.

Effective hypermutation requires the V-gene promoter and transcription-enhancer sequences. Indeed, the position of the V-gene promoter defines the start of the hypermutation domain, which spans about 2000 nucleotides. Any heterologous sequence that is introduced into the V gene segment locus will become a target of the hypermutation machinery. Thus SHM can sometimes play a role in lymphomas and leukemias, where oncogenes have been linked to Ig promoters and enhancers.

Class-Switch Recombination

Upon transition from the immature to the mature state and leaving bone marrow, the B cell starts to express IgD as well as IgM. Both IgM and IgD antibodies use the same V_HDJ_H-exon and

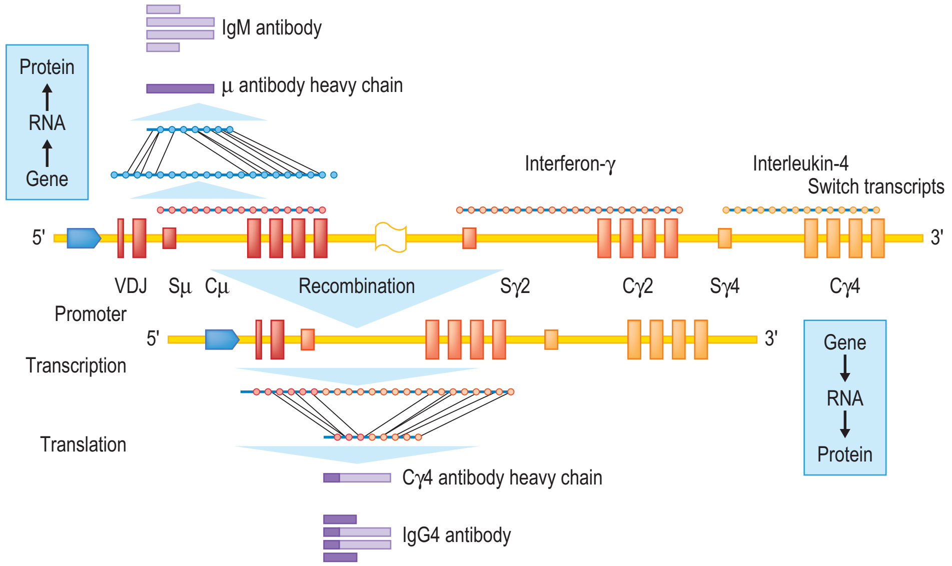

FIG 7.5 Antibody Class-Switch Recombination (CSR). Recombination between switch regions (Sµ and Sε) is preceded by transcription of these switch regions. Transcription is targeted by cytokines to distinct switch regions. IgM, Immunoglobulin M.

promoter (Fig. 7.5). The molecular basis of coexpression of IgM and IgD by the same B cell is attributed to differential termination of transcription and splicing of the primary transcripts. Although sequences have been identified that are required for the control of termination and splicing of the Cµ and Cδ transcripts, none of the proteins involved is known. The role of IgD remains unclear, but there are indications that IgM and IgD form different types of signal transduction structures on the cell surface. In mice, targeted inactivation of IgD has shown that it is not critical for B-cell activation and differentiation. However, IgD$^{-/-}$ B cells show a slightly reduced capability for affinity maturation.

Unlike IgD, the other antibody classes are not stably expressed together with IgM. B cells can switch from expression of their V_HDJ_H-exon with Cµ to expression of the same V_HDJ_H-exon with any of the downstream C_H genes (*e.g.,* $C\alpha_{1,2}$, $C\gamma_{1,2,3,4}$, or Cε) (Chapter 4). CSR, like SHM, is a hallmark of B-cell activation. It can be induced by T cell–independent signals (*e.g.*, lipopolysaccharide [LPS]) or by signals derived from T cells (*e.g.*, CD40L). CD40L-deficient humans (X-linked hyper-IgM syndrome [X-HIM]; Chapter 34) are severely impaired in the expression of Ig classes other than IgM.

TATA-less promoters located in front of the switch regions respond to signals from cytokines and B-cell activation–inducing ligands (*e.g.,* CD40L binding to CD40 on the B cell). These promoters initiate transcription just upstream of a small I-exon located between the promoter and the switch region. Transcription continues through the switch region itself and finishes after including the entire C_H gene sequence. Transcription is essential in targeting switch recombination to the transcribed switch region.

The choice of C_H gene targeted for switch recombination in a particular B cell appears to be dependent on external cytokine signals (Chapter 9). IFN-γ targets CSR to IgG2 in humans and IgG2a in mice, IL-4 to IgG4 and IgE in humans and IgG1 and IgE in mice, and TGF-β to IgA in both humans and mice. Other switch-targeting cytokines have been described, although our knowledge is far from complete. It is evident, however, that the cytokines central for the organization of cellular, humoral, and mucosal immunities, respectively, recruit exactly those classes of antibodies that provide the most useful functions for their respective branches of the immune system.

Both SHM and CSR Require Activation-Induced Cytidine Deaminase

Both CSR and SHM are dependent on an activation-induced cytidine deaminase (AID).[28] Mice deficient in this enzyme express only IgM antibodies without SHM, and patients with homozygous AID LOF mutations present with hyper-IgM syndrome (Chapter 34). Recently it was shown that DNA modifications are not limited to the rearranged V-region gene. As AID is active on single-stranded DNA (ssDNA), it may target all genes that are transcribed during the GC reaction. Subsequently, all DNA modifications, except the ones introduced into the rearranged V-region sequence, undergo repairs. As a result, retained SHMs are concentrated on the V-regions of the BCR alone.

Hypermutation is proposed to occur in two steps.[28] The mechanism is induced by AID-catalyzed deamination of deoxycytidine (C) to deoxyuridine (U). The mispairing of U and deoxyguanosine (G) is than processed by uracil DNA glycosylase and targeted by repair pathways. As a consequence, mutations at C–G pairs are observed. In the second step, mutations at A–T pairs are induced, probably during a mutagenic patch repair of U–G mismatches introduced by AID. A number of proteins, such as MSH2 and MHS6 (homologues 2 and 6 of the *Escherichia coli* MutS), polymerase η, or exonuclease-1, seem to be involved; however, the mechanism is not clear.

In CSR, AID is targeted to the switch regions located upstream (5') of each C_H gene. These switch regions are composed of 1–6 kilobase–long GC-rich repetitive sequence motifs. G–C pairs within these motifs are targeted by AID. Deamination of C and processing by uracil DNA glycosylase creates an abasic site that facilitates the introduction of double-stranded DNA (dsDNA) breaks. Joining and repair requires the presence of DNA-phosphokinases, Ku70, Ku80, and probably other members of the general double-strand repair mechanism (Chapter 4).

Both mechanisms, SHM and CSR, need to be tightly controlled, since the introduction of double-strand breaks into the DNA can not only pose a risk to the longevity of the B cell but also permit translocations involving and activating oncogenes.[31] For example, for Burkitt lymphoma cells and for plasma cell–derived myeloma cells, the translocation and ectopic expression of the *c-MYC* gene is an apparent consequence of abnormal SHM and CSR.

B-CELL MEMORY

One of the key features of the immune system is immunological memory for antigens encountered in the past. In humoral immune responses, there are two layers of memory, long-lived B memory cells and B effector cells (*i.e.*, plasma cells). The generation of these long-lived cells is dependent on antigen activation of B cells in the presence of T helper cells and thus the induction of germinal centers.

Memory B Cells

Although long-term protection of the organism is provided by both memory B and plasma cells, their contribution varies; some individuals are protected mainly by memory B cells, whereas others are primarily protected by plasma cells.[32] This can be of vital importance in special situations, such as transplantation, where activation of the immune system should be avoided. For example, treatment of transplant recipients with rituximab, an mAb specific for CD20, depletes memory B cells but has no effect on long-living plasma cells secreting transplant-specific antibodies.

After a lag-phase of 1–2 days, primary B-cell responses start with secreted low-affinity IgM antibodies. High-affinity antibodies of other Ig classes require the passage of time to be generated. In contrast, a second encounter with antigen induces a rapid development of memory B cells into new plasma cells, secreting antibodies of high quality (Fig. 7.6).

Plasma Cells

Protective humoral memory is provided by long-lived plasma cells.[33,34] These cells are generated in the secondary lymphoid organs and then migrate to bone marrow or to a site affected by inflammation. In bone marrow, plasma cells survive in highly specialized niches provided by the underlying reticular stromal cells. Here they can live on for long periods without further activation and proliferation, but their maintenance is dependent on survival factors, such as APRIL and IL-6. Eosinophils have been shown to be the main providers of these cytokines, and when they are depleted, plasma cells rapidly go into apoptosis.[35]

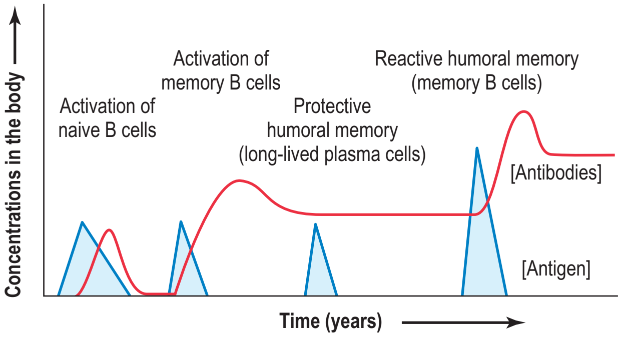

FIG 7.6 Active and Reactive B-Cell Memory. Memory B cells provide reactive memory, whereas long-lived plasma cells provide active protective memory. The relative concentrations of antibody and antigen over time are indicated.

By continuously secreting antibodies, long-lived plasma cells provide the individual with long-term humoral protection.

CLINICAL RELEVANCE

Abnormal B-Cell Development and Diseases of Immune Function

- Failure to generate B cells or a normal repertoire of antibodies leads to humoral immune deficiency, which is commonly marked by recurrent sinopulmonary infections.
- Failure to prevent the formation of antibodies with high avidity or high affinity to self antigens can lead to autoimmune diseases.
- The process of antibody repertoire diversification lends itself to the creation of mutations that can activate and modify oncogenes as well, leading to leukemia or lymphoma. Mechanisms include:
  - Recombinase activating gene (RAG)1/2-catalyzed juxtaposition of an oncogene to an immunoglobulin promoter or enhancer, activating the oncogene.
  - Activation-induced cytidine deaminase (AID)–induced DNA double-strand breaks and chromosome alterations.
  - AID-induced somatic hypermutation (SHM) of oncogene, altering its function.

ECTOPIC LYMPHOID TISSUE AND B-CELL DEVELOPMENT

In autoimmune diseases, in infection, and in tumors (cancer), ectopic lymphoid tissue can develop in the affected tissue or organ. Inflammatory cytokines and the presence of B cells can support the development of additional lymphoid tissue.[32]

The growth of ectopic lymphoid tissue in the rheumatoid synovium (Chapter 52) offers an excellent example of this disease-related phenomenon. In healthy individuals, the synovium is made up by a thin lining layer of synoviocytes. In contrast, in patients with rheumatoid arthritis, the diseased joint is highly infiltrated by varying numbers of T cells, B cells, plasma cells, macrophages, and DCs. In the majority of patients, these mononuclear cells are dispersed loosely throughout the synovium. However, well-organized, large lymphoid structures, which are similar in appearance to the lymphoid follicles seen in the secondary lymphoid organs, can develop in some patients.[32] At the center of these cell clusters, a network of FDCs are found. Antigen presented by FDCs appears to activate B cells, which induces proliferation. The central B cells are surrounded by a layer of T cells, which may support local B-cell differentiation. A central question concerns which antigens drive these immune responses and select B cells to differentiate into memory and plasma cells. The ectopic lymphoid tissue may function as additional lymphoid tissue. Equally likely, it may support a self-specific immune response. These questions remain topics of active investigation.

ON THE HORIZON

- Elucidation of the mechanisms used to control the antibody repertoire and shape B-cell epitope recognition offer the promise of being able to direct immunity toward production of broadly neutralizing or anti-tumorigenic antibodies, and away from pathogenic autoantibodies.
- Elucidation of the mechanisms that prevent the development of self-reactivity during affinity maturation could yield new insights into autoimmunity, as well as vaccination.
- A better understanding of the mechanisms that lead to long-lived plasma cells could lead to single, long-lasting vaccination strategies.

MULTIPLE-CHOICE QUESTIONS

1. The first quality control checkpoint for immunoglobulin H chain function occurs at what stage of B-cell development?
   A. ProB cells
   B. PreB cells
   C. Immature B cells
   D. Transitional B cells
   E. B-1 cells

2. Somatic hypermutation (SHM) occurs at what stage of B-cell development?
   A. ProB cells
   B. PreB cells
   C. B-1 cells
   D. Marginal zone (MZ) B cells
   E. Germinal center (GC) B cells

3. The best cell surface marker for B cells is:
   A. CD10
   B. CD19
   C. CD20
   D. CD21
   E. CD24

4. Which one of the following is a transcription factor critical for B-cell development?
   A. TdT
   B. PAX5
   C. LCK
   D. BLNK
   E. BTK

8

T-Cell Development

Laurie E. Harrington

T cells and B cells (Chapter 7) are the two major components of the adaptive immune system. T cells are instrumental for protective immunity to numerous pathogens, yet these cells are also linked to the pathogenesis of multiple autoimmune disorders. One aspect unique to T-cell development as opposed to other hematopoietic cells, including B cells, is the requirement for the thymus (Chapter 2). Defective generation of the thymus manifests as reduction in T-cell numbers and resultant T-cell immune deficiency (Chapter 35). T-cell development begins with hematopoietic stem cells (HSCs) in the fetal liver and later in bone marrow. T-cell progenitors then travel to the thymus, where they undergo a highly intricate and defined series of differentiation steps that ultimately culminate in the mature peripheral T-cell population. The process of T-cell development is dependent on several signaling events and cellular interactions. Ultimately this process provides the host with the diverse repertoire of T cells needed for the recognition of a wide array of ancient and novel antigens (Chapters 4 and 6) and for the subsequent generation of effective adaptive immune responses toward those antigens.

KEY CONCEPTS

Early T-Cell Development

- Peripheral T cells are the progeny of hematopoietic stem cells (HSCs) from bone marrow or fetal liver.
- T-cell development occurs in and requires the thymus.
  - Patients without a thymus as a result of *FOXN1* mutations or DiGeorge syndrome lack circulating T cells.
- Early thymic progenitors (ETPs) are the first cells to seed the thymus.
- T-cell lineage commitment requires:
  - Notch signals
  - Upregulation of lineage-defining transcription factors
  - Progression through the double negative (DN) stage
- T-cell formation requires production of functional αβ or γδ T-cell receptor (TCR)

THYMUS: THE SITE OF T-CELL DEVELOPMENT

T-cell development is dependent on the presence of the thymus. In its absence, the generation of T cells is severely impaired.[1] Whether the absence of a thymus is the result of a germline mutation or of surgical removal at the time of birth, peripheral T cells do not develop in mice that do not have a thymus. For example, *nude* mice lack a thymus and lack T cells. However, when bone marrow from *nude* mice is transplanted into mice with an intact thymus, T-cell development and function are restored. Similarly, the genetic disorder DiGeorge syndrome further exemplifies the central role of the thymus in T-cell development in humans. Patients who develop DiGeorge syndrome (Chapter 35) as a result of deletions in chromosome 22q11 and patients with the rare FOXN1 deficiency are both unable to generate a complete thymus, and both types of patients exhibit the immunodeficiency associated with decreased peripheral T cells. In both human conditions, transplantation of thymic tissue is able to restore T-cell development and function.[2,3] Collectively, these observations demonstrate the fundamental need for the thymus in the generation of mature, peripheral T cells.

The anatomy of the thymus provides the unique microenvironment necessary to support T-cell development. The thymus is home not only to T-cell precursors but also to various stromal cell populations, including endothelial cells, fibroblasts, and importantly thymic epithelial cells (TECs) that are fundamental to the selection of functional T cells. TECs are not hematopoietic in origin and require the transcription factor FOXN1 for development. This helps explain why FOXN1 is central to thymus organogenesis and T-cell development and why transplantation of the thymus, but not bone marrow, will overcome the T-cell defect caused by FOXN1 mutations.

The thymus is divided into outer and inner regions, which are termed *cortex* and *medulla,* respectively (Chapter 2). These distinct areas foster specific aspects of T-cell commitment and differentiation. This can be partially attributed to the TECs resident to those regions: cortical thymic epithelial cells (cTECs) and medullary thymic epithelial cells (mTECs). The cTECs and mTECs can be distinguished by their location within the thymus, the expression of certain proteins, and distinct cytokines and chemokines that facilitate development of a diverse repertoire of mature T cells and deletion of autoreactive T cells.

Development of T cells in the thymus is a precisely orchestrated process involving interactions with specific cell types in specific locations. (The molecular and cellular cues that shape T-cell development and selection will be discussed in detail later in this chapter.) T-cell precursors from the circulation first enter the thymus via vessels at the corticomedullary junction. Guided by cues from stromal cells, such as cTECs, these immature thymocytes traffic into the cortex area, where commitment to the T-cell lineage occurs. As thymocyte differentiation progresses through the double-negative (DN) stage, the cells migrate further into the cortex, to the subcapsular region. Upon rearrangement of the αβ T-cell receptor (TCR), double-positive (DP) thymocytes can be found interspersed in the cortex area, where interactions with cTECs mediate positive selection. The DP thymocytes that survive positive selection begin to downmodulate either the CD4 or CD8 coreceptor. This is accompanied by the movement of these cells into the medulla of the thymus. Once in the medullary region, interactions with mTECs support negative selection of the maturing T cells, ensuring the deletion of autoreactive T cells from the repertoire. Surviving single-positive (SP) thymocytes exit the thymus as mature T cells.

LINEAGE COMMITMENT

T-cell lineage commitment is the result of a stepwise developmental program that starts with HSCs in bone marrow.[4,5] These HSCs are already endowed with the potential to differentiate into T cells when directly transplanted into the thymus. However, these HSCs do not fulfill this fate because they lack the ability to migrate to the thymus. Hence, further differentiation is necessary.

THE COMMON LYMPHOID PROGENITOR

Early in ontogeny, a bifurcation event occurs that gives rise to the common myeloid progenitor (CMP) and the common lymphoid progenitor (CLP). The CLP produces T cells, whereas the CMP represents the first stage at which the potential for the T-cell lineage is extinguished. At the fate bifurcation event, a series of epigenetic modifications are established in the CMP, and they silence the lymphoid differentiation program in the cells and further imprint erythroid, granulocyte, and myeloid potential.[6] In contrast, the CLP program enables its progeny to develop into T cells, B cells, natural killer (NK) cells, or dendritic cells (DCs). Again, however, T-cell commitment will only occur following entry to the thymus, whereas B-cell, NK-cell, or DC differentiation occurs in bone marrow and fetal liver without the need for migration.

Migration into the thymus is not a random event; hematopoietic precursor cells utilize specific homing molecules to facilitate this process. A fraction of the circulating CLP subset expresses the chemokine receptors CCR7 and CCR9, as well as the homing molecule P-selectin glycoprotein ligand-1 (PSGL-1). It is these molecules that enable the recruitment of circulating CLP cells to the thymus.[4]

The Early Thymic Progenitor

The first hematopoietic cell to seed the thymus is termed the early thymic progenitor (ETP) cell. ETP cells do not take up permanent residence in the thymus. Thus they must be continually generated from HSCs in bone marrow. Upon entry into the thymus, the B-cell potential of this cell population is extinguished. However, it still retains some level of multipotency in that it can differentiate into NK cells and some myeloid cell populations as well as T cells.

Double-Negative Thymocytes

In the thymus, T-cell development progresses from the ETP in a highly structured order that is marked by the expression of a particular set of surface molecules (Fig. 8.1).[7] The earliest stages in this process are characterized by the absence of CD3, CD4, and CD8 expression on the surface of maturing thymocytes. CD3 is composed of four distinct chains: CD3γ, CD3δ, and two CD3ε chains. Together, this heterotetramer associates the TCR and the ζ chain (zeta chain) to generate an activation signal in T lymphocytes. The TCR, ζ-chain, and CD3 molecules together constitute the TCR complex. CD4 is a coreceptor that assists TCR with binding to major histocompatibility complex (MHC) class II peptide complexes on the cell surface of antigen-presenting cells (APCs). CD8 is a coreceptor that assists the TCR with binding to MHC class I peptide complexes on the surface of most nucleated cells in the body. CD3$^-$CD4$^-$CD8$^-$ cells are termed *DN cells* in reference to the absence of CD4 and CD8.[5]

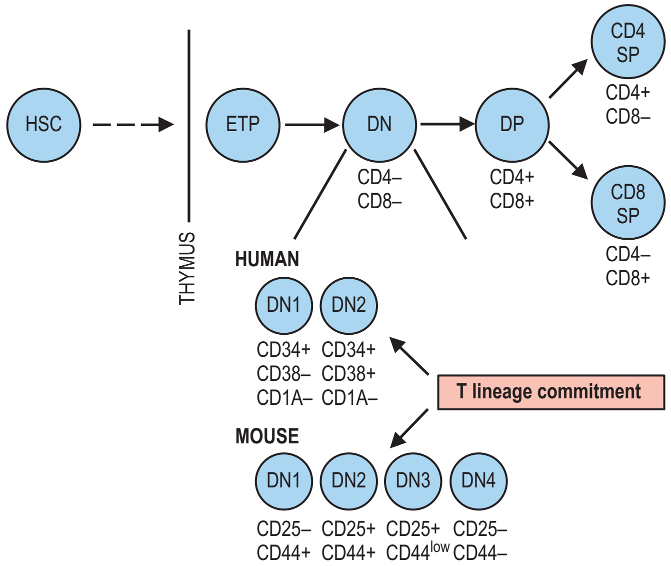

FIG 8.1 **Stages of Thymocyte Development.** T-cell development in the thymus is marked by the progression of cells through distinct stages of differentiation. The stages are defined by the presence of specific cell-surface molecules that are known to correspond with defined epigenetic and transcriptional changes. The double-negative (DN) thymocyte stage is slightly different between humans and mice, and a simplified depiction of this is shown.

KEY CONCEPTS

Double-Negative (DN), Double-Positive (DP), and Single-Positive (SP) Thymocytes

- Progressive stages of thymocyte development are identified by the expression profiles of CD4 and CD8 coreceptors.
- DN (CD4$^-$CD8$^-$) thymocytes give rise to DP (CD4$^+$CD8$^+$) and then SP (CD4$^+$CD8$^-$ or CD4$^-$CD8$^+$) thymocytes.
- CD4 and CD8 T-cell lineage determination is coordinated by the major histocompatibility complex (MHC) recognition of the T-cell receptor (TCR).
- MHC class II restriction leads to CD4 T cells, and MHC class I restriction leads to CD8 thymocytes, which then leave the thymus to become mature CD4 or CD8 T cells.

Cells of the DN phenotype are quite heterogeneous. In mice, differential surface expression of CD44 and CD25 can be used to divide these cells into four distinct stages. CD44 is a broadly distributed cell surface protein thought to mediate cell attachment to extracellular matrix (ECM) components or specific cell-surface ligands, including hyaluronate and chondroitin-4 and -6 sulfates. It thus plays a role in matrix adhesion, lymphocyte activation and lymph node homing. CD25 is the interleukin-2 (IL-2) receptor α (IL-2RA) chain. Homodimeric α chains (IL-2RA) create a low-affinity receptor for IL-2. CD25 can create a high-affinity receptor for IL-2 when associated with CD122, the IL-2 receptor β chain (IL-2RB), and CD132, the IL-2 receptor γ chain (IL-2RG). IL-2RG is also termed the common γ chain (γ_C), and it can contribute to IL-4, IL-7, IL-9, IL-15, and IL-21 receptor complexes in addition to IL-2. Activation of the IL-2 receptor pathway promotes T-cell proliferation.

In mice, CD44 DN1 cells express CD44 but not CD25 ($CD44^+CD25^-$). Thus they are primed for binding to ECM components or specific cell-surface ligands, but not for cell proliferation. DN2 cells express both CD44 and CD25 ($CD44^+CD25^+$) and are thus primed for location and proliferation. DN3 cells express low levels of CD44 and are positive for CD25 ($CD44^{lo}CD25^+$). They are thus more mobile while still being primed for proliferation. Finally, DN4 cells lack both CD44 and CD25 expression ($CD44^-CD25^-$).[8]

In humans, the DN precursor cell population can be segregated on the basis of expression of CD34, CD38, and CD1a into two stages, DN1 and DN2. The DN1 less mature precursors being ($CD34^+CD38^-CD1a^-$), whereas the DN2 more mature DN cells express CD34, CD38, and CD1a ($CD34^+CD38^+CD1a^+$).[8] CD34 is a cell-surface glycoprotein that can mediate the attachment of stem cells to the ECM or directly to stromal cells. CD38 is also known as cyclic adenosine diphosphate (cADP) ribose hydrolase. It is a glycoprotein that also functions in cell adhesion, as well as in signal transduction and calcium signaling. Unlike most MHC class I genes, which are located on the short arm of chromosome 6 within the MHC (Chapter 5), the CD1 genes are a nonpolymorphic cluster of MHC class I–like genes on human chromosome 1. CD1a molecules associate with the β_2 microglobulin and present antigen to T cells through their TCRs (Chapter 4). However, instead of peptides, CD1a molecules bind and present lipid and glycolipid antigens.

Commitment to the T-cell lineage is solidified in thymocytes of the DN phenotype. In mice, lineage commitment occurs during the DN2 to DN3 transition,[5] whereas T-cell lineage commitment is associated with the $CD34^+CD38^+CD1a^+$ population of thymocytes in humans.[8] Rearrangement of the TCR β, γ, and δ loci can be detected at this stage (Chapter 4). The pre-TCR is expressed by αβ T-cell precursors to test for TCRβ structural integrity; and, most importantly, the cells that pass this checkpoint stage no longer retain the ability to differentiate into other hematopoietic lineages.

Fate Commitment

After the cells pass through the DN stage, most of the T lineage–committed thymocytes will follow one of two fates. A minor fraction of these cells will express a functional γδ TCR on the surface and be exported into the periphery. But the bulk of the DN cells will begin to coexpress both CD4 and CD8 on the cell surface.[5,7] The $CD4^+CD8^+$ DP thymocytes constitute the majority of cells in the thymus. These are the precursors to the αβ T-cell lineage. It is at this stage of development that T-cell progenitors finalize the αβ TCR pairing through rearrangement of the TCR α loci and then initiate processes (positive and negative selection) to eliminate cells with nonproductive or autoreactive TCRs. Less than 5% of the DP thymocytes survive the selection processes, and the cells that endure downmodulate one of the two coreceptors from the cell surface, yielding either CD4 or CD8 SP thymocytes. After this stage of development, the SP cells are exported from the thymus and enter the periphery as mature CD4 or CD8 T cells.

TRANSCRIPTIONAL REGULATION OF COMMITMENT TO T-CELL LINEAGE

Notch

T-cell development is dependent on a number of molecular interactions and signaling events mediated by the cells resident to the thymus.[7,9] Among these, the Notch signaling pathway is integral to the generation of T cells.[5,10,11] The highly conserved Notch signaling pathway is known to dictate cell-fate decisions in numerous biological systems. Notch receptors are transmembrane molecules. In mammals, there are four members in the Notch family (Notch1–4). Of these, Notch1 expression plays a crucial role in T-cell progenitors.

Notch Ligand

Of the two types of Notch ligands, experimental evidence indicates that the δ-like (DL) family ligands function primarily during T-cell development. Upon interaction with its ligand, Notch receptors undergo a proteolytic cleavage event that releases the intracellular portion of the molecule. This portion then translocates into the nucleus to mediate transcription of target genes. Using elegant *in vitro* systems to dissect the factors that drive T-cell development, it has been determined that Notch signaling is critical for commitment to the T-cell lineage.[12] Ligation of Notch1 on hematopoietic progenitors by OP-9 cells expressing DL1, as well as by overexpression of active Notch1 in the progenitor cells, promotes T-cell development and suppresses B-cell development. Conversely, deletion of Notch1 expression in hematopoietic precursor cells prevents the development of T cells in the thymus and instead allows the emergence of immature B cells at this anatomical site.[13] Notch signaling alone does not commit a cell to the T-cell lineage, but it works with other transcription factors to imprint the T-cell fate. Importantly, some of the transcription factors are targets of active Notch in the cells.

T-Cell Factor 7

Notch target genes that encode molecules critical for T-cell commitment include the transcription factors T-cell factor-7 (TCF-7) and the TCF-7 splice variant TCF-1, which are both encoded by the *Tcf7* gene.[14,15] TCF1 is highly expressed in the ETP population in the thymus and deletion of *Tcf7* results in a reduction in these cells. Overexpression of TCF-1 in progenitor cells upregulates the expression of genes linked to the T-cell lineage and restores T-cell development even in the absence of Notch signaling. Hence, TCF-1 is necessary for initiating T-cell lineage development.

Enhancer Binding Protein GATA-3

Another transcription factor regulated by Notch signaling and necessary for T-cell development is GATA-binding protein 3 (GATA-3). GATA-3 is a zinc-finger transcription factor that is required during multiple stages of T-cell development, as well as in T-cell function. GATA-3 is expressed as early as the ETP stage and is critical for the development of this cell population. Loss of GATA-3 does not perturb the early stages of hematopoiesis, including the CLP stage of development, but does yield few, if any, ETPs, indicating a nonredundant function for GATA-3 in promoting T-cell development. As cells progress from the ETP stage to the DP stage, GATA-3 expression is maintained, and this transcription factor is known to have distinct functions in the various steps of T-cell development, including CD4 T-cell delineation.[16]

B-Cell Chronic Lymphocytic Lymphoma/Lymphoma 11B (Bcl11b)

Although Notch, TCF-1, and GATA-3 are all essential in promoting the T-cell lineage, an additional molecule, the transcriptional repressor Bcl11b, is important in suppressing alternative fates. Bcl11b is only expressed in T-cell progenitors, and it is not expressed in other hematopoietic cells. This molecule is upregulated as early as the DN2 stage of differentiation. It is necessary for T-lineage commitment, but it does not control the expression of many T lineage–specific genes.[17,18] Bcl11b is necessary to suppress the myeloid potential in the developing T-cell progenitors, and interestingly, in mice, deletion of Bcl11b from T-cell progenitors results in the cells adopting an alternative NK cell phenotype.[19]

T-CELL RECEPTOR REARRANGEMENT AND β SELECTION

One key step in T-cell lineage commitment is rearrangement of a functional TCR, be it an αβ or γδ TCR.[7] Rearrangement of the TCR gene loci within the developing thymocyte is a highly ordered sequence of recombination events mediated by the recombinase activating gene (RAG) enzymes (Chapter 4). RAG proteins are induced early in DN thymocytes and initiate recombination of the TCR γ, δ, and β genes. VDJ (or VJ) recombination of these loci must yield successful, in-frame rearrangements or the cell will stall at this stage and die.

γδ T cells

For cells of the γδ T-cell lineage, signaling via the newly rearranged γδ TCR complex directs the maturation and export of the γδ T cell into the periphery. This developmental checkpoint is critical for the selection of the γδ T-cell repertoire and, if unsuccessful, the thymocytes may either die or be redirected to the αβ lineage.

αβ T cells

For cells that will enter the αβ T-cell compartment, the developmental checkpoints are distinct from that of γδ T cells. Upon productive rearrangement of the TCR β gene, this protein will pair with preT α chain (surrogate α chain) to create the pre-TCR complex. The pre-TCR complex associates with the CD3 molecules and induces constitutive signaling within the cells.

β Selection and the Appearance of Double-Positive Thymocytes

Signaling by the pre-TCR complex in DN thymocyte facilitates the process of β selection, which instructs the cell to undergo a burst of proliferation and suppresses further β–chain rearrangement. After β selection, the thymocytes will begin to coexpress both CD4 and CD8 on the cell surface. These cells are termed DP cells. They subsequently initiate recombination of the TCR α gene loci. As a result of the organization of the TCR α loci, DP thymocytes have multiple opportunities to generate a successful TCR α rearrangement. Consequently most DP thymocytes express an αβ TCR. Only a fraction of these cells will progress into the periphery as CD4 or CD8 SP T cells.

KEY CONCEPTS

Positive Selection and Negative Selection

- Positive selection promotes the survival of double-positive (DP) thymocytes whose αβ T-cell receptor (TCR) can interact with MHC–self peptide complexes expressed by the thymic cortical epithelial cells.
- Negative selection deletes self-reactive T cells from the repertoire by inducing apoptosis in thymocytes expressing an αβ TCR with high affinity for self peptides, promoting central tolerance.

POSITIVE AND NEGATIVE SELECTION

Following the productive rearrangement and pairing of an αβ TCR, the DP T-cell precursor must pass through multiple checkpoints in the thymus before the cell can be released into the periphery. These processes, termed *positive selection* and *negative selection,* aim to eliminate T-cell clones expressing self-reactive, as well as unnecessary, nonfunctional αβ TCRs from the host.[20] This is critical, as rearrangement of both the α and β TCR genes occurs independent of MHC and antigen (Chapter 5). Therefore the antigen-specificity and the MHC restriction of any given αβ TCR pair are not predetermined. During both positive selection and negative selection, the ability of the αβ TCR pair to interact with peptide–MHC complexes is tested (Chapter 6), and the strength of the reaction determines the fate of the cell.

Positive Selection

Positive selection refers to the ability of the αβ TCR on the DP thymocyte to interact with self peptide–MHC complexes expressed by the cortical epithelial cells of the thymus.[20] If the αβ TCR is unable to bind the peptide–MHC complex, the DP thymocytes will not receive the appropriate signal and thus die by neglect in a matter of days. This is the fate of the majority of DP thymocytes for two main reasons: MHC alleles are highly diverse, and rearrangement of both α and β TCR genes is random. The combination of these two factors does not favor the generation of an αβ TCR pairing capable of binding the peptide–MHC complex with appropriate affinity.[21] If, however, the interaction is successful, the cell is rescued from programmed cell death. Positive selection has been demonstrated experimentally in mice that are genetically engineered to express a single αβ TCR with a known antigen-specificity and MHC restriction.[22] In mice that express the αβ TCR transgene and the correct MHC allele in the thymus, positive selection will proceed, and mature SP T cells will be exported into the periphery. In contrast, if the mice do not express the appropriate MHC allele, the αβ TCR transgenic DP thymocytes will fail positive selection and die by neglect in the thymus.

Importantly, the positive selecting MHC molecule, be it MHC class I or MHC class II, dictates expression of the corresponding CD8 or CD4 coreceptor that will be retained by the DP thymocyte as it matures (Fig. 8.2). In mice that lack MHC class I complexes, selection of CD4 SP cells proceeds normally, but CD8 SP cells are not generated.[23,24] Likewise, in mice deficient in MHC class II expression, CD8 SP cells develop and mature, but CD4 SP cells do not.[25,26] Notably, positive selection of DP thymocytes cells can be rescued in MHC-deficient hosts by restricting MHC expression to the thymic cortical epithelial cells, and this demonstrates the crucial role of MHC and the cortical epithelial cells of the thymus in regulating T-cell development.

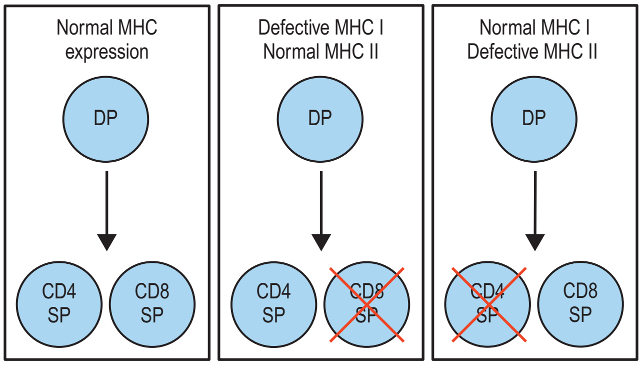

FIG 8.2 **Positive Selecting Major Histocompatibility Complex (MHC) Dictates CD4/CD8 Coreceptor Expression.** Positive selection in the thymus is determined by the ability of the αβ T-cell receptor (TCR) to bind to MHC. Upon selection, the immature T cell must coordinate expression of the CD4 or CD8 coreceptor with that MHC. If the thymocyte is positively selected by a class I MHC–peptide complex, the T cell will utilize the CD8 coreceptor. Conversely, if the double-positive (DP) thymocyte is positively selected by a class II MHC–peptide complex, the developing T cell will maintain expression of the CD4 coreceptor. SP, Single-positive.

Negative Selection

Positive selection ensures that the αβ TCR expressed by a DP thymocyte is capable of interacting with MHC, whereas negative selection is the means by which an immature T-cell clone encoding a self-reactive αβ TCR is eliminated from the host.[20] In a seminal experiment, negative selection was validated by using transgenic mice engineered to express an αβ TCR specific for the male antigen encoded by the Y chromosome (Fig. 8.3).[27] In female mice expressing the male-specific TCR, T-cell development proceeded normally. However, in male mice with the same TCR transgene, T-cell development was aborted at the DP stage, and no SP T cells emerged from the thymus. The different outcomes are the direct result of the presence or absence of self-antigen recognition, in this case the male antigen, by the αβ TCR in the thymus. The deletion of self-reactive T-cell clones mediated by negative selection is key to establishing *central tolerance.*

During negative selection, self antigens are displayed by the MHC on the surface of thymic epithelial cells and in the cortex and the medulla, or thymic-resident, bone marrow–derived DCs and macrophages. The self antigens presented in the thymus encompass ubiquitously expressed proteins, as well as tissue-restricted proteins, such as insulin. The expression of some tissue restricted antigens in the thymus is mediated by the autoimmune regulator (AIRE).[28] Humans who possess mutations in *AIRE* develop the autoimmune disease autoimmune polyendocrinopathy with candidiasis and ectodermal dysplasia (APOCED) (Chapter 50).[29] In mice, *Aire* deficiency also results in tissue-specific autoimmune disease.[30,31] Hence, the breadth of self antigens presented in the thymus during negative selection directly impacts the deletion of autoreactive αβ T-cell clones, thereby influencing autoimmunity.

Role of the Major Histocompatibility Complex in Negative Selection and Positive Selection

The processes of positive and negative selection are highly sensitive to the degree by which the TCR interacts with self peptide–MHC complexes. Weak interactions with peptide–MHC complexes are necessary to protect the developing T cells from death by neglect and promote the positive selection of the cells. However, an interaction with the peptide–MHC complex that is too strong induces negative selection, causing the cells to die via apoptosis. Nevertheless cells do escape this process, and self-reactive cells can thereby enter the periphery. Interestingly, the current concept is that regulatory T cells (Tregs) have a TCR that can bind with higher affinity to the selecting peptide–MHC complexes, inferring the self-reactivity of this particular subset of cells.

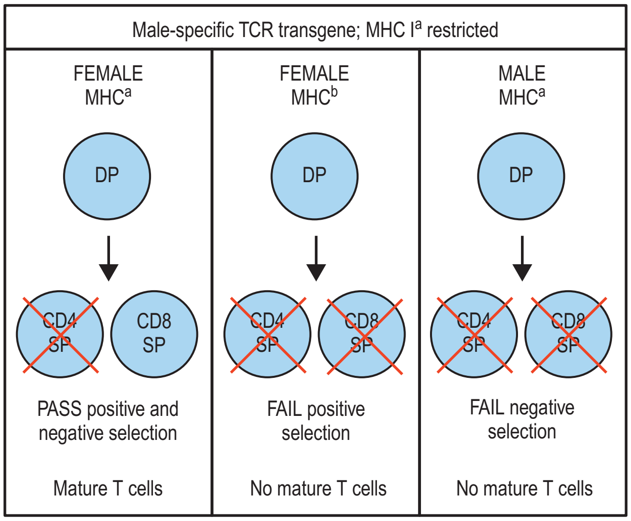

FIG 8.3 **Positive Selection and Negative Selection of Double-Positive (DP) Thymocytes Is Driven by Major Histocompatibility Complex (MHC) Restriction and Self Antigen Recognition.** The study of T-cell receptor (TCR) transgenic mice has yielded considerable insight into the processes of positive selection and negative selection. Positive selection will only occur if an MHC allele capable of binding the appropriate peptide and the transgenic TCR is expressed in the thymus. If the mice do not express an MHC molecule that will bind both the peptide and the TCR, the cells will die via apoptosis (middle panel). Negative selection will delete cells that possess a TCR with too high an affinity for self-antigen in the context of MHC (right panel). SP, Single-positive.

CD4 AND CD8 T-CELL DETERMINATION

Transition From Double-Positive to Single-Positive CD4 or CD8 Thymocytes

The final stage in T-cell development prior to exit from the thymus is transition of the DP thymocyte into the immature, SP CD4 or CD8 T-cell pool. The developing αβ T cell must coordinate expression of the CD4 or CD8 coreceptor with the corresponding MHC molecule, hence the CD4 versus CD8 decision is made during positive selection. Currently a kinetic model of TCR signaling is proposed to govern the CD4/CD8 determination. This model purports that CD4 T cells require a longer period of TCR signaling compared with CD8 T cells. When the DP thymocyte interacts with the MHC on thymic cortical epithelial cells, the CD8 molecule is transiently downmodulated. If the TCR–MHC interaction is sustained, this selects CD4 SP cells. However, if the TCR–MHC interaction is limited, the thymocyte will reexpress CD8 on the cell surface and repress CD4 expression.

Factors That Dictate CD4 Versus CD8 Commitment

Extensive research is being performed to understand the mechanisms and factors that dictate the CD4/CD8 decision. There are known transcription factors that facilitate this process and are necessary for the differentiation of functional CD4 and CD8 T cells.[7] Two transcription factors identified as being key to enforcing the CD4 and CD8 T-cell lineages are T-helper–inducing POZ-Kruppel factor (ThPOK) and Runt-related transcription factor 3 (Runx3), respectively. These molecules function to counterregulate each other. ThPOK promotes CD4 T-cell commitment and silences CD8 T-cell development, in part by repressing expression of Runx3.[16,32-34] Conversely, Runx3 is essential for CD8 T-cell generation and silences CD4 expression in these cells.[35] Importantly, these two transcription factors are necessary, but not sufficient, to induce CD4 and CD8 SP cells, and other factors, including GATA-3, are critical in this decision.[16]

Migration of Thymocytes Into the Periphery

Upon maturation, specific proteins facilitate the migration of CD4 and CD8 SP T cells from the thymus. One molecule responsible for certain aspects of the thymic egress process is the transcription factor Kruppel-like factor 2 (Klf2).[36] Klf2 is increased after positive and negative selection in SP cells and drives the expression of sphingosine 1 phosphate receptor 1 (S1P1) and L-selectin. Upregulation of S1P1 on the maturing T cells is necessary for migration from the thymus, as mice deficient in S1P1 have significantly reduced numbers of circulating peripheral T cells because the cells are unable to exit the thymus.[37] L-selectin is involved in the recruitment of the newly emerged T cells to lymph nodes. L-selectin interacts with various ligands, including GlyCAM-1 and CD34, expressed by the high endothelial venules in the lymph nodes to coordinate movement of the cells into the secondary lymphoid organs.[38] Together, these molecules, as well as others, deliver mature CD4 and CD8 T cells to the lymph nodes where these cells can function in adaptive immune responses.

ON THE HORIZON

- Deducing how the T-cell receptor (TCR) senses major histocompatibility complex (MHC) class I versus MHC class II and coordinates the expression of the appropriate CD8 or CD4 coreceptor, respectively
- Understanding additional molecular events that facilitate negative selection of tissue-specific antigens in the thymus
- Better tools and markers to study αβ T-cell development and the acquisition of innate-like functions prior to thymic export
- Developing strategies to combat thymic involution with age and increase T-cell development, especially following bone marrow transplantation

MULTIPLE-CHOICE QUESTIONS

1. The process of positive selection ensures that the developing T cell can interact with the corresponding major histocompatibility complex (MHC) molecules with appropriate affinity. How does the process of negative selection impact the maturing T cell?
   - **A.** Negative selection refers to the inability of the rearranged T-cell receptor (TCR) to interact with the MHC.
   - **B.** Negative selection induces the deletion of maturing T cells that express the inappropriate CD4 or CD8 coreceptor.
   - **C.** Negative selection induces apoptosis in the maturing T cells that recognize self antigen with high affinity.
   - **D.** Negative selection induces proliferation in maturing T cells that recognize self antigen with high affinity.
   - **E.** Negative selection promotes expression of the CD4 or CD8 coreceptor in the developing T cells.

2. DiGeorge syndrome is a rare genetic disorder, which results in immunodeficiency in some patients. Why does this group of patients have defects in T-cell development?
   - **A.** These patients have a mutation in the gene *FOXN1* and do not develop a thymus.
   - **B.** These patients have a deletion on chromosome 22 and do not develop a thymus.
   - **C.** These patients have a mutation in the gene *AIRE* that prevents T-cell export from the thymus.
   - **D.** These patients have a mutation in the gene that encodes the sphingosine 1 phosphate receptor 1 (S1P1), which results in failure to export T cells from the thymus.
   - **E.** These patients have a mutation in the *RAG* gene that prevents rearrangement of a functional TCR.

3. During T-cell development in the thymus, early thymic progenitors progress through a sequential series of events that culminates in a mature T cell. How do these processes differ between humans and mice?
   - **A.** In humans, the double-negative (DN) subset of thymocytes comprises the DN1 and DN2 stages, whereas in mice the DN subset consists of the DN1, DN2, DN3, and DN4 stages.
   - **B.** In humans, T-cell lineage commitment occurs at the double-positive (DP) stage of development, whereas in mice lineage commitment occurs in the DN stage.
   - **C.** In mice, surface expression of CD1A is used to discriminate the DN stages, whereas in humans surface expression of CD44 and CD25 distinguishes cells in the DN stages.
   - **D.** In humans, the DN subsets of thymocytes comprises the DN1, DN2, DN3, and DN4 stages, whereas in mice the DN population consists of the DN1 and DN2 stages.
   - **E.** There are no known differences in T-cell development between humans and mice.

Cytokines and Cytokine Receptors

John J. O'Shea, Massimo Gadina, Richard M. Siegel

Cytokines play pivotal roles in controlling the development and function of a variety of immune and nonimmune cells. These include immune regulation, disease pathogenesis, and, increasingly, modulation and treatment of immune-mediated diseases. The term *cytokine* encompasses factors that are structurally or functionally unrelated. Included among cytokines are a number of different factors produced by lymphoid and nonlymphoid cells that mediate intercellular communication. The term *lymphokines* was originally used to denote products of lymphocytes,[1] whereas the term *interleukin* was introduced to emphasize the importance of these factors in communication between leukocytes.[2] Although the designation *interleukin* has remained in use, it is inaccurate in that some cases individual interleukins are made by cells other than leukocytes.

Because of the way they were discovered, the complex nomenclature and classification that have developed can be a barrier to understanding cytokines. Many were first identified by researchers in different disciplines, and they were named on the basis of their original observed functions, which may not necessarily reflect the full spectrum of an individual cytokine's actual biological functions.

Cohen et al.[3] coined the word *cytokine* to emphasize the point that these factors need not be made by one specific cell source. This was an important insight because many immunologically relevant cytokines are made by nonlymphoid cells. Cytokines are thus defined operationally as polypeptides secreted by leukocytes and other cells that act principally on hematopoietic cells, the effects of which include modulation of immune and inflammatory responses. However, there are clear exceptions to even this broad definition. Some definitions distinguish cytokines from hormones and growth factors, which act on nonhematopoietic cells.

Cytokines are typically characterized as factors made by more than one cell type that act locally, whereas hormones are secreted by specialized cells and act at a distance on a restricted set of target cells. Although many cytokines act locally in an autocrine or paracrine fashion, some do enter the bloodstream and can act in a typical endocrine fashion. Consequently, the boundary between cytokines and hormones is rather indistinct. In fact, classic hormones, such as growth hormone (GH), prolactin (PRL), and erythropoietin (EPO), and a more recently identified hormone, leptin, are all clearly cytokines, as evidenced by the structure of their receptors and their modes of signaling. Perhaps it is just simplest to accept that cell–cell communication and host defense went hand-in-hand during evolution, and so functional and structural similarities exist among families of molecules that act on the immune, hematopoietic, endocrine, and nervous systems.

KEY CONCEPTS

Cytokine Characteristics

- Cytokines have pleiotropic effects: they may have more than one receptor.
- Cytokines can be redundant—their receptors often share subunits.
- Cytokines can have specific and unique functions—their receptors typically have ligand-specific subunits as well.

CYTOKINE CLASSIFICATION

A major challenge in discussing cytokines is how best to classify them. One can legitimately group cytokines in different ways, but here, we classify cytokines on the basis of the type of receptor that they bind. Our scheme emphasizes the evolutionary relatedness of cytokines, growth factors, and hormones and highlights the similarities in signal transduction. The classification used is adapted from Vilcek[4] and includes the following receptors: the so-called type I (hematopoietin family) and type II (interferon family) cytokine receptors, tumor necrosis factor (TNF) family receptors, interleukin (IL)-1 receptor and the related Toll-like receptors (TLRs), IL-17 receptors, receptor tyrosine kinases, and the transforming growth factor-β (TGF-β) family receptor serine kinases (Table 9.1; Fig. 9.1). A sixth group, known as chemokines, form a separate family and bind seven transmembrane domain receptors (Chapter 10). This chapter reviews in detail only a selected set of cytokines with important immunological functions (Fig. 9.2).

TYPE I AND II CYTOKINE RECEPTORS (HEMATOPOIETIN FAMILY AND INTERFERON RECEPTORS)

Ligand and Receptor Structure

Cytokines (see Table 9.1) that bind the class of receptors, termed *type I* or *hematopoietic cytokine receptor superfamily,* include hormones, such as EPO, thrombopoietin (TPO), PRL, GH, and leptin; colony-stimulating factors (CSFs), such as granulocyte–colony-stimulating factors (G-CSFs), granulocyte macrophage–colony-stimulating factors (GM-CSFs); and IL-2–IL-7, IL-9, IL-11–IL-13, IL-15, IL-21, IL-23, IL-27, IL-31, and IL-35. Also included in this family are ciliary neurotrophic factor (CNTF), leukemia inhibitory factor (LIF), oncostatin M (OSM), and cardiotropin 1 (CT-1). Closely related are the interferons (IFN-α, -β, -τ, -ω, limitin) and IL-10-related cytokines,

TABLE 9.1 Cytokines Classified by Receptor Families

Receptor Family	Cytokine	Signaling	Source	Target	Action	Knock-out Phenotype
Type 1 (hemato-poietin)	GH	Janus kinase (JAK)2, signal transducer and activator of transcription 5b (STAT5b)	Two growth hormone (GH) genes, pituitary, placental	Diverse tissues	Growth, adipocyte differentiation	Dwarfism
	Prl	JAK2, STATa	Two *Prl* genes pituitary, uterus	Mammary epithelium	Growth, differentiation	Infertility, lactation defects
	Erythropoietin (EPO)	JAK2, STAT5	Kidney, liver	Erythroid precursors	Erythroid differentiation	Embryonic lethal, severe anemia
	Thrombopoietin (TPO)	JAK2, STAT5	Liver, kidney	Committed stem cells and megakaryocytes	Platelet	Severe thrombocytopenia
	Leptin	JAK2/STAT3	Adipocytes	Hypothalamus, thyroid	Satiety, controls metabolic rate	Obesity
	Granulocyte–colony-stimulating factor (G-CSF)	JAK2, STAT3	Many tissues, macrophages, endothelium, fibroblasts	Committed progenitors	Differentiation, activates mature granulocytes	Neutropenia
	Interleukin (IL)-6	JAK1, STAT3	Macrophages, fibroblasts, endothelium, epithelium, T cells, other	Liver, B cells, T cells, thymocytes myeloid cells, osteoclasts	Acute-phase reactants proliferation, differentiation, costimulation	Reduced immunoglobulin (Ig), especially IgA; T lymphopenia; impaired acute-phase response; and T-helper 17 (Th17) cells
	IL-11	JAK1, STAT3	Stromal cells, synoviocytes, osteoblasts	Hematopoietic stem cells, hepatocytes, macrophages, neurons	Proliferation	Female infertility
	IL-27	JAK1, STAT1, STAT3, STAT4, STAT5	Activated dendritic cells (DCs), macrophages, epithelial cells	T cells and natural killer (NK) cells, other cells	Enhancement of Th1 responses, and IL-10; inhibition of Th1, Th2, and Th17 responses	Fatal inflammatory disease with infection
	IL-31	JAK1, STAT3, STAT5	Th2 cells CD8 T cells	Monocytes, epithelial cells, keratinocytes, eosinophils basophils	Induces chemokines, PMN recruitment	
	Ciliary neurotropic factor (CNTF)[a]	JAK1, STAT3	Schwann cells	Neuronal	Survival	Progressive atrophy and loss of motor neurons
	Leukemia inhibitory factor (LIF)[a]	JAK1, STAT3	Uterus, macrophages, fibroblasts, endothelium, epithelium, T cells	Embryonic stem cells, neurons hematopoietic cells	Survival	Decreased hematopoietic progenitors, defective blastocyst implantation
	Oncostatin M (OSM)	JAK1, STAT3	Macrophages, fibroblasts, endothelium, epithelium	T cells, myeloid cells, liver, embryonic stem cells	Differentiation, acute-phase induction	
	Cardiotropin-1 (CT-1)	JAK1, STAT3	T cells, others, myocardium	Myocardium	Growth	
	Granulocyte macrophage–colony-stimulating factor (GM-CSF)	JAK1, STAT3	T cells, macrophages, endothelium, fibroblasts	Immature and committed myelomonocytic progenitors macrophages and granulocytes, DCs	Growth, differentiation survival, activation	Pulmonary alveolar proteinosis
	IL-3	JAK2, STAT5	T cells, macrophages, mast cells, natural killer T cells (NKT cells), eosinophils	Immature hematopoietic progenitors of multiple lineages	Growth, differentiation survival	No defects in basal hematopoiesis

TABLE 9.1 Cytokines Classified by Receptor Families—cont'd

Receptor Family	Cytokine	Signaling	Source	Target	Action	Knock-out Phenotype
	IL-5	JAK2, STAT5	Th2 T cells, activated eosinophils, NK cells, NKT cells	Eosinophil, B cells, basophils, mast cells	Proliferation, activation	Decreased eosinophilia, defective CD5, B1-cell development
	IL-2	JAK1, JAK3, STAT5	T cells, NK cells, NKT cells	T cells, B cells, NK cells, macrophages	Proliferation, cytotoxicity interferon-γ (IFN-γ) secretion, antibody production	Lymphoproliferation[a]
	IL-4[b]	JAK1, JAK3, STAT6	Th2 cells, mast cells, NKT cells, γ/δ T cells	T cells, B cells, macrophages	Proliferation, Th2 differentiation, IgG1 and IgE production, inhibition of cell-mediated immunity	Defective Th2 differentiation and IgE production, decreased allergic responses
	IL-7	JAK1, JAK3, STAT5	Bone marrow, thymic stromal cells, spleen DCs, keratinocytes, monocytes, macrophages	Thymocytes, T cells, B cells	Growth, differentiation, survival	Severe combined immunodeficiency (SCID)[a]
	IL-9	JAK1, JAK3, STAT5	Th2 and Th9 T cells, mast cells, eosinophils	T cells, B cells, mast cell precursors	Proliferation, Th1 inhibition	Not essential for Th2 pathology
	IL-15[b]	JAK1, JAK3, STAT5	Many cells	T cells, especially memory cells, NK and NKT cells	Proliferation, survival and activation	Absence of NK and memory cells
	IL-21	JAK1, JAK3, STAT3	T cells, Th17 cells, Tfh cells	T cells, B cells, and NK cells, DCs, macrophages, keratinocytes	Isotype switching, plasma cell differentiation, enhances CD8 and NK-cell responses, promotes Th17 cell differentiation	Acts in concert with IL-4 Decreased Th17 cells
	IL-13	JAK1, TYK2, STAT6	Activated T cells, NKT cells, mast cells, basophils	B cells, mast cells, macrophages, epithelial cells, smooth muscle cells	Costimulator of proliferation, IgE increased CD23 and class II, inhibits cytokine secretion and cell-mediated immunity	Defective Th2 responses and IgE production, decreased allergic responses
	IL-12	JAK2, TYK2, STAT4	Macrophages, DCs, B cells	T cells, NK cells	Th1 differentiation, proliferation, cytotoxicity	Defective Th1 differentiation, susceptibility to bacterial infections*
	IL-23	JAK2, TYK2, STAT3, STAT5	Macrophages, DCs	T cells, macrophages	IL-17 production	Reduced arthritis, inflammation
	IL-35	?	Tregs	T cells	Treg proliferation Suppresses proliferation and functions of Th17	Reduced Treg activity
	Thymic stromal lymphopoietin (TSLP)	JAK1, JAK2, STAT1 STAT3, STAT5	Epithelial cells, keratinocytes	DCs (human) B cells (mouse)	Th2 differentiation (human)	Shared receptor usage with IL-7R
Type II (interferon)	IFN-α/β	JAK1, TYK2, STAT1, STAT2	Plasmacytoid DCs, macrophages, fibroblasts, other	All, NK cells	Antiviral, antiproliferative increased major histocompatibility complex (MHC) class I activation	Susceptibility to viral infections[a]
	IFN-γ	JAK1, JAK2, STAT1	Th1 cells, NK cells	Macrophages, endothelium, NK cells	Activation, increased MHC class II expression, increased antigen presentation	Susceptibility to bacterial infections[a]
	IL-10	JAK1, TYK2, STAT3	Th2 cells, other cells	Macrophages	Decreased MHC class II expression, decreased antigen presentation	Exaggerated inflammatory response and autoimmune disease

Continued

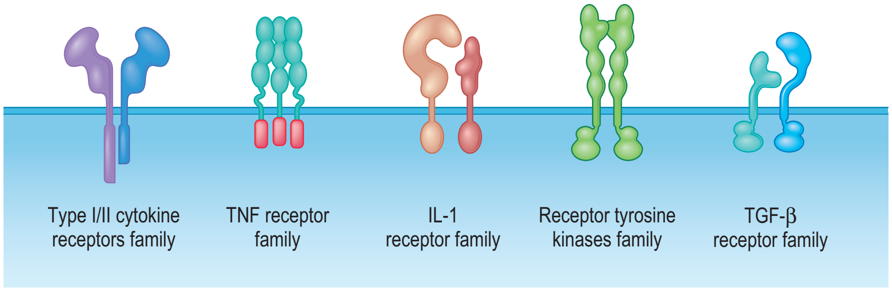
TABLE 9.1 Cytokines Classified by Receptor Families—cont'd

Receptor Family	Cytokine	Signaling	Source	Target	Action	Knock-out Phenotype
	IL-19, -20, -22, -24, -26	STAT1, STAT3	T cells, monocytes, melanocytes, NKT cells	T cells, keratinocytes, epithelial cells	Induces production of inflammatory cytokines, Th2 responses, activation of epithelial cells	
	IL-28, -29, -30	STAT1, STAT2, STAT3, STAT4, STAT5	DCs, many cells	Many cells	Antiviral	
IL-1/TLR	IL-1α/β	IRAK (IL-1 receptor-associated kinase), MyD88, TRAF6 (TNF receptor–associated factor 6), nuclear factor (NF)-κB	Many cells, especially macrophages	Central nervous system, endothelial cells, liver, thymocytes, macrophages, T cells	Fever, anorexia, activation acute-phase reactants costimulation, activation, cytokine secretion, differentiation of Th17 cells	Reduced inflammation, cooperates with tumor necrosis factor (TNF) in host defense
	IL-18	IRAK, MyD88, TRAF6, NF-κB	Many cells, especially macrophages, keratinocytes, osteoblasts	T cells, NK cells, macrophages, epithelial cells		Increased susceptibility to infection, reduced arthritis
	IL-33			T cells, nuocytes (ILC2)	Enhanced Th2 responses	
	IL-36		Skin			
	IL-37					
	IL-38			Macrophages		
IL-17	IL-17A		Th17 cells, CD8 T cells, γ/δ T cells	Endothelium, many cells	Inflammation	Susceptibility to extracellular bacteria
	IL-17B, -C, -D		Many cells	Monocytes, epithelial cells	Inflammation, chondrogenesis	
	IL-17E (IL-25)	TRAF2	Mast cells, Th2 cells	Th2 cells	Enhanced Th2 responses	Increased susceptibility to helminths
	IL-17 F		Th17 cells, CD8 T cells, γ/δ T cells	Endothelium, many cells	Inflammation	
Transforming growth factor (TGF)-β receptor serine kinase family	TGF-β_1, -β_2, -β_3		T cells, macrophages, other	T cells, macrophages, other	Inhibits growth and activation, promotes Th17	
Receptor tyrosine kinases	Stem cell factor	Ras/Raf/ mitogen-activated protein kinase (MAPK), stromal cells	Bone marrow	Pluripotent stem cells	Activation, growth	Defective hematopoietic stem cell proliferation, melanocyte production and development
	CSF-1 (macrophage (M)-CSF)	Ras/Raf/MAPK	Macrophages, endothelium, fibroblast, other	Committed myelomonocytic progenitors	Differentiation, proliferation, survival	Monocytopenia, osteopetrosis, female infertility
	FMS-like tyrosine kinase 3 ligand (FLT-3) ligand	Ras/Raf/MAPK	Diverse tissues	Myeloid cells, especially DCs	Proliferation, differentiation	Reduced repopulating hematopoietic stem cells; reduced B-cell precursors
	IL-32	NF-κB, p38 MAPK	T cells, NK cells, monocytes, epithelia	Monocytes	Induces TNF, IL-1, IL-6, IL-8	
	IL-16		T and B cells, mast cells, eosinophils	CD4 T cells		
	IL-3	Extracellular signal–regulated kinase (ERK)	Many cells	Monocytes	Proliferation binds CSF-1 receptors	

In cases where STAT5a or STAT5b are designated, the cytokines appear to use either interchangeably.

[a] LIFR is shared by these cytokines.

[b] Note that two forms of the IL-4 and perhaps IL-15 receptor exist.



Type I/II cytokine receptors family
TNF receptor family
IL-1 receptor family
Receptor tyrosine kinases family
TGF-β receptor family

FIG 9.1 Schematic representation of prototypical receptors from five of the major cytokine receptor superfamilies.

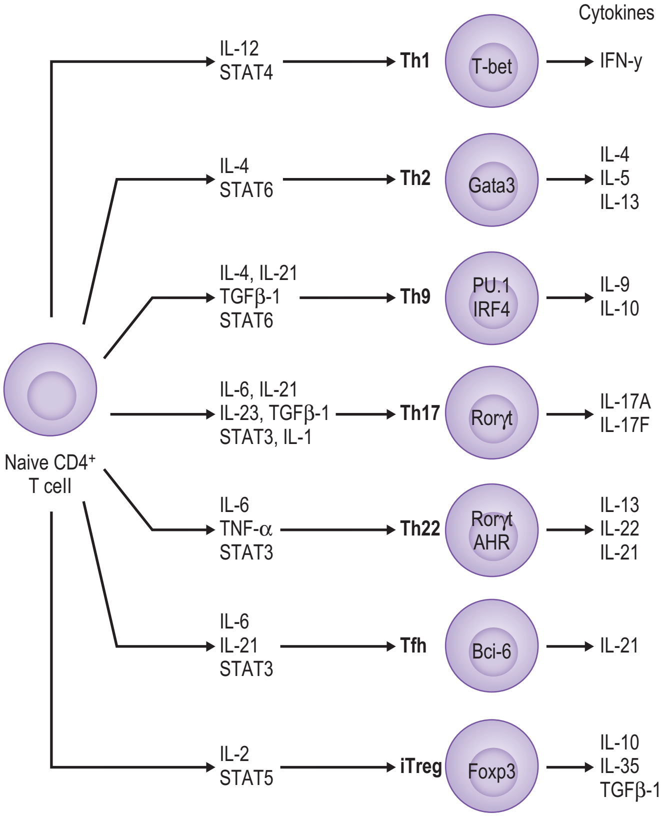


FIG 9.2 Differentiation of T-helper cell subtypes.

IL-19, IL-20, IL-22, IL-24, IL-26, and the IFN-related cytokines IL-28A (IFN-λ2), IL-28B (IFN-λ3), IL-29 (IFN-λ1), which bind type II receptors. The ligands and receptors in this superfamily are structurally similar and utilize related molecules for signal transduction.[5,6]

A central feature of type I cytokines is a similarity in their basic structure. Each contains four antiparallel α helices with two long and one short loop connections arranged in an up–up/down–down configuration. Because of this structure, these cytokines have also been referred to as the *α-helical bundle cytokine family.*

Structurally, the receptors in the type I family have conserved cysteine residues, a conserved Trp–Ser–X–Trp–Ser motif (where X indicates any amino acid), and fibronectin-like repeats in their extracellular domains. These receptors have a single transmembrane domain and divergent cytoplasmic domains. Within the cytoplasmic portion of these receptors, two segments of homology can be discerned, termed *Box 1* and *Box 2 motifs.* The membrane proximal domain binds Janus kinases (JAKs; see below). Some of the cytokine receptors are homodimers, such as the receptors for EPO, TPO, PRL, and possibly leptin, whereas other receptors for type I cytokines are heterodimers, containing two distinct receptor subunits. On the basis of this characteristic, the type I family of receptors can be divided into subfamilies. Each member of the subfamily uses a shared receptor subunit in conjunction with a ligand-specific subunit. For example, the receptors for IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 all use a common cytokine γ chain, γc (see Table 9.1), whereas a common β chain, βc, is shared by IL-3, IL-5, and GM-CSF. Similarly, gp130 is a shared subunit for IL-6 family cytokines (IL-6, IL-11, IL-27, IL-35, CNTF, LIF, OSM, and CT-1). IL-12 and IL-23 also share a receptor subunit, as do members of the IL-10 family.

Other levels of shared receptor usage also exist. For example, the receptors for LIF, CNTF, OSM, and CT-1 all share the LIF receptor subunit, IL-31 and OSM also share one receptor chain, whereas IL-2 and IL-15 utilize the same β and γ c chains. Conversely, IL-4 can bind two different receptor complexes. The classic IL-4 receptor is composed of the IL-4Rα chain and the γc chain. Additionally, IL-4 can also bind the IL-13 receptor, which comprises a heterodimer of the IL-4Rα chain and the IL-13Rα chain. IL-13 only utilizes the IL-13 receptor complex for signaling.

The utilization of common receptor subunits explains the phenomenon of shared biological activities (cytokine redundancy) between cytokines that belong to the same subfamily. Within a subfamily, actions distinct for each cytokine can be attributed, at least in part, to the ligand-specific subunits. The pleiotropic effects of a single cytokine can be accounted for by the existence of more than one receptor for that cytokine.

Family Members and Their Actions

Homodimeric Receptors

Many of the cytokines that use homodimeric receptors are classic hormones. These include EPO GH, PRL, and leptin. EPO is required for erythrocyte growth and development and is widely used to treat anemia. Similarly, TPO is required for megakaryocyte development and may have a use in the treatment of thrombocytopenia. G-CSF not only regulates the production of neutrophils through its action on committed progenitor cells but also supports the survival of mature neutrophils, enhancing their functional capacity. G-CSF is widely used clinically to treat patients with granulocytopenia. As one would predict, G-CSF–deficient mice have marked neutropenia, and mutations of the G-CSF receptor (G-CSFR) result in severe congenital neutropenia in humans.

Cytokine Receptors Utilizing gp130

gp130 is a receptor component for IL-6, IL-11, IL-27, and IL-35 as well as LIF, OSM, CNTF, and CT-1.[7] Targeted disruption of the gp130 gene is lethal in early embryogenesis, causing defects in myocardial, hematological, and placental development. LIF binds to gp130 in association with the LIF receptor (LIFR), as do the cytokines OSM, CNTF, and CT-1. Deletion of the *LIFR* gene is also embryonically lethal, creating defects in placental architecture and developmental abnormalities in neural tissue and bone. Targeted disruptions of LIF lead to failure of blastocyst implantation. Another critical role of LIF is the maintenance of stem cell pluripotency in culture.

Interleukin-6. The IL-6 receptor (IL-6R) consists of a soluble IL-6 binding protein (α chain) (CD126) and membrane bound gp130. IL-6 has a wide array of biological actions on both lymphoid and nonlymphoid cells with the consequences of signaling by the membrane bound and soluble receptors being distinct.[8] IL-6 is important in host defense, and IL-6–deficient mice are susceptible to infection with *Candida* and *Listeria.* IL-6 is a growth and differentiation factor for B cells, inducing the production of immunoglobulin (Ig), including IgE. IL6$^{-/-}$ mice have normal numbers of B cells with reduced Ig response to immunization and reduced IgA production. IL-6 also promotes T-cell growth and differentiation. Consequently, IL6$^{-/-}$ mice have reduced numbers of thymocytes and peripheral T cells. IL-6 is important for T-helper 17 (Th17) cell differentiation and the cytotoxic T-cell response to viruses. IL-6 functions synergistically with IL-3 in hematopoiesis, and IL-6–deficient mice have reduced numbers of progenitor cells.

IL-6 is a major inducer of fever, inflammation, and the synthesis of acute-phase proteins (*e.g.,* fibrinogen, serum amyloid A, haptoglobin, C-reactive protein [CRP], etc.) in the liver. The elevation of the erythrocyte sedimentation rate (ESR) in inflammatory disease largely reflects the accelerated synthesis of these proteins, and IL-6–deficient mice are defective in this response. IL-6 reduces synthesis of albumin and transferrin in the liver and initiates hepatocyte regeneration. IL-6 induces adrenocorticotrophic hormone and anterior pituitary hormones, such PRL, GH, and luteinizing hormone (LH). IL-6 also plays a role in osteoporosis by affecting osteoclast function. IL-6–deficient mice are protected from bone loss following estrogen depletion.

Levels of IL-6 in serum are low in the absence of inflammation but rapidly increase in response to bacterial and viral infections, inflammation, or trauma. Patients with rheumatoid arthritis (RA), cardiac myxoma, Castleman disease, and other autoimmune diseases have high serum levels of IL-6. This cytokine may also contribute to malignancies, such as multiple myeloma.

IL-6 is produced by many cells, but its expression in mononuclear phagocytes has been well documented. Stimulation of monocytes with IL-1, TNF, or lipopolysaccharide (LPS) stimulates the expression of IL-6, whereas IL-4 and IL-13 inhibit its production. The *IL6* gene contains binding sites for nuclear factor-κB (NF-κB), nuclear factor for IL-6 (NF-IL-6, or CCAAT element-binding protein), activator protein-1 (AP-1), cyclic adenosine monophosphate (cAMP) response element-binding protein (CREB), and the glucocorticoid receptor.

Not surprisingly, much effort has been made to develop biological IL-6/IL-6R antagonists. Tocilizumab, an anti–IL-6 receptor antibody approved for treatment of RA, juvenile idiopathic arthritis, and other diseases and another anti–IL-6R monoclonal antibody (mAb), sarilumab, is in development. Anti–IL-6 mAbs (olokizumab, siltuximab, and clazakizumab) are also being developed for similar indications.

Interleukin-11. IL-11 and its receptor are widely expressed. IL-11 stimulates stem cells, megakaryocytes, myeloid precursors, and erythroid precursors, as well as promoting B-cell differentiation. It also acts on nonhematopoietic cells, including bone and liver cells. IL-11 is induced by proinflammatory cytokines (IL-1, TNF) and by TGF-β.

Interleukin-27. IL-27 is composed of two subunits designated EBI3 and p28 and signals through gp130 and WSX-1/TCCR (T-cell cytokine receptor). The receptor is expressed on naïve CD4 T cells. IL-27 promotes Th1 differentiation but also has essential antiinflammatory properties, inhibiting Th17 differentiation and enhancing IL-10 production.[9]

Cytokine Receptors Utilizing the β_c Chain

IL-3, IL-5, and GM-CSF bind to a ligand-specific α subunit associated with the common βc receptor subunit (common β subunit). Mice, but not humans, have a second β chain, βIL3. This species-specific redundancy may explain why gene targeting of βc in the mouse did not result in loss of IL-3 responses, although βc-null mice did have reduced GM-CSF and IL-5 responses.

Interleukin-3. IL-3 synergizes with other cytokines to stimulate the growth of immature progenitor cells of all lineages and is termed *multilineage colony-stimulating factor*. It promotes survival of macrophages, mast cells, and megakaryocytes. IL-3 is produced mainly by lymphoid cells, but also by mast cells and eosinophils. IL-3–deficient mice have no obvious defect in hematopoiesis, suggesting that the major role of IL-3 *in vivo* may be in the response to stress.

Interleukin-5. IL-5 is unusual in that it is a disulfide-linked homodimer, with each component containing three α-helical bundles. It promotes the growth, differentiation, and activation of eosinophils and so is very important in pathogenesis of allergic disease. IL5$^{-/-}$ mice fail to develop eosinophilia in response to parasitic or aeroallergen challenge and exhibit minimal signs of inflammation and damage to lungs. IL-5 deficiency does not affect the worm burden of infected mice, indicating that eosinophilia may not play an essential role in the host defense against helminths *per se.* Both IL-5 and IL-5R knock-out mice have decreased numbers of CD5^{+} B cells (B-1 cells) and concomitant low serum IgM and IgG3 levels. IL-5 is produced by activated helper T cells of the Th2 phenotype (see below), mast cells, and eosinophils in an autocrine manner. Mepolizumab and reslizumab are anti–IL-5 mAbs that have been approved for the treatment of severe eosinophilic asthma disease.

Granulocyte macrophage–colony-stimulating factor. GM-CSF acts on hematopoietic precursors to support myelomonocytic differentiation. It activates mature neutrophils and macrophages, increasing their microbicidal activity and inducing the production of proinflammatory cytokines. Along with IL-4 and IL-13, GM-CSF is a major stimulatory cytokine for the *in vitro* production of dendritic cells (DCs). GM-CSF induces proliferation and activation of eosinophils and upregulates adhesion molecules on fibroblasts and endothelial cells. Deletion of the GM-CSF gene (*Csf2*) in mice, however, does not affect steady-state hematopoiesis. Instead, these animals develop alveolar proteinosis and lymphoid hyperplasia. βc$^{-/-}$ mice also develop alveolar proteinosis, characterized by the accumulation of surfactant in the lungs. A similar defect may be responsible for disease in a subset of humans with this abnormality.

The production of GM-CSF can be induced by proinflammatory cytokines and LPS. GM-CSF is made by activated lymphocytes and other stimulated cells and is an important driver of immune pathology in murine models of autoimmunity.[10,11] GM-CSF is not ordinarily detectable in blood except under pathological conditions, such as asthma. GM-CSF has been used clinically to treat chemotherapy-induced neutropenia, especially in the context of certain infections (*e.g.,* fungal), and has been tested in myelodysplastic syndrome and aplastic anemia. Mavrilimumab is an anti–GM-CSF antibody being studied in rheumatoid arthritis.[12]

Cytokine Receptors Utilizing the γc Chain

The cytokines IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21 all bind to receptors that share a common γc receptor subunit. The γc subunit and the ligand-specific subunits are expressed predominantly on lymphocytes, although they can be found on other hematopoietic cells as well. Mutation of the γc gene is responsible for X-linked severe combined immunodeficiency (SCID), characterized by a lack of T cells and natural killer (NK) cells, and poorly functioning B cells (T^-B^+ SCID) (Chapter 35).[13] The lack of γc abrogates signaling by all cytokines that utilize this subunit (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21). The lack of IL-7 and IL-15 signaling is largely responsible for the lack of T and NK cells, respectively.

Interleukin-2. The IL-2 receptor consists of three subunits, α, β, and γc. The latter two are members of the type I cytokine receptor family. NK cells constitutively express these latter two subunits and respond to high doses of IL-2, whereas in T cells the IL-2Rα subunit is induced upon activation, creating a high-affinity receptor for IL-2. IL-2Rα is also inducible in activated monocytes and B cells. IL-2Rα, however, is not a member of the type I cytokine receptor family. Rather, it resembles members of the complement family and IL-15R (see below).

IL-2, one of the first cytokines to be intensively studied, is produced principally by activated T cells. It is a prototypical autocrine T-cell growth factor and is required for *in vitro* T-cell proliferation. It is an important factor in determining the magnitude of T-cell and NK-cell responses *in vivo,* although other factors also contribute. It is thus redundant to some degree for this function. It augments the cytolytic activity of T and NK cells and enhances IFN-γ secretion. IL-2 is also important in programming CD8 memory T cells, which undergo secondary expansion in viral infections.[9] IL-2 is a growth factor for B cells and induces class switching. It also activates macrophages.

IL-2–deficient mice develop massive enlargement of peripheral lymphoid organs, hemolytic anemia, inflammatory bowel disease (IBD), and infiltrative granulopoiesis. In addition, the mice have high levels of IgG1 and IgE. They succumb to widespread autoimmune and lymphoproliferative disease, which points to the nonredundant roles of IL-2 in promoting tolerance and preventing autoimmunity.[14] A similar phenotype is seen in humans with IL-2Rα mutations.

Regulatory T cells (Tregs) in both mice and humans express high levels of IL-2Rα. Maintenance of peripheral Treg numbers is dependent on IL-2.[15] In addition, IL-2 inhibits Th17 and T-follicular helper (Tfh) cell differentiation.[16,17]

IL-2 is produced by activated T cells but also myeloid cells, including DCs. The *IL2* gene has been extensively characterized and contains binding sites for nuclear factor of activated T-cells (NFATs), AP-1, and NF-κB. IL-2 production is also regulated by stabilization of its messenger RNA (mRNA).

IL-2 is approved by the US Food and Drug Administration (FDA) for the treatment of renal cancer; however, its clinical utility is limited by its toxicity, two important manifestations being hepatic dysfunction and the so-called capillary or vascular leak syndrome. However, the anti–IL-2Rα mAbs daclizumab and basiliximab are used to prevent rejection of allotransplants and, more recently, have been found to be effective in the treatment of multiple sclerosis (MS).[18] Polymorphisms of IL-2Rα are also associated with MS.

Interleukin-4. Two classes of IL-4R appear to exist. The first consists of the IL-4Rα subunit in conjunction with γc. It is expressed on hematopoietic cells.[19] The second, which is more widely expressed, is a “type II” receptor. It consists of the IL-4Rα subunit in associated with IL-13R α chain. Two IL-13R subunits have been cloned, so the exact composition of the type II IL-4R remains uncertain. The existence of two receptors helps explain why IL-4 has diverse actions on both hematopoietic and nonhematopoietic cells. The loss of IL-4Rα would be predicted to block the actions of both IL-4 and IL-13, which could explain why gene targeting of IL-4Rα leads to a more severe phenotype than that observed in IL-4–deficient mice. Polymorphisms of IL-4Rα have been reported to be associated with a propensity to atopy.[20]

In general, IL-4 promotes allergic responses and inhibits cell-mediated immune responses. Among the most important roles of IL-4 is its ability to promote differentiation of naïve CD4 T cells into a subset that produces IL-4 and IL-5,[21] denoted as Th2 subset, as opposed to Th1 cells, which produce IFN-γ (Chapter 16). In conjunction with CD40 activation, IL-4 also promotes B-cell proliferation and class switching, particularly to IgG1 and IgE in mice and to IgG4 and IgE in humans. Mice deficient in IL-4 have normal B lymphopoiesis but marked reductions in IgG1 and IgE production in response to parasites. These mice have residual Th2 responses because IL-13, which also binds IL-4Rα, can partially compensate for the defect.

IL-4 upregulates the expression of surface IgM, major histocompatibility complex (MHC) class II, and CD23 on B cells. In conjunction with GM-CSF, it is a growth factor for mast cells and basophils, as well as a potent inducer of DC differentiation. IL-4 inhibits macrophage activation and the production of proinflammatory cytokines. It antagonizes the effects of IFN-γ, blocks cytokine-induced proliferation of synoviocytes, downregulates the expression of adhesion molecules, and antagonizes the induction of some acute-phase reactants in hepatocytes by IL-6.

IL-4 is made by the Th2 subset of CD4 T cells, NK1.1$^+$ CD4$^+$ T cells, basophils, and mast cells. A number of transcription factors appear to be important in regulating IL-4 production, including NFAT, NF-IL6, C/EBP, c-MAF, and GATA-3. The *IL4* gene has multiple signal transducer and activator of transcription 6 (STAT6) binding sites, consistent with the fact that IL-4 regulates its own expression. Epigenetic control and chromatin remodeling are also important aspects.[22]

Clinically, IL-4 has been tested in the treatment of malignancies and some autoimmune disorders. The ability of IL-4 to generate DCs is being exploited in the use of tumor vaccines. Conceivably, soluble IL-4R might also be useful in the treatment of allergic disease. Dupilumab is an anti-IL-4/13R mAb being studied in severe atopic dermatitis.[23]

Interleukin-7. The IL-7 receptor consists of the IL-7Rα chain (CD127) in association with γc. It is expressed on both immature and mature thymocytes. Humans with loss-of-function (LOF) mutations of IL-7Rα have T^-B^+ SCID but, unlike in individuals with γc mutations, display normal NK-cell development (Chapter 35). Gain-of-function (GOF) mutations of the IL-7Rα chain result in constitutive JAK1 signaling and cell transformation and give rise to T-cell acute lymphoblastic leukemia (Chapter 78).

IL-7Rα expression is tightly regulated during thymocyte development (Chapter 8). IL-7 plays an important role in both developing thymocytes and mature T cells. Its receptor is expressed in double-negative thymocytes, downregulated in double-positive cells, and then reexpressed in single-positive thymocytes and mature peripheral T cells. This may be a reflection of its anti-apoptotic effects, which are attributable to the induction of Bcl-2 family members. IL-7 promotes the growth of thymocytes, as well as the expression and rearrangement of T-cell receptor (TCR) genes and the expression of *RAG1* and *RAG2* (Chapter 4). IL-7Rα is expressed on cutaneous T-cell lymphomas, which also produce this cytokine; thus the autocrine response to IL-7 may contribute to the growth of these tumors.

IL-7– and IL-7R–deficient mice exhibit impairments in both T- and B-cell development. Postnatal B-cell development in $Il7^{-/-}$ mice is blocked at the transition to pre–B cells and is arrested even earlier in $Il7ra^{-/-}$ mice. Why these abnormalities do not occur in humans with IL-7Rα mutations is not clear.

IL-7 is produced by a wide variety of cells, including marrow and perhaps thymic stromal cells, as well as in the kidney, spleen, and epithelial cells and keratinocytes. This is consistent with its role in the maintenance of function in both immature and mature lymphocytes.

Clinically, IL-7 may be useful to restore immune function in some congenital immunodeficiencies, after bone marrow transplantation, and in human immunodeficiency virus (HIV) infection. Polymorphisms of the *IL7R* gene are associated with MS.

Interleukin-9. IL-9 has some of the same properties as IL-4. It synergizes with stem cell factor to promote the growth and differentiation of mast cells and regulate mast cell function. IL-9 potentiates IgE production induced by IL-4 in B cells. Although first identified as a T-cell growth factor, a physiological role in T-cell development has not been established. IL-9 is produced by activated Th2 cells, mast cells, and eosinophils. Recently, a new subset of Th cells, termed *Th9,* has been proposed. These cells have been shown to not only secrete IL-9 but also to enhance inflammatory responses. Interestingly, IL-9 inhibits Th1 cytokine production. Some lymphoid tumors also produce IL-9, where it may serve as an autocrine growth factor. A subset of innate lymphoid cells, ILC2 (Chapter 3), also produces IL-9, which is thought to contribute to the pathogenesis of allergy and asthma.

Interleukin-15. The IL-15 receptor consists of the IL-2Rβ and γc subunits in association with a unique ligand-specific subunit, IL-15Rα, which is homologous to IL-2Rα. These receptor proteins contain protein-binding motifs termed "sushi domains." In both humans and mice, these receptors and their cognate ligands are physically linked in the genome. Given their shared receptor usage, there are many similarities in the actions of IL-2 and IL-15, particularly in terms of the effects on lymphoid cells. Like IL-2, IL-15 induces proliferation and cytokine production in T and NK cells. However, despite the similarities between these two ligands/receptors, there are some important differences. In T cells, IL-15 is less efficient than IL-2 in inducing effector memory T-cell differentiation or sensitivity to apoptosis.[24] IL-15Rα is more widely expressed than IL-2Rα, IL-2Rβ, and γc. IL-15Rα is expressed by lymphoid cells, DCs, fibroblasts, and epithelial, liver, intestine, and other cells and is thought to present IL-15 in *trans* to cells expressing IL-15β and γ chains. IL-15– and IL-15Rα–knock-out mice are defective in NK-cell production and in the generation of memory T cells, explaining the absence of NK development in patients with γc mutations.

IL-15 mRNA is expressed broadly in hematopoietic and nonhematopoietic cells but is not typically produced by T cells. (human T-lymphotropic virus 1 [HTLV-1]–transformed T cells are an exception in that they produce abundant IL-15.) Following the pattern seen in IL-7 and IL-9, there are multiple triplet repeats of adenosine, uradine, guanosine (AUGs) in the 5′ untranslated portion of the IL-15 message that interfere with translation. Thus IL-15 is controlled by translational regulation. IL-15 protein is also controlled at the level of secretion of the protein, but this is incompletely understood. High levels of IL-15 protein have been reported in synovial fluids from patients with RA, alveolar macrophages from patients with sarcoidosis, and peripheral blood mononuclear cells from patients with ulcerative colitis.

Interleukin-21. IL-21 is a T-cell–derived cytokine that works in concert with other γc cytokines. It synergizes with IL-7 and IL-15 to expand and activate CD8 T cells. IL-21 also augments the activity of NK cells. IL-21, along with IL-6, drives differentiation of Tfh. Tfh cells are found preferentially in B-cell follicles, where, under the control of the transcription factor BCL6, they regulate B-cell development, activation, and class switching. Tfh cells are also a source of IL-21.[25] IL-21 appears to have some anticancer properties, and it has been tested in the treatment of melanoma.[26,27]

Other Heterodimeric Receptors

Interleukin-12. IL-12 is a heterodimer composed of two disulfide-linked polypeptide chains, p35 and p40, derived from two distinct genes.[28,29] IL-12 p35 shares homology with other cytokines, such as IL-6, whereas p40 resembles the IL-6 receptor. Thus IL-12 can be viewed as being synthesized as a ligand–receptor complex. IL-12R consists of two chains, and because the ligand already comprises the α subunit, the two chains of the IL-12R are denoted IL-12Rβ_1 and β_2. Expression of high-affinity IL-12R is very restricted, being found predominantly on T and NK cells. IL-12Rβ_1 and β_2 are highly inducible upon T-cell activation, and IL-4 inhibits IL-12Rβ_2 expression. This is important because IL-12Rβ_2 is required for IL-12 signaling and the activation of the STAT4. NK cells constitutively express IL-12Rβ_1 and IL-12Rβ_2.

IL-12 plays a pivotal role in promoting cell-mediated immune responses. Humans with *IL12R* mutations, as well as mice with IL-12 and IL-12R deficiency, have very blunted immune responses and are highly susceptible to infections by intracellular pathogens. An important function of IL-12 is that it promotes the differentiation of uncommitted Th cells to the Th1 subset (*i.e.,* T cells that produce LT-α and INF-γ). Th1 differentiation is markedly impaired in IL-12– and IL-12R–deficient mice. A major action of IL-12 is its ability to induce the production of IFN-γ, doing so synergistically in combination with IL-2 or IL-18. Consequently, many of the actions of IL-12 are blocked in IFN-γ or IFN-γR knock-out mice. IL-12 also induces proliferation and cytolytic activity of T and NK cells.

DCs and macrophages are the major producers of IL-12 in response to various pathogens, occupancy of TLRs, and CD40. The *IL12p40* gene is complex and contains NF-κB sites, IFN response elements (IREs), and ETS-binding sites. As with other cytokine genes, nucleosome remodeling is important in the regulation.[30]

Because of its profound effects on cell-mediated immunity, IL-12 has been used in the treatment of malignancies and infectious diseases. However, its utility has been limited because of significant toxicity. IL-12 may also have use in vaccines as an adjuvant. Conversely, antagonizing the actions of IL-12 has been found to be useful in Th1-mediated diseases, including IBD (Chapter 75). Ustekinumab inhibits both IL-12 and IL-23 and is approved for psoriasis and psoriatic arthritis.

Interleukin-23. IL-23 is another heterodimeric type I cytokine. It is composed of two disulfide-linked polypeptide chains, p19 and IL-12 p40. The IL-23 receptor also shares the IL-12Rβ_1 chain paired to the IL-23R. The IL-23R complex is expressed on T cells and ILCs and regulates production of IL-17 (Th17, see below). As such, IL-23 is thought to be important in host defense against extracellular bacteria and the pathogenesis of autoimmune and autoinflammatory disorders. IL-23 is produced primarily by DCs in response to TLR agonists. IL23R polymorphisms are associated with IBD, ankylosing spondylitis, and other autoimmune diseases. Tildrakizumab and guselkumab inhibit IL-23 but not IL-12.

Interleukin-35. IL-35 is a dimer consisting of IL-12 p35 and EB13. It is preferentially produced by Tregs. Tregs are also the main cellular target of IL-35, where it induces proliferation and production of IL-10. A synthetic form of IL-35, obtained by covalently linking EBI3 to IL-12p35, can reduce the incidence of arthritis in mouse models.[26]

Interleukin-13. IL-13 has many of the same effects as IL-4 and shares a receptor subunit(s) with IL-4. IL-13–deficient mice have reduced levels of IL-4, IL-5, and IL-10, with lower IgE levels and eosinophils. In mice deficient for both IL-4 and IL-13, these Th2 responses are abolished, and the ability to clear parasites is severely impaired. These double-knock-out mice default to Th1 responses, with concomitant production of INF-γ, IgG2a, and IgG2b. It thus appears that IL-4 and IL-13 cooperate in promoting Th2 responses, having both overlapping and additive roles. Anti–IL-13 mAbs in clinical trials include lebrikizumab and tralokinumab for severe asthma.[31,32]

Interleukin-31. IL-31 signals through the heterodimeric receptor IL-31Rα and oncostatin M receptor (OSMR). It is produced by activated Th2 cells. Overexpression of IL-31 results in atopic dermatitis, but surprisingly, IL-31Rα–deficient mice showed an increased Th2 response.[33,34]

Thymic stromal lymphopoietin. Thymic stromal lymphopoietin (TSLP) is an IL-7–like cytokine expressed by epithelial cells and keratinocytes. Its receptor comprises TSLP receptor (TSLPR) and IL-7Rα, which is expressed primarily on monocytes and myeloid-derived DCs, as well as on B cells. TSLP-treated human DCs promote Th2 differentiation.[35] A major means by which TSLP exerts its effect is through promotion of basophil hematopoiesis.[36] Elevated TSLP levels have been found in humans and animal models of airway inflammatory disease and atopic dermatitis. In the mouse, TSLP contributes to prenatal B-cell development.

Interferons

Type I Interferons

Interferon-α/β. The type I IFNs include IFN-α, IFN-β, and IFN-ω. IFN-β and IFN-ω are encoded by single genes, whereas IFN-α includes at least 14 separate genes, each encoding structurally distinct forms. These intronless genes are all clustered on the short arm of chromosome 9 and appear to have diverged from a common ancestor more than 100 million years ago. Each of these molecules binds to the same IFN-α/β receptor, and their actions are similar. The receptor is a heterodimer composed of two subunits termed *IFNAR1* and *IFNAR2*. These subunits have limited similarity to type I cytokine receptors, although they lack the WSXWS motif.

A major effect of type I IFNs is their antiviral action.[37] Discovered in 1957, they act on all cells to inhibit viral replication as well as cellular proliferation. It is unclear why there are so many type I genes. Given that their relative potencies differ, it is possible that these genes evolved in response to various viral pathogens. Alternatively, IFN gene duplication may affect the magnitude of antiviral responses. A major mechanism is the inhibition of protein translation. Type I IFNs also upregulate MHC class I and can block the ability of IFN-γ to upregulate MHC class II expression.[38] IFN-α/β increase the cytolytic activity of NK cells. IFNARI knock-out mice are extremely susceptible to infections, even though lymphoid development is normal.

IFNs are produced ubiquitously. Recognition of extracellular and intracellular foreign DNA, produced in viral infection, is a major inducer of their transcriptional regulation. Type I IFN is also induced by intracellular bacterial pathogens and LPS. Immunoregulatory effects of IFN-α/β are being increasingly recognized, and it is notable that a subset of DCs produces very high levels.[39,40] IFN genes are bound by multiple transcription factors, including NF-κB, interferon regulatory factor 3 (IRF-3), IRF-7, and STAT1.

Type I IFN is used clinically in the treatment of certain infections (*e.g.,* viral hepatitis). Because of its antiproliferative action, it is also used in the treatment of certain malignancies, particularly hairy cell leukemia. IFN-β is used in the treatment of MS.

Newer IFN-like cytokines, including IL-28A, IL-28B, and IL-29 (also designated IFN-λ1, -λ2, and -λ3), have been identified. They bind to a receptor designated IL-28R. The exact *in vivo* functions of these IFN-like cytokines are poorly understood, although they probably contribute to antiviral responses.

Interferon-γ. IFN-γ is a major activator of macrophages, enhancing their ability to kill microorganisms by augmenting their cytolytic machinery. IFN-γ exerts this effect by causing the cell to increase its production of reactive oxygen intermediates, including hydrogen peroxide, nitric oxide, and indoleamine dioxygenase. It also upregulates MHC class II expression. IFN-γ acts on CD4 T cells to promote Th1 differentiation while inhibiting the generation of Th2 cells. It promotes the maturation of CD8 T cells to cytotoxic cells. IFN-γ augments NK-cell cytolytic activity and regulates B-cell class switching. Endothelial cells and neutrophils are also activated by IFN-γ. Like IFN-α/β, IFN-γ also contributes to antiviral defenses.

The IFN-γ receptor is a heterodimer composed of two subunits, IFN-γRα and IFN-γRβ. When one IFN-γ homodimer binds, a complex of two α and two β receptors is created.[41] Mice with a disrupted IFN-γR develop normally and have normal lymphoid development but are highly susceptible to viral and bacterial infections, especially those by intracellular microbes. They have diminished macrophage MHC class II expression, decreased NK function, and reduced serum IgG2a concentrations. Humans with mutations of IFNGR subunits (OMIM #209950) are also susceptible to mycobacterial and *Salmonella* infections.

IFN-γ is produced by Th1 and NK cells. Transcription factors, including STAT4, T-BET, and EOMES, play an important roles in IFN-γ gene regulation.[22] IFN-γ has been used to treat patients with immunodeficiencies (*e.g.,* chronic granulomatous disease [CGD]) and in certain patients with disseminated mycobacterial infections.[22] A monoclonal anti-IFN-γ antibody, fontolizumab, is being studied in the treatment of autoimmune diseases.

Interleukin-10 and related cytokines. The major function of IL-10 is to serve as an antiinflammatory and immunosuppressive cytokine. Unlike other cytokines in this family, it is a disulfide-linked dimer. A single IL-10R has been cloned, but the receptor may have additional components. IL-10R is expressed on macrophages, mast cells, and most other hematopoietic cells. It is also inducible in nonhematopoietic cells by stimuli, such as LPS.

IL-10 strongly inhibits the production of proinflammatory cytokines. It inhibits macrophage antigen presentation and decreases expression of MHC class II, adhesion molecules, and the costimulatory molecules CD80 (B7.1) and CD86 (B7.2). The importance of IL-10 as an endogenous inhibitor of cell-mediated immunity is emphasized by the finding that IL-10–deficient mice develop autoimmune disease, which manifests with severe IBD and exaggerated inflammatory responses. Humans with mutations of the *IL10* and *IL10R* genes suffer from IBD.

IL-10 is made by T cells, B cells, macrophages, keratinocytes, bronchial epithelial cells, and other cells. LPS and TNF are inducers of IL-10. IL-10 is readily detected in the blood of patients with septic shock and other inflammatory and immune disorders. Because of its antiinflammatory properties, IL-10 has been used experimentally in the treatment of some Th1-mediated autoimmune diseases. IL-10 is elevated in patients with systemic lupus erythematosus (SLE), and there is a correlation between levels of IL-10 and autoantibody production.

There are viral homologues of IL-10 that may blunt the immune response to these pathogens. IL-10 also contributes to the immunosuppression seen in lepromatous leprosy or parasitic infestations. Other IL-10–related cytokines include IL-19, IL-20, IL-22, IL-24, and IL-26, but their biological actions are incompletely understood.[42]

Signaling

Neither type I nor type II receptors exhibit intrinsic enzymatic activity. However, the conserved membrane proximal segment of each of these receptors serves as the site at which these receptors bind JAKs (see Table 9.1). These JAKs play a pivotal role in signaling via this family of cytokine receptors.[5]

Janus Kinases

Four mammalian JAKs, JAK1, JAK2, JAK3, and TYK2, have been identified. JAKs are structurally unique, consisting of a C-terminal catalytically active kinase domain that is preceded by a segment termed the *pseudokinase domain.* The latter gives JAKs their name and has regulatory functions. A key feature of the JAKs is their association with cytokine receptors, which appears to be mediated by the N-terminus.

Ligand binding to type I and II receptors induces the aggregation of receptor subunits, which brings JAKs in close proximity and allows them to phosphorylate and activate each other. After activation, the JAKs phosphorylate receptor subunits on tyrosine residues, which allow the recruitment of proteins with SRC homology-2 (SH2) or phosphotyrosine-binding (PTB) domains. These proteins can also be phosphorylated by JAKs. Phosphorylation results in the activation of a number of biochemical pathways. Importantly, phosphorylation of cytokine receptors generates docking sites for a class of SH2-containing transcription factors termed *STATs* (see below) (Fig. 9.3).

The pivotal function of the JAKs is vividly illustrated by mice or humans that are deficient in these kinases. Consistent with the association of JAK3 with the common gamma chain, γc, mutations of JAK3 cause autosomal recessive T^-B^+ SCID (Chapter 35).[43] *Jak3*$^{-/-}$ also exhibit SCID. Indeed, mutation of either γc or JAK3 leads to the same functional defects. These findings led to the notion that JAK inhibitors might represent a new class of immunomodulatory drugs. Multiple JAK inhibitors have been approved or are in late phase clinical development (Chapter 87).

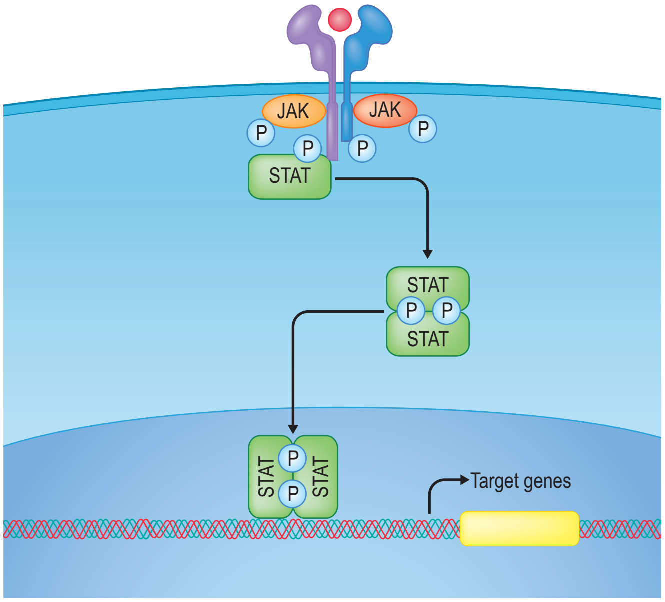

FIG 9.3 The roles of Janus kinases (JAKs) and signal transducer and activator of transcription factors (STATs) in signal transduction by type I and II cytokine receptors.

Gene targeting of *Jak1* and *Jak2* results in diverse abnormalities. *Jak1*$^{-/-}$ mice not only die perinatally as a result of neurological defects but also have a SCID phenotype similar to *Jak3*$^{-/-}$ mice. This is explained by the fact that γc-containing cytokine receptors utilize JAK1 in association with their ligand-specific receptor subunit. Other cytokines that are dependent on JAK1 include those that use gp130 cytokine receptors (IL-6, LIF, OSM, CNTF, and IL-11) and type II receptors (IL-10, IFN-γ, and IFN-α/β). Gene-targeting of *Jak2* was embryonically lethal, principally because JAK2 is essential for erythropoietin function, and the mice fail to form blood. In addition, JAK2 is necessary for signaling of other cytokines, including IL-3.

The importance of the JAKs is also substantiated by mutations in many leukemias and lymphomas. Mutation in the pseudokinase domain of *JAK* underlies most cases of polycythemia vera. Loss of function mutations of *TYK2* are associated with immunodeficiency.

Signal Transducer and Activator of Transcription (STAT)

Members of the STAT family of DNA-binding proteins serve a key role in transducing signals from cytokine receptors on the cell surface to the nucleus, where they regulate gene transcription. STATs are latent, cytosolic transcription factors that have SH2 domains (phosphotyrosine-binding modules) that allow them to be recruited to phosphorylated cytokine receptors (see Fig. 9.3). Different STATs bind to specific cytokine receptors (see Table 9.1). STATs are themselves tyrosine phosphorylated by JAKs, and this promotes their dimerization. STATs translocate to the nucleus, bind DNA, and regulate transcription.

There are seven mammalian STATs: STAT1, STAT2, STAT3, STAT4, STAT5A, STAT5B, and STAT6. *Stat* knock-out mice document the essential and specific functions of these transcription factors in transmitting cytokine signals. *Stat1*$^{-/-}$ mice develop normally but have extreme susceptibility to viral and some bacterial infections, consistent with the defects seen in *Ifng*$^{-/-}$ and *Ifngr*$^{-/-}$ mice. Humans with loss of function mutations of *STAT1* have increased susceptibility to *Salmonella* and mycobacterial infections, whereas GOF mutations of *STAT1* cause chronic mucocutaneous candidiasis (CMC). Gene targeting of *Stat3* leads to early embryonic lethality, the lethality being related, in part, to interference with Lif function. Conditional knock-outs of *Stat3* in myeloid cells display exaggerated inflammatory responses as a result of failure of IL-10 signaling. STAT3 is also essential for Th17 cells, and mutations of *STAT3* underlie the primary immunodeficiency Hyper-IgE syndrome (HIES, or Job's syndrome) associated with impaired IL-17 production. Polymorphisms of *STAT3* are associated with IBD (Chapter 75). STAT4 is activated by IL-12. *Stat4*$^{-/-}$ mice develop normally but have defective Th1 differentiation and IFNγ production combined with augmented Th2 development.

STAT6 is activated by IL-4. *Stat6*$^{-/-}$ mice have defective Th2 development with defective IgE responses following infection with parasites. Lack of STAT6 dramatically attenuates allergic and asthmatic disease in animal models of these diseases. IL-13 also activates STAT6, and its responses are abrogated in *Stat6*$^{-/-}$ mice.

STAT5A and STAT5B are highly homologous, but nonetheless have different functions. *Stat5a*$^{-/-}$ mice have impaired mammary gland development and failure of lactation, whereas *Stat5b*$^{-/-}$ mice have defective sexually dimorphic growth and growth hormone–dependent regulation of liver gene expression. *Stat5a/5b* doubly deficient mice manifest increased perinatal lethality, decreased size, female infertility, and impaired lymphocyte development.

Stat5$^{-/-}$ mice develop lymphoproliferative disease reminiscent of IL-2- and IL-2R–deficient mice, related to loss of Tregs with expansion of Tfh and Th17 cells.

Patients with *STAT5B* mutations have short stature and immune dysregulation.

CLINICAL RELEVANCE

Type I and II Cytokine Receptors

- Mutations of genes encoding interleukin (IL)-7R, γc, and Janus kinase 3 (JAK3) cause severe combined immunodeficiency (SCID).
- TYK2 and signal transducer and activator of transcription 3 (STAT3) mutations cause hyper-IgE syndrome (HIES).
- STAT1 mutations cause autosomal dominant chronic mucocutaneous candidiasis (CMC) with increased susceptibility to mycobacterial and viral infections.
- Mutations of genes encoding IL-12, IL-12R, and interferon-γ receptor (IFN-γR) are associated with susceptibility to intracellular infections.
- Polymorphisms of IL-2R and IL-7R are associated with multiple sclerosis (MS).
- Polymorphisms of IL-23R are associated with inflammatory bowel disease (IBD).
- Polymorphisms of STAT4 are associated with rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE).
- Erythropoietin (EPO), granulocyte–colony-stimulating factor (G-CSF), and thrombopoietin (TPO) are used to treat cytopenias.
- Anticytokine and/or cytokine receptor monoclonal antibodies (mAbs) are used to prevent transplant rejection and treat several autoimmune and inflammatory diseases.

Attenuation of Type-I and Type-II Cytokine Signaling

Perhaps as important as the triggers that initiate signal transduction are the mechanisms for extinguishing the response.[44] There are several families of proteins involved in downregulating cytokine signaling. Among these are phosphatases, cytokine-inducible inhibitor molecules, and transcriptional repressors. The phosphatase SHP-1 interacts with cytokine receptors and downregulates signaling. Mice with the naturally occurring "moth-eaten" mutation in *SHP-1* lack a functional SHP-1 protein and die at an early age as a result of autoimmune disease.

Another family of proteins that attenuate cytokine signaling is the suppressors of cytokine signaling (SOCS), which are alternatively termed JAB, SSI, and CSIS. These are SH2-containing proteins that bind to either cytokine receptors or to JAKs and inhibit signaling. There are at least eight members of this family. Largely as a result of systemic hyperresponsiveness to IFN-γ, *Socs-1*$^{-/-}$ mice die within a few weeks of birth. SOCS-2 has been recently shown to regulate Th2 differentiation and allergic responses. Another family member, SOCS-3, is important in controlling Th17 differentiation.[45-47]

KEY CONCEPTS

Properties of the Tumor Necrosis Factor (TNF) Receptor Superfamily

- Activation of a TNF receptor can lead to a wide range of effects, from proliferation to apoptosis.
- Transduction of signals through TNF receptor–associated factors (TRAFs) leads to the enhancement of survival.
- Signaling through death domains leads to the induction of apoptosis.

THE TNF CYTOKINE AND RECEPTOR SUPERFAMILY

This large family of structurally related ligands, receptors, and inhibitory decoy receptors has various roles both within and outside the immune system. The first two members of this family to be discovered were TNF and lymphotoxin-α (LTα; formerly named TNF-β). These molecules are secreted principally by activated myeloid and T cells. They have similar proinflammatory functions and belong to a large family of related molecules that includes CD30 ligand, CD40 ligand, FAS ligand, and TNF-related apoptosis inducing ligand (TRAIL). Indeed, the TNF cytokine family now contains 18 ligands and 29 receptors, each of which exhibits marked differences in tissue expression, ligand specificity, receptor binding, and biological function (Fig. 9.4) This section describes general aspects of TNF and TNF receptor (TNFR) biology, with examples from three of the best-studied TNF-family members. More complete listings of TNF-family cytokines and their receptors can be found in Table 9.2 and Table 9.3.

Ligand and Receptor Structure

Much of our understanding of the structural and functional characteristics of the TNF ligand and receptor superfamilies has come from the analysis of TNF (TNFSF2), LTα (TNFSF1), FASL (TNFSF6), and their receptors. Among these, TNF and LTα are closely related homotrimeric proteins (32% identity). Human TNF is synthesized as a 233-amino acid glycoprotein. It contains a long (76 residue) amino-terminal sequence that anchors it to the cell membrane as a 25-kilodalton (kDa) type II membrane protein. A secreted 17-kDa form of TNF is generated through

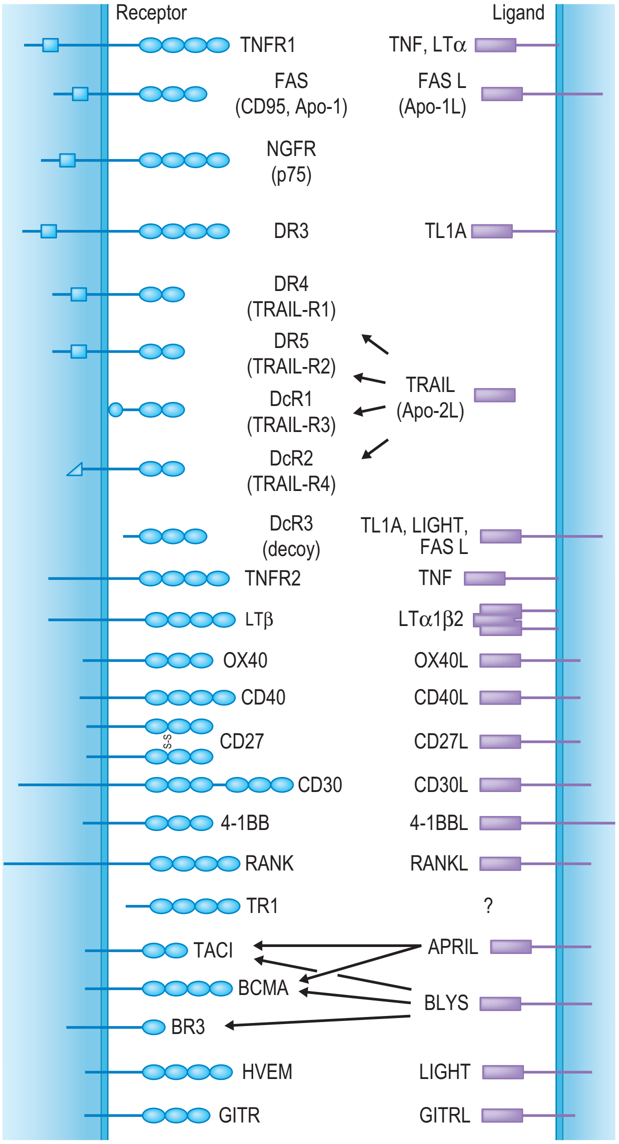

FIG 9.4 Schematic representation of members of the tumor necrosis factor (TNF) ligand and receptor superfamily.

the enzymatic cleavage of membrane-bound TNF by a metalloproteinase termed TNF-α–converting enzyme (TACE). Both soluble and membrane forms of TNF are thought to be homotrimers held together by noncovalent interactions through a trimerization domain. Both membrane-bound and soluble forms of TNF are biologically active. They have different affinities for the two TNF receptors and thus can exhibit different biological properties (see below).

LTα differs from TNF in that it is synthesized as a secreted glycoprotein. Human LTα is synthesized as a 205-amino acid glycoprotein that in native form exists as a 25-kDa homotrimer. It can bind both TNF receptors with affinities comparable to those of TNF and has similar biological effects. A membrane-bound form of LT has been identified that consists of a heterotrimeric complex containing one LTα subunit noncovalently linked to two molecules of an LTα-related type II membrane protein termed LTβ. The LT$\alpha_1\beta_2$ heterotrimer, also known as *mLT,* is not cleaved by TACE and is thought to exist exclusively as a membrane-bound complex. mLT does not bind either of the two TNF receptors, but rather exerts its effects on another member of the TNF receptor superfamily, the lymphotoxin β receptor (LTβR). TNF and the two LT subunits are encoded by closely linked single-copy genes situated in the MHC class III locus, at chromosome 6p21.3 in humans (Chapter 5).

The two receptors for TNF (and LTα) are type-I transmembrane glycoproteins. They are designated TNFR1 (TNFRSF1A) and TNFR2 (TNFRSF1B). (TNFR1 is also known as p60 in humans and p55 in mice, and TNFR2 is known as p80 in humans and p75 in mice.) These receptors are characterized by cysteine-rich repeats of about 40 amino acids in their aminoterminal extracellular domains. Each extracellular domain consists of three or four cysteine-rich regions containing 4–6 cysteines involved in intrachain disulfide bonds. The cytoplasmic domains of these receptors have no obvious similarity to any known kinase and are thought to lack intrinsic enzymatic activity. Signal transduction is, therefore, achieved by the recruitment and activation of adaptor proteins that recognize specific sequences in the cytoplasmic domains of these receptors. Recruitment of adaptor molecules activates a number of characteristic signaling pathways that can lead to a remarkably diverse set of cellular responses. These include differentiation, activation, release of inflammatory mediators, and apoptosis.

Family Members and Their Actions

Tumor Necrosis Factor, Lymphotoxin-α, and Receptors

TNF is a major physiological mediator of inflammation. It is one of the first cytokines made in response to TLR4 stimulation by bacterial (LPS) and other TLR ligands.[48] IFN-γ also induces TNF and augments its effects. TNF has been shown to induce fever, activate the coagulation system, induce hypoglycemia, depress cardiac contractility, reduce vascular resistance, induce cachexia, and activate the acute-phase response in the liver. Thus TNF is the major mediator of septic shock. TNF also upregulates MHC class I and class II expression, activates phagocytes, and induces mononuclear phagocytes to produce cytokines, such as IL-1, IL-6, chemokines, and TNF itself. Activation by TNF causes increased adhesion of cells to the endothelium and can be cytotoxic, particularly to tumor cells. TNF-deficient mice are resistant to septic shock induced by high doses of LPS but have increased susceptibility to bacterial infection. The dual role of TNF in controlling bacterial replication and in septic shock emphasizes the point that although the goal of an immune response is to eliminate invading microorganisms, the response itself can be injurious to normal host tissues. Septic shock is an extreme example of this. Although the primary source of TNF is the mononuclear phagocyte, it is also produced by T cells, NK cells, and mast cells. LTα shares many of the same biological effects as TNF, mainly because of its ability to bind the same receptors. However, LTβR plays a unique role in the development of secondary lymph nodes.

Fas Ligand and Its Receptor Fas/APO-1/CD95

Fas (Apo-1/CD95/TNFRSF6) is a type I integral membrane protein structurally related to TNFR1. Fas can trimerize and transduce proapoptotic signals upon binding of its ligand, FasL. Similar to TNF, the physiological ligand for Fas (CD95L or FasL)

is synthesized as a type II membrane protein and is expressed on activated B cells, T cells, and NK cells. Fas-induced apoptosis can play an essential role in the termination of T-cell responses, particularly in the peripheral immune system. Fas can also play a key role in the induction of cell death by cytotoxic T cells (CTLs) and NK cells (Chapter 17), where it functions in conjunction with perforin. Nonapoptotic functions of FasL include lymphocyte costimulation and T-cell differentiation into short-lived effector memory cells.[49,50]

CD40 Ligand and CD40

CD40 is expressed by a variety of cell types, including B cells, DCs, monocytes, macrophages, and endothelial cells. It plays a major costimulatory role in B-cell differentiation and recombination and promotes survival through the induction of BCL-2 family members. Studies of both CD40-deficient mice and patients with hyper-IgM syndrome (Chapter 34) reveal that its function extends beyond the humoral immune response, with CD40 signaling also playing a role in cell-mediated immunity. CD40 ligand (CD154) is a 39-kDa protein expressed by activated CD4 T cells that can bind to and activate CD40 by cell–cell contact.

CD40L on T cells triggers antigen-presenting cell (APC) activation, including upregulation of the CD28 ligands B7-1 and B7-2. This indirectly boosts costimulation of the T-cell response. Because of its critical role in mediating T-cell help for B-cell class switching and autoantibody formation, blocking CD40L/CD40 interactions has been a therapeutic goal in autoimmune diseases. Clinical trials of a blocking anti-CD40L antibody in SLE showed promising results but were halted because of thrombotic events, likely resulting from the off-target effects of these antibodies on CD40L expressed on platelets.[51] More recently, antagonistic antibodies against CD40 with possible applications to treat transplantation and autoimmune diseases have been developed.[52]

Other TNF-Family Cytokines

Other members of the TNFR family play various roles in the development and function of the immune system. OX-40, CD27, CD30, and 4-1BB can mediate costimulation of T-cell activation. The TNF family ligand BAFF (BlyS/TALL1/TNFSF13B) promotes B-cell maturation and antibody secretion and can bind three distinct receptors, TACI (TNFRSF13B), BADD-R (TNFRSF13C), and BCMA (TNFRSF17).

Signaling

The TNF receptor superfamily can be divided into three subfamilies on the basis of the types of intracellular signaling molecules recruited (*e.g.,* FAS-associated death domain [FADD], TNF receptor-associated death domain [TRADD], or TNF receptor–associated factor [TRAF]) (Fig. 9.5).[53] The cytoplasmic domains of several receptors, including death receptor 3 (DR3), DR4, DR5, TNFR1, and FAS contain a conserved ≈80-amino acid motif termed the death domain (DD). This element is required for recruitment of DD-containing adaptor molecules that are involved in the initiation of apoptotic cell death (Chapter 13). For this reason, these receptors have been termed "death receptors." The function of a number of death receptors can be regulated by decoy receptors. These are cell surface molecules that bind ligand but lack functional intracellular domains. Other TNF receptor superfamily receptors that lack death domains (*e.g.,* CD27, CD30, CD40, HVEM, TNFR2, LT-βR, OX-40, and 4-1BB) associate with different types of adapter molecules, most notably members of the TRAF family.

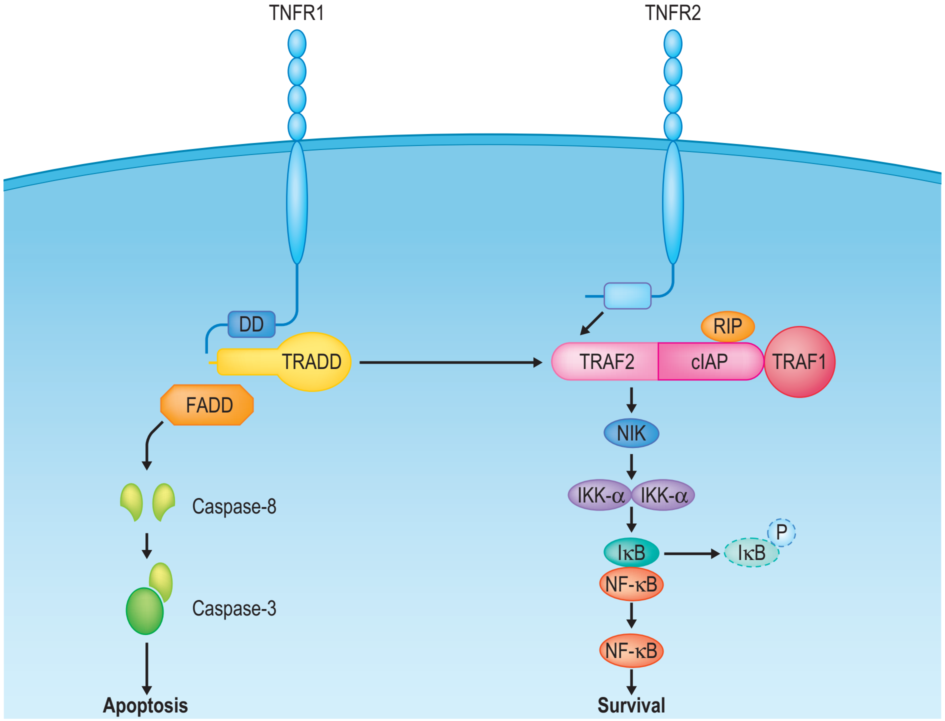

FIG 9.5 The role of the death domain (DD)– and death effector domain (DED)–containing molecules (e.g., Caspase-8) in signaling by tumor necrosis factor receptor 1 (TNFR1) and TNFR2.

Death Domains: TNF Receptor-Associated Death Domain and FAS-Associated Death Domain

The primary molecule transducing signals for TNFR1 is TRADD, which is directly recruited to TNFR1 after activation by TNF. This DD motif is found in both adaptor molecules, such as TRADD, and the cytoplasmic domains of the receptor itself (Fig. 9.6).

FIG 9.6 Signaling by tumor necrosis factor (TNF) family cytokines and their receptors.

The binding of TRADD to TNFR1 leads to the recruitment and activation of numerous associated signaling molecules. TNF-induced apoptosis is generally thought to be achieved by the interaction of TRADD with FADD (also known as MORT1), a ≈27-kDa protein that oligomerizes with TRADD through the DDs contained in both molecules. In turn, recruitment of FADD coordinately activates several members of the caspase family.[54]

Caspase-8, which is generally considered to be the apical caspase in the TNF and FAS pathways, is recruited to FADD in the activated complex and activated through increased local concentration. Cleaved caspase-8 can subsequently activate downstream caspases, notably caspase-3, which play a more proximal role in apoptosis. TRADD also has a TRAF-binding motif that leads to the recruitment of TRAF1 and -2 and the subsequent TRAF-dependent activation of proinflammatory signaling mediated by activation of NF-κB and mitogen-activated protein kinase (MAPK) pathways.

Although cell death in tumor cells can be induced by TNF, the most common result of TNFR1 ligation in primary immune cells is inflammation and sometimes protection from TNF-induced apoptosis. Recent evidence suggests that activation of proapoptotic and proinflammatory signaling by TNFR1 is not simultaneous but proceeds by sequential steps.

Unlike TNFR1, FAS can directly recruit FADD to its cytoplasmic DD, leading to the rapid formation of a death-inducing signaling complex (DISC), which contains FADD/MORT1 and caspase-8, thereby permitting activation of downstream caspases. FADD is recruited through interactions between charged residues in the DDs of FAS and FADD. Caspase-8 recruitment is accomplished through a structurally related domain termed the death-effector domain (DED). FADD DED contains two hydrophobic patches not present in the DD, which are vital for binding to the DEDs in the prodomain of caspase-8 and for apoptotic activity.[54]

Rather than DDs, the cytoplasmic domains of many receptors in the TNFR superfamily, including TNFR2, CD30, and CD40, contain short peptide consensus sequences that enable recruitment of a different family of adaptors, the TRAF proteins. A separate consensus sequence has been identified for TRAF6 versus other TRAF proteins, and other mechanisms probably operate to maintain the specificity of TRAF recruitment. Structural studies have revealed a mushroom-like structure for the TRAF proteins, with a trimer of the three TRAF subunits stabilized by a stalk-like coiled-coil domain.

TRAF proteins activate NF-κB and MAPK pathways through recruitment and activation of protein complexes that stimulate these signaling cascades. The exact mechanisms by which this occurs are not yet clear, but recent studies have called attention to the ability of TRAF proteins to catalyze ubiquitination of target signaling complexes, which can function as an activating step. TRAF6, which mediates NF-κB activation by a number of TNF-family receptors, associates with a protein complex that mediates K63-linked ubiquitination and activation of the inhibitor of κB kinase (IKK) complex, which consists of two catalytic subunits, IKKα and IKKβ, and a regulatory protein IKKγ or nuclear factor κB (NF-κB) essential modulator (NEMO).[55] Rather than causing degradation of IKK, K63-linked ubiquitination activates the kinase, leading to phosphorylation and degradation of IκB (inhibitor of NF-κB) and the release of active NF-κB subunits. Active NF-κB subunits translocate to the nucleus, where they regulate the expression of a wide variety of genes involved in the inflammatory response.

Some TNF-family receptors use other mechanisms to activate NF-κB. LTβ receptor activates the IKK complex via the serine–threonine kinase NIK, which was initially identified through its ability to associate with TRAF2. A naturally occurring mouse mutation termed *alymphoplasia* (*aly*) is the result of a point mutation of NIK. *Aly/aly* mice lack lymph nodes and Peyer patches and also exhibit disorganized splenic and thymic structures. This mutation, and the phenotype of LTβR knock-out mice, revealed the critical role of this receptor in normal lymph node development and the formation of "tertiary" lymphoid tissue in inflammation.

When a single TNF-family ligand, such as TNF, binds both a death receptor (TNFR1) and a non–death receptor (TNFR2), a number of mechanisms regulate receptor signaling and the cellular outcome. Rather than functioning in cell death, the physiological function of TNFR2 may be as a costimulator of lymphocyte proliferation.[56]

CLINICAL RELEVANCE

Tumor Necrosis Factor Receptor (TNFR) Superfamily Cytokines and Receptors and Disease

- Dominant mutations of in the gene encoding TNFR1 are associated with autosomal dominant periodic fever syndromes, known as TNFR1-associated periodic syndromes (TRAPS).
- Loss-of-function mutations in the gene encoding CD40L are associated with X-linked hyper-IgM syndrome (X-HIM).
- Dominant interfering mutations in *TNFRSF6,* encoding the Fas receptor are associated with autoimmune lymphoproliferative syndrome (ALPS).
- Rheumatoid arthritis (RA) often responds to therapeutic use of TNF antagonists.

Clinical Relevance

Mutations affecting the TNFR1 protein are associated with periodic fever syndromes (Chapter 60). Patients with the TNFR1-associated periodic syndrome (TRAPS) have missense mutations in exons encoding the extracellular regions of TNFR1 that affect normal TNFR1 function, prompting the designation. The mutated TNFR1 in TRAPS accumulates intracellularly and signals in a TNF-independent fashion to amplify inflammatory responses through the wild-type TNFR1.[57] Both TNF blockade with etanercept and IL-1 blockade have efficacy in reducing symptoms in TRAPS.[58]

The *in vivo* role of Fas signaling in the regulation of the immune system was confirmed when the naturally arising lpr and gld mouse strains were found to harbor homozygous mutations of Fas and Fas ligand, respectively. Both these mouse strains are characterized by lymphadenopathy and splenomegaly resulting from the accumulation of unusual $CD4^-CD8^-$ T cells, as well as the production of autoantibodies. Heterozygous dominant negative mutations in the gene encoding Fas cause the autoimmune lymphoproliferative syndrome (ALPS) (Chapter 35).

The gene encoding CD40 ligand is defective in X-linked hyper-IgM syndrome (X-HIM), a rare inherited disorder in which affected male children generate only IgM antibodies, many of which are autoantibodies (Chapter 34). Patients with X-HIM frequently suffer opportunistic infections, usually bacterial, and have an increased susceptibility to cancer. The physiological role of the B cell–activating factor (BAFF) receptor in mouse B-cell development is illustrated by BAFF-R mutations in the A/WySnJ mouse, which lacks peripheral B cells. TACI knock-out mice have hyperactive B cells, but in humans, dominant negative TACI mutations have been found in patients with common variable immunodeficiency affecting B-cell numbers and function (Chapter 34), which argues that in humans TACI serves as a positive modulator of B cells.

KEY CONCEPTS

Properties of the Interleukin-1 Receptor/Toll-Like Receptor (IL-1R/TLR) Family

- IL-1 plays a key role in fever and acute-phase responses.
- IL-18 augments T-helper 1 (Th1) cell differentiation.
- TLRs modulate proinflammatory signals in response to bacterial proteins.

INTERLEUKIN-1/TOLL-LIKE RECEPTOR FAMILY

Ligand and Receptor Structure

The IL-1/TLR family of receptors comprises at least 11 members, including the IL-1RI, IL-1RII, IL-1R-associated protein (IL-1RAcP), IL-18R, IL-18RAcP, IL-1Rrp2, IL-1RAPL, IL-33R(T1/ST2), TIGGIR, SIGGIR, and the mammalian TLRs.[59] The ligands for these receptors include IL-1, IL-18, IL-33, and IL-1 F5–IL-36 α, β, and γ; IL-36RA; IL-33 and IL-37; and IL-38.[60]

Family Members and Their Actions

Interleukin-1

There are two cell surface receptors for IL-1, type I (IL-1R1) and type II (IL-1R2). Both these bind ligand (see Fig. 9.4), but only IL-1R1 transduces signals. The extracellular domain of IL-1R1 has three Ig-like domains and a 200-amino acid cytoplasmic domain. Upon ligand binding, IL-1R1 associates with IL-1R accessory protein (IL-1RAcP), which is critical for the initiation of signaling. The IL-1R2 cytoplasmic domain is extremely short and has been suggested to be a "decoy" receptor, competing with IL-1RI for ligand binding and attenuating signaling. Both IL-1Rs are susceptible to proteolytic cleavage near the membrane surface. Thus they can be found as soluble proteins that can "buffer" IL-1 signaling. These soluble receptors are readily detectable in the circulation.

There are three members of the IL-1 gene family: two agonists, IL-1α and IL-1β, and one antagonist, IL-1 receptor antagonist (IL-1Ra). Both IL-1α and IL-1β are synthesized as precursor proteins. IL-1α and IL-1β are structurally similar and have similar actions, but they are regulated differently. IL-1α is processed by a calpain-like converting enzyme, but granzyme B and neutrophils and mast cell proteases can also cleave the precursor. The proform of IL-1α has biological activity, but cleavage results in increased biological activity. IL-1β is regulated at the levels of mRNA stabilization and translation, and it requires proteolytic activation. Pro–IL-1β remains in the cytoplasm until it is cleaved by proteases, such as caspase-1. It is then transported out of the cell.

The cleavage of IL-1β occurs in a multiprotein complex called the *inflammasome.* The key components of the inflammasome are caspase-1 and a recognition/assembly component nucleotide-binding oligomerization domain (NOD)–like receptor (NLR). Another protein called ASC (a simple adapter protein containing both pyrin and CARD domains) is required to facilitate assembly. NLR proteins are intracellular pattern-recognition receptors that contain three domains: *(i)* a segment with multiple leucine-rich repeats, whose role is to recognize the trigger for activation (whether directly or indirectly remains unclear); *(ii)* a portion called a NACHT domain, which leads to adenosine triphosphate (ATP)–dependent dimerization of the NLR after trigger recognition; and *(iii)* a protein–protein interaction domain, most commonly either a pyrin or a CARD domain, which recruits caspase-1.

The NLRP3 inflammasome is the best studied. Recognition of the trigger by NLRP3 causes its dimerization, recruitment of ASC via interaction of the pyrin domains of NLRP3 and ASC, and subsequent recruitment of caspase-1 via the CARD domains present in both ASC and caspase-1. Dimerization of caspase-1 upon inflammasome assembly allows for autoactivation by cleavage of the proform to generate active enzyme. The NLRP3 inflammasome can be activated by ATP, components of gram-positive bacterial cell walls, intracytoplasmic DNA, molecules resulting from tissue damage, uric acid crystals, alum, silica, asbestos, and amyloid-β among others. Cigarette smoke and cholesterol crystals also activate caspase-1.[61]

Similar to IL-1α, IL-1β can be cleaved and activated by other proteases, including neutrophil elastase, cathepsin, and proteinase-3 (PR-3). Mast cell proteases, as well as caspase-8, have also been shown to cleave IL-1β precursor. The mechanism of release of IL-1 and related family members from cells is somewhat mysterious because they lack a classic signal peptide and do not enter the secretory pathway. Although there is some evidence that IL-1β can be cleaved and released from cells without cell death, a large body of evidence suggests that IL-1 family proteins are released from cells upon lysis. Because of this, and the large numbers of cellular insults that result in release of IL-1 and related proteins and trigger inflammation, it has been proposed that they function as “alarmins” and act as sentinels of cellular damage.

The principal functions of IL-1 include the induction of acute-phase protein synthesis, cachexia, and fever. In fact, it was the first endogenous pyrogen to be identified. It induces the production of IL-6 and chemokines, promotes hematopoiesis, stimulates adhesion of vascular leukocytes to the endothelium, and has procoagulant effects. Importantly, IL-1 is a critical differentiation factor for Th17 cells, which underscores the role of this cytokine in inflammation and inflammatory diseases. Interestingly, it has recently been shown to activate ILC2, inducing proliferation and cytokine expression.[62] Unlike Fas and some of the other TNF-family cytokines, IL-1 does not directly induce cell death. Mononuclear phagocytes are the main, but not exclusive, source of IL-1. IL-1RI$^{-/-}$ and IL-1β$^{-/-}$ mice have blunted fever responses to some (but not all) stimuli. This indicates that despite the impressive actions of IL-1, it is evidently redundant to some extent in febrile responses.

Interleukin-18

A major action of IL-18, which is constitutively expressed by most cell types, is the induction of IFN-γ, and NK cells activation, a function it typically performs synergistically with IL-12. These functions are important for its antitumor activity. It has also been shown to promote angiogenesis and tumor progression.[63] IL-18 can induce IL-4 and IL-13 production, indicating a somewhat broader range of action. IL-18 precursor can be cleaved by the NRLP3 inflammasome as well as the NRLC4. IL-18–binding protein interacts with IL-18 and prevents association with IL-18R. IL-18R was first designated IL-1Rrp (IL-1R–related protein) before being recognized as the receptor for IL-18. The receptor is expressed predominantly on T cells, B cells, and NK cells. It associates with an accessory protein, IL-18RAcP.

Interleukin-33

IL-33 (previously known as IL-1 F11) appears to be a cytokine that acts by binding to a specific extracellular receptor, namely, the IL-1R –related protein ST2, also known as IL-33R. It also acts as a transcriptional repressor by associating with chromatin. Because of this dual effect and because of the expression of ST2 on different cell types, IL-33 acts on both immune and nonimmune cells. It acts on T and B cells, promoting Th2-associated cytokines, including IL-4, IL-5, and IL-13.[64] IL-33 acts on mast cells, promoting degranulation, an effect also shown on basophils and granulocytes in general, but also enhancing cell survival. Upon cleavage by mast cell proteases, IL-33 can also activate ILC2, inducing cytokines production and eosinophils recruitment.[65,66] Interestingly, IL-33–treated basophils have been shown to suppress arthritic inflammation. IL-33 can also act on endothelial and epithelial cells to induce angiogenesis and production of other cytokines and chemokines.

Interleukin-36

The three members of the IL-36 subfamily, IL-36α, β, and γ, are encoded by separate genes. They bind to a receptor composed of IL-36R and IL-1RacP. These cytokines are mostly expressed in skin. IL-36α transgenic mice exhibit skin inflammation, and these IL-36 cytokines can play a role in psoriasis.[67] IL-36 receptor antagonist (IL-36Rα, also known as IL-1 F5) acts as an antagonist for the three IL-36 family cytokines. *IL36RA* mutations are associated with generalized pustular psoriasis. Keratinocytes from patients with deficiency of IL-36 receptor antagonist (DITRA) have elevated levels of multiple inflammatory cytokines in lesional skin. They are highly expressed in skin and airway and may be involved in skin diseases, such as psoriasis (Chapter 64).

Interleukin-37

IL-37 (also known as IL-1 F7) exists in several splice variants of which IL-1F 7b has been the most studied. IL-37 binds to IL-18Rα chain, although with a lower affinity than IL-18. It uses TIR8 (also known as SIGIRR) as second chain of the receptor. Despite binding to the same receptor and its capacity to complex with IL-18Acp, IL-37 does not seem to act as a receptor antagonist for IL-18. IL-37 translocates to the nucleus and binds Smad3, enabling regulation of gene transcription. Cleavage of IL-37 appears to be dependent on caspase-1 and -4. Its antiinflammatory activity is dependent on ASC or NLRP3. IL-37 negatively regulates excessive inflammatory responses. Macrophages expressing IL-37 no longer secrete proinflammatory cytokines, and IL-37 transgenic mice are resistant to LPS-induced shock.[68]

Interleukin-38

IL-38 (IL-1 F10) has a 43% homology with IL-36Rα and, similarly, has an antiinflammatory activity. It is released by apoptotic cells to limit macrophage activation. Polymorphic IL-38 genes have been associated with increased susceptibility for autoimmune and autoinflammatory diseases (*e.g.,* RA, spondyloarthritis, and psoriatic arthritis).

Other Members of the Interleukin-1 Family

The remaining members of the IL-1 and IL-1R families are the receptor homologues APL and TIGIRR. These receptors have limited tissue distribution, with TIGIRR found almost exclusively in the brain and APL in the brain and a small number of other tissues.[69] Little is known of about the function of TIGIRR or

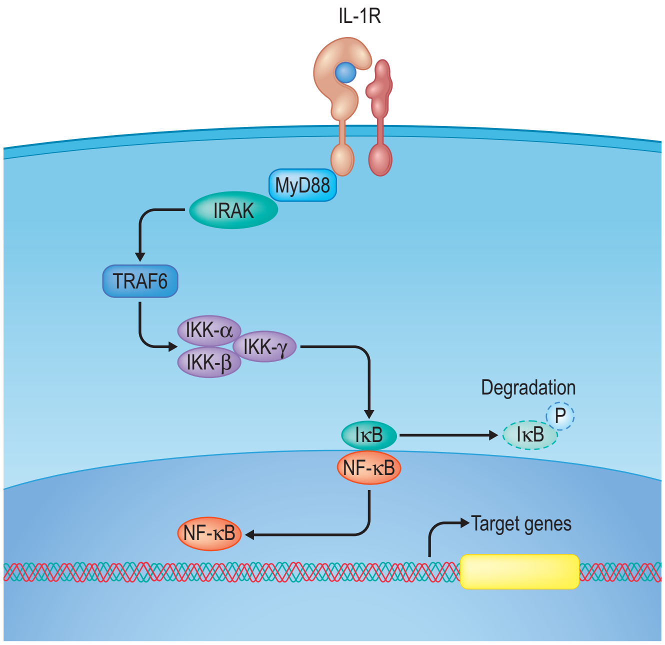

FIG 9.7 Mechanism of signal transduction by interleukin-1 receptor (IL-1R) and related receptors.

about APL in any organ other than the brain. Most insight into APL has come from the finding that deletions or mutations of this gene cause mental retardation.

Signaling

Ligand binding to IL-1R, IL-18R, and TLRs results in NF-κB activation (Fig. 9.7). These receptors all associate with the adapter protein MyD88 (Chapter 3). MyD88 has a C-terminal TIR domain and an N-terminal DD. MyD88 allows the recruitment of IL-1 receptor-associated kinase (IRAK), which also has an N-terminal DD. IRAK, in turn, permits the recruitment and activation of a member of the TRAF family, TRAF6. This leads to the activation of the serine kinases TAB2 and TAK1 (TGF-β–associated kinase-1), as well as that of the inhibitor of the κB kinases IKKα and IKKβ. With IKKγ or NEMO, these kinases phosphorylate IκB, which leads to its degradation within proteasomes, freeing bound NF-κB for nuclear translocation. Mice deficient in MyD88, IRAK, or TRAF6 have diminished responses to IL-1R/TLR family ligands. Other adapter molecules, including Mal and TRIF, are involved in TLR signaling.

CLINICAL RELEVANCE

Diseases Associated With the Interleukin-1 (IL-1) Family of Cytokines

- Mutations in genes involved in the formation of the inflammasome complexes result in increased secretion of IL-1 and other IL-1 family members.
- Mutations in the gene coding for IL-1 receptor antagonist cause a systemic autoinflammatory disease.

Clinical Relevance

The actions of IL-1 are tempered by the actions of a critical natural cytokine antagonist, IL-1Ra, which is encoded by the *IL1RN* gene. Mutations in *IL1RN* can cause a systemic autoinflammatory disease, which is denoted deficiency of IL-1Ra or DIRA.[70] Mutations in *NLRP3* contribute to several hereditary periodic fever syndromes (Chapter 60), including familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome, and neonatal-onset multisystem inflammatory disease (NOMID; in Europe called chronic infantile, neurological, cutaneous, and articular [CINCA] syndrome). NLRP3 is also called *cryopyrin;* thus these disorders have been collectively referred to as *cryopyrinopathies.*[71] Mutations in the alternative inflammasome component NRLC4 have also been showed to result in autoinflammation caused by excessive IL-18 production and, ultimately, macrophage activation syndrome.[72]

INTERLEUKIN-17 RECEPTORS

Although their precise functions are incompletely understood, IL-17 and related cytokines are major inducers of inflammation and serve to recruit inflammatory cells.

Ligand and Receptor Structure

The IL-17 receptor family is incompletely understood but comprises at least five receptors: IL-17AR and IL-17BR (IL-17RH1), IL-17RL (receptor like), IL-17RD, and IL-17RE, which are ubiquitously expressed.[73,74] These receptors have a single transmembrane domain and exceptionally large cytoplasmic tails. The ligands in the IL-17 family include IL-17A–F. The precise interactions between ligands and receptors have not been defined. A viral IL-17 homologue, designated HVS-13, is present in the *Herpesvirus saimiri* genome. Structurally, the IL-17 family contains cysteine knots. In this respect, these cytokines are related to other, better-known cytokines, such as nerve growth factor.

IL-17 (IL-17A) is located on human chromosome 6 (mouse chromosome 1) and is produced by activated CD4, γ/δ and CD8 T cells. Recent findings have suggested that CD4 T cells that preferentially produce IL-17 (Th17 cells) represent a distinct lineage of effector Th cells (Chapter 16). These cells can be differentiated via varied sets of stimuli that include IL-1β, IL-6, IL-21, and TGF-β. IL-23 appears to have a critical role in regulating the biological activity of these cells. IL-17F is located adjacent to IL-17. Although it seems to be regulated in a similar manner, it may be more widely expressed than IL-17. Less well studied are IL-17B, IL-17C, and IL-17D. All of these are thought to be expressed in a variety of nonhematopoietic tissues, although IL-17D is reported to be produced by CD4 T cells.

IL-17A and IL-17F evoke inflammation, largely by inducing the production of chemokines, G-CSF, and GM-CSF, and this leads to the subsequent recruitment of polymorphonuclear leukocytes. IL-17 also induces production of matrix metalloproteinase (MMP) by epithelial cells, which may be an important aspect of the proinflammatory effects. IL-17 family cytokines appear to be important in host defense against *Klebsiella pneumoniae* and *Mycobacterium tuberculosis.* Abundant data also point to the pathogenic roles of IL-17A in models of immune-mediated disease and in human autoimmune disorders. IL-17E, which is also known as IL-25, is produced by Th2 cells and mast cells. It evokes an inflammatory response characterized by overproduction of Th2 cytokines, mucus production, epithelial cell hyperplasia, and eosinophilia. This cytokine is essential for the elimination of helminthic parasites.[75]

Signaling

Engagement of the IL-17 receptor activates MAPKs, the PI3 kinase pathway and NF-κB. Signaling via IL-25 is reported to be dependent on the adapter molecule TRAF6. IL-17 acts synergistically with TNF.[76] The IL-17R associates with an adapter molecule, called *Act,* through the SEFIR domains, which are part of both the receptor and the adaptor.

CLINICAL RELEVANCE

Therapeutic Application of Interleukin-17 (IL-17) Blockade

Monoclonal antibodies (mAbs) neutralizing IL-17 or antagonizing the IL-17 receptor are effective in treating psoriasis and psoriatic arthritis.

Clinical Relevance

Many human diseases and animal models of autoimmune disease have been associated with increased levels of IL-17. The inflammatory effects of IL-23 and IL-17 also appear to be associated with malignant transformation. Targeting IL-17 ligands and receptors could thus be a useful strategy. However, IL-17A and IL-17F are essential for mucocutaneous immunity against *Candida albicans,* and IL-17 deficiency results in chronic mucocutaneous candidiasis.[77]

CYTOKINES ACTIVATING RECEPTOR TYROSINE KINASES

Ligand and Receptor Structure

Many growth factors, such as insulin and epidermal growth factor, utilize receptor tyrosine kinases (RTKs). Some, but not all, of these factors can be classified as cytokines. These include CSF-1 (colony-stimulating factor 1 or M-CSF), stem cell factor (SCF, c-KIT ligand, or steel factor), platelet-derived growth factor (PDGF), and FMS-like tyrosine kinase 3 ligand (FLT3-L). All of these have important hematological effects and tend to be included in discussions of cytokines. The structure of SCF and CSF-1 is similar to that of the cytokines that bind type I receptors, as they too form four α-helical bundles, even though their receptors are entirely distinct. The similarities in their three-dimensional structures point to a common evolutionary ancestor. The receptors in this subfamily typically have five Ig-like loops in their ligand-binding extracellular domains. The cytoplasmic domain contains a tyrosine kinase catalytic domain interrupted by an "insert region" that does not share homology with other tyrosine kinases. This segment is used to recruit various signaling molecules.

Family Members and Their Actions

Stem Cell Factor

Bone marrow stromal cells can synthesize SCF (c-KIT ligand or Steel factor) as either a secreted or a transmembrane protein. SCF is required to make stem cells responsive to other CSFs. SCF is widely expressed during embryogenesis and is also detectable in blood circulation in normal adults. It has effects on germ cells, melanocytes, and hematopoietic precursors and has important effects on the differentiation of mast cells as well. Naturally occurring mouse mutations of SCF (Steel) or its receptor (W) have been recognized for many years. These mice have defects in hematopoiesis and fertility, lack mast cells, and have absent coat pigmentation.

Colony-Stimulating Factor 1

CSF-1, also known as monocyte–macrophage–CSF or macrophage-CSF (M-CSF), is a hematopoietic growth factor that supports the survival and differentiation of monocytic cells. It is produced by a wide variety of cells, including monocytes, smooth muscle cells, endothelial cells, and fibroblasts. M-CSF–deficient mice manifest monocytopenia and osteopetrosis. IL-34 is a new cytokine that binds to the CSF-1 receptor.

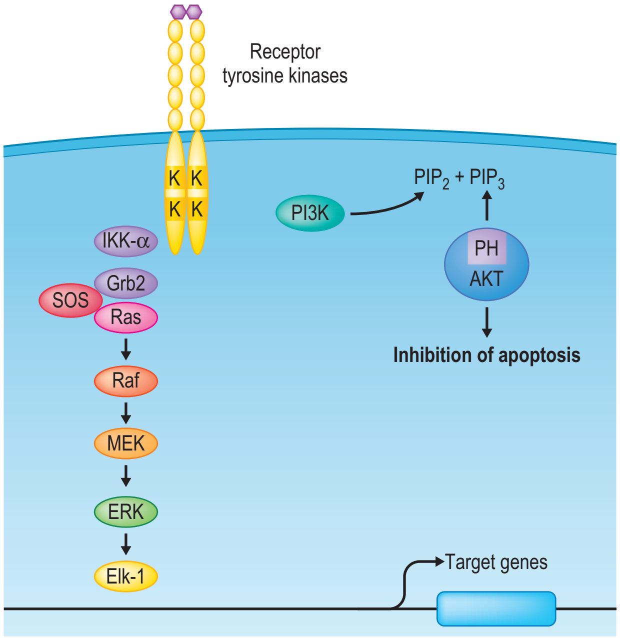

FIG 9.8 Mechanism of signal transduction by receptor tyrosine kinases.

FMS-like tyrosine kinase 3 ligand (FLT3-L) synergizes with other cytokines, including SCF, in inducing proliferation of hematopoietic precursors. FLT3-L is an important regulator of DCs.

Signaling

The first step in signaling by the RTKs is ligand-induced receptor dimerization (Fig. 9.8). Dimerization brings the two kinase domains into proximity and results in the activation of phosphotransferase activity. This leads to autophosphorylation of the receptor subunits on the tyrosine residues, which are then bound by a variety of signaling molecules, initiating signal transduction. During this important step, the signaling and adapter molecules recognize phosphotyrosine residues on the RTKs by virtue of either their SH2 domains or their PTB domains.

A major pathway activated by RTKs is the RAS/RAF/ERK pathway. RAS is a small G protein with intrinsic low guanosine diphosphate/guanosine triphosphate (GDP/GTP) exchange activity. In RTK signal transduction, two adapter proteins, GRB2 and SHC, have important functions in RAS activation. In some cases, GRB2 binds directly to phosphotyrosine residues on the cytoplasmic tail of the receptor via its SH2 domain. Alternatively, SHC can bind first and then recruit GRB2. In addition to an SH2 domain, GRB2 has two SH3 domains that bind proline-rich segments of the guanine nucleotide exchange factor son of sevenless (SOS) protein, recruiting it to the membrane and allowing it to activate RAS. Activated RAS binds and activates the serine/threonine kinase RAF, which, in turn, phosphorylates the dual-specificity kinase MEK. Activated MEK phosphorylates and activates ERK (extracellular signal–regulated kinase), which then translocates to the nucleus, where it phosphorylates and modulates the activity of various transcription factors, including ELK-1. Accordingly, mutations of RAS that lead to the constitutive activation of the ERK pathway have been found in a wide variety of human cancers.

Another important pathway activated by RTKs is the phosphatidylinositol 3′-OH kinase (PI3-kinase) pathway.[78] PI3-kinase catalyzes the formation of phosphatidylinositol-3,4,5-trisphosphate (PtdIns[3,4,5]P3) and PtdIns(3,4)P2. These phospholipids are recognized by proteins with pleckstrin homology (PH) domains. One such protein is protein kinase B (PKB or AKT), which has been implicated in the regulation of apoptosis. The PI3-kinase pathway is inhibited by the lipid phosphatase PTEN, which dephosphorylates PI3-kinase–generated phosphatidylinositides. Deletion of PTEN has been found in numerous tumor types, demonstrating a role for this protein as a tumor suppressor.

GOF mutations of c-kit result in a disorder termed *systemic mastocytosis* (Chapter 23). Mutations resulting in a fusion between the *PDGFRA* and *FIP1L1* genes underlie hypereosinophilic syndrome.[79,80]

KEY CONCEPT

Properties of the Transforming Growth Factor-β (TGF-β) Receptor Family

- TGF-β receptors play a key role in lymphoid homeostasis, with pro- and antiinflammatory actions.
- TGF-β promotes the differentiation of regulatory T cells and T-helper 17 (Th17) cells.
- TGF-β receptors transduce signals through SMAD proteins.
- TGF-β receptor function is dysregulated in many forms of human cancer.

TRANSFORMING GROWTH FACTOR-β LIGAND AND RECEPTOR FAMILIES

TGF-βs are a family of over 40 cytokines that inhibit cellular proliferation and can induce apoptosis of a variety of cell types. TGF-βs are involved in a number of biological processes, including tissue remodeling, wound repair, development, and hematopoiesis. Mutations of the elements in this pathway also contribute to malignant transformation. The mammalian ligands that belong to this family include TGF-β_1, -β_2, and -β_3, bone morphogenic proteins (BMPs), activins, inhibins, and müllerian-inhibiting substance. Despite their name, TGF-βs inhibit the growth of many other cells and, in combination with other cytokines and growth factors, may induce growth instead. TGF-βs also induce collagen and fibronectin production by fibroblasts, which are thought to be responsible, at least in part, for diseases characterized by fibrosis (*e.g.,* systemic sclerosis and pulmonary fibrosis). Functionally, TGF-β inhibits many aspects of lymphocyte function, including T-cell proliferation and CTL maturation. Transgenic mouse studies have been performed by using dominant negative forms of the TGF-β receptor. These mice exhibit massive expansion of lymphoid organs and develop T-cell lymphoproliferative disorders.[46]

Ligand and Receptor Structure

TGF-βs are expressed as biologically inactive disulfide-linked dimers that are cleaved to form active dimers. On translocation into the endoplasmic reticulum, the N-terminal leader peptide is cleaved, and the mature protein is subsequently generated by a second cleavage event that releases an N-terminal proregion. The proregion can remain associated with the biologically active C-terminal region, inhibiting its activity.

The biological effects of TGF-βs and their related ligands are mediated by two classes of receptor, designated type I (RI) and type II (RII).[81] A third group of receptors, denoted type III, also exists (*e.g.,* TGF-β RIII in the case of TGF-β). This latter group does not actively participate in signal transduction but is thought to function to present ligands to the functional receptors. Similar to the RTKs described previously, the cytoplasmic domains of TGF-β receptors possess intrinsic kinase activity. However, TGF-βRI and TGF-βRII encode serine/threonine kinases. The signaling cascade appears to be initiated by the binding of TGF-β to the type II receptor, inducing the assembly of a ternary complex containing TGF-β, TGF-βRII, and TGF-βRI.

TGF-β Family Members and Their Actions

The three known human TGF-βs—TGF-β_1, TGF-β_2, and TGF-β_3—all have expressed molecular weights of 25 kDa. These three isoforms of TGF-β are closely related and have very similar biological functions. TGF-β_1, the most abundant form, is the only isoform found in platelets. T cells and monocytes mainly synthesize TGF-β_1, a critical function of which is to antagonize lymphocyte responses.

Approximately half of TGF-$\beta_1^{-/-}$ mice survive until birth, and 3–4 weeks later, they typically succumb to an overwhelming autoimmune state characterized by lymphoid and mononuclear infiltration of heart, lung, and other tissues, and by autoantibody production. These studies, along with selective inhibition of TGF-β function in T cells, indicate that TGF-β plays a crucial role in T-cell homeostasis and the prevention of spontaneous T-cell differentiation. TGF-β_1 induces FoxP3, promotes adaptive Treg-cell differentiation, and inhibits IFN-γ production. Conversely, TGF-β_1 with IL-6 induces IL-17, a proinflammatory cytokine. Thus TGF-β_1 has both proinflammatory and antiinflammatory activities.

TGF-β_2 is the most abundant TGF-β isoform in body fluids, whereas TGF-β_3 is the least abundant of the three. TGF-β_2– and TGF-β_3–null mice exhibit defects distinct from those observed in TGF-β knock-out mice, particularly in bone and internal organ formation. Their deficiency is embryonically lethal, demonstrating that although the three isoforms functional similarly *in vitro,* they play distinct roles *in vivo.*

The human type II receptor is an 80-kDa glycoprotein that is the principal receptor for TGF-β. Upon binding of its ligand to RII, the type I receptor is recruited into the complex and activated through phosphorylation of its GS domain. The principal type I receptor in the TGF-β pathway is the ≈55-kDa activin-like kinase-5 (ALK-5). ALK-1 can also be recruited into the complex and can transduce TGF-β–mediated signals.

Signaling

Ligand binding to the type II receptor allows the recruitment of the type I receptor[81] (Fig. 9.9). Although the receptor subunits have some affinity for one another, the complex of the receptor subunits bound to ligand is more stable. The type II receptor is thought to be a constitutively active kinase. Upon ligand binding, the type II receptor phosphorylates the type I receptor. The type I receptor is structurally distinct from the type II receptor in having a glycine- and serine-rich sequence juxtamembrane domain that precedes the kinase domain, which is referred to as the *GS domain.* It is this site that is phosphorylated by the

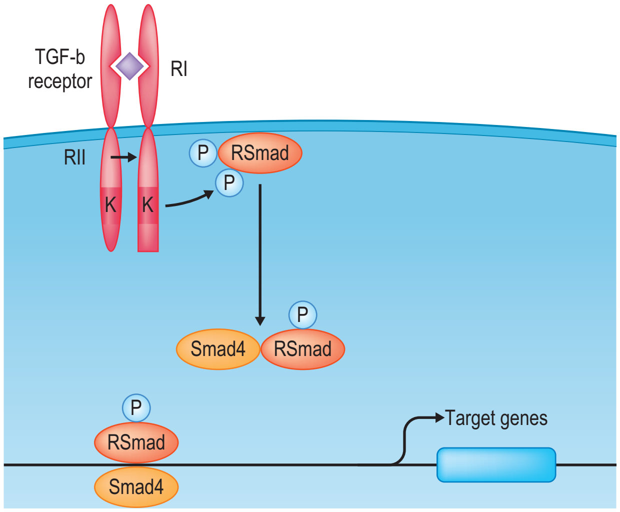

FIG 9.9 SMADs and signaling by transforming growth factor-β (TGF-β) superfamily receptor serine kinases.

type II receptor. In turn, the type I receptor is responsible for phosphorylating key signaling intermediates. It is not clear whether activation of the type I receptor results from enhancement of its kinase activity, the appearance of substrate-binding sites, or a combination of the two.

SMADs

The primary substrates activated by the type I receptors are SMADs, a group of related proteins that have been highly conserved throughout evolution and play a critical role in TGF-β signal transduction.[82] Eight mammalian SMADs have been identified. All exhibit a high degree of specificity for conserved motifs in the cytoplasmic tail of type I receptors. These proteins do not contain any previously known structural or enzymatic motifs. However, they have two homology domains, termed the MH1 and MH2 domains, at the N- and C-termini, respectively, which are separated by a central linker domain. The extreme C-terminus of some SMADs is a critical site of phosphorylation, as described below. SMADs have been subdivided into three classes based on functional distinctions.

R-SMADs. The receptor-regulated SMADs (R-SMADs) directly interact with, and are phosphorylated by, the type I receptor. These include SMAD1, -2, -3, -5, and -8. SMAD2 and SMAD3 are phosphorylated in response to TGF-β, whereas SMAD1, -5, and -8 are primarily activated in response to BMP activation. R-SMADs bind to the GS domain of type I receptor and are phosphorylated at a conserved SSXS motif in their C terminus. The interaction of R-SMADs with TGF-β receptors can also be regulated by another molecule termed SARA (SMAD anchor for receptor activation). SARA binds unphosphorylated SMAD2 and SMAD3. By virtue of its FYVE domain, SARA can bind phospholipids and localize SMADs to the plasma membrane, facilitating receptor binding. Phosphorylation of SMADs also permits dissociation from SARA.

Once phosphorylated, R-SMADs dissociate from the activated type I receptor and associate with SMAD4 in the cytoplasm. This is followed by nuclear translocation of the heteromeric SMAD complex, the binding to cognate DNA motifs in the promoters of TGF-β–responsive genes, and the concomitant induction of transcription. The SMAD MH1 motif mediates sequence-specific DNA binding, whereas the MH2 domain contains the transcriptional activation domain.

SMAD2-null mice lack anterior/posterior specification and fail to develop mesoderm. SMAD3-deficient mice have limb malformations and defective immune function. SMAD3-null mice exhibit defective TGF-β responses. However, these mice also display accelerated wound healing compared with normal mice, which seems to contradict the role of SMAD3 as a positive regulator of TGF-β in enhancing wound healing.

Upon recruitment to their cognate activated type I receptor, R-SMADs are phosphorylated on C-terminal serine residues, triggering homodimerization of R-SMADs or heterodimerization with another class of SMAD, the common SMAD or C-SMAD (see below).

C-SMADs. SMAD4 is the only known C-SMAD in vertebrates. It is thought to function as the central and essential downstream mediator of other SMADs in all TGF-β/BMP pathways. The SMAD MH2 domain is important for both receptor interaction and SMAD dimerization. SMAD4 lacks the SSXS element conserved in the R-SMADs and thus is not phosphorylated, rendering it unable to bind type I receptors directly. SMAD4-deficient mice die early in embryogenesis and exhibit severe defects in gastrulation.

I-SMADs. The third subfamily of SMADs is the inhibitory SMADs, or I-SMADs. In mammals, SMAD6 and SMAD7 are the I-SMADs. SMAD6 utilizes an alternative mechanism and is thought to function by competing with SMAD4 for binding to an R-SMAD. Studies with SMAD6-deficient mice indicate a role in the development and homeostasis of the cardiovascular system. SMAD7 is induced by TGF-β and binds to TGF-β receptors inhibiting the phosphorylation of R-SMADs, thus serving as a classic feedback inhibitor.

Consistent with their key functions in development, gene targeting of SMAD molecules has been shown to produce severe phenotypic abnormalities.

SMAD pathways. Although a canonical SMAD DNA-binding element (SBE) has been described (AGAC), comparison of the TGF-β responsiveness of synthetic promoters to natural promoters has revealed that SMADs can only partially account for the gene-regulatory effects of TGF-β signaling. SMADs also interact with a variety of other transcription factors, transcriptional coactivators, and transcriptional corepressors to regulate transcription of a select subset of complex promoters in a coordinated manner. For example, FAST-1 (forkhead activin signal transducer), a winged helix forkhead transcription factor, associates with the SMAD2/SMAD4 complex. SMADs also bind to c-JUN/c-FOS, and AP-1 sites frequently overlap with SBE sites in the naturally occurring promoters of TGF-β–responsive genes. SMADs can also bind ATF2, the vitamin D receptor, and other transcription factors and can recruit the coactivators CBP/p300. Additionally, the SKI and SNON corepressors can interact with SMADs and antagonize TGF-β signaling.

Other TGF-β–Activated Pathways

Other signaling pathways are known to mediate TGF-β signals. In particular, a number of members of the MAPK family are activated in response to TGF-β. TGF-β induces ERK, JNK, and p38 MAPK activity. Inhibition of several of these pathways inhibits TGF-β–mediated transcriptional activation. In addition, a MAPK family member, TAK1, has been implicated in TGF-β signaling. TAK1 is activated in response to ligand binding and has been shown to associate with another molecule, TAB1 (TAK1-associated binding protein), which activates TAK1 kinase activity. Together, they have been reported to activate the MAPK pathway(s), leading to activation of p38/MPK2 and c-JUN N-terminal kinase (JNK), with evidence that this may take place via MKK6 and MKK4, respectively.

Clinical Relevance

Although the relevance of TGF-β to clinical immunology remains unclear, defects in the TGF-β pathway have been identified in a range of human cancers. SMAD4 is deleted in half of all human pancreatic carcinomas. Mutations in SMAD2 have been identified in patients with colon cancer, and somatic mutations in TGF-β receptors have been identified in colon and gastric cancers. Loss of SMAD3 is associated with leukemia. In addition, oncogenic RAS has been shown to repress SMAD signaling by negatively regulating SMAD2 and SMAD3.

OTHER CYTOKINES

Interleukin-14

Several new cytokines have been identified, but their functions are less clear compared with those discussed above. IL-14 was identified as a high-molecular-weight B-cell growth factor produced by T cells and some B-cell tumors. The precise nature of this putative cytokine is still unclear.

Interleukin-16

IL-16 was formerly termed *lymphocyte chemoattractant factor* because of its ability to recruit CD4 T cells.[83] It is unrelated to other cytokines, and its only known receptor is the CD4 molecule. It was originally identified as a product of CD8 T cells, but its message is widely expressed. CD4 T cells, eosinophils, and mast cells can all secrete IL-16. It is present in bronchoalveolar lavage (BAL) fluids from patients with asthma and those with sarcoidosis. It has also been detected in blister fluid from bullous pemphigoid lesions. The physiological function of IL-16 has yet to be clarified.

Interleukin-32

IL-32 is one of the newest cytokines, and it, too, is structurally distinct.[84] It is inducible by the combination of IL-12 and IL-18. IL-32 induces the expression of various cytokines, including TNF, IL-1, IL-6, and chemokines. It can synergize with muramyl dipeptides. IL-32 signals via NF-κB and p38. IL-32 is present in the rheumatoid synovium, and injection of IL-32 induces inflammation and recruitment of inflammatory cells.[85]

THERAPEUTIC TARGETING OF CYTOKINES AND CYTOKINE RECEPTORS

Because of their important activities in numerous diseases outlined in this chapter, cytokines and their receptors have been actively studied as therapeutic targets or as therapeutic agents (Table 9.4; Chapter 89). IFNs were the first cytokines to be considered as antiviral agents. Currently, type I IFNs are used to treat a wide array of disease from viral hepatitis (IFN-α and IFN-λ) to MS (IFN-β). IL-2 is currently marketed (as aldesleukin) for the treatment of renal cancer and melanoma. TNF was investigated after its discovery as an antitumor agent, but its inflammatory properties made it a highly successful target for the treatment of autoimmune and inflammatory diseases.

With the advent of molecular biology techniques and mAb engineering, targeting of these molecules has become a highly successful strategy to modulate the immune response (Chapter 89). IL-2 is not only a therapeutic protein but also a target. Daclizumab and basiliximab are mAbs directed against the IL-2Rα chain and have been approved for use in transplantation, MS, uveitis, and ulcerative colitis. IL-6, one of the most important proinflammatory cytokines, has also been targeted and several anti–IL-6 antibodies are now under development. Tocilizumab, which targets the IL-6R, has been approved for the treatment of several autoimmune diseases ranging from RA to ankylosing spondylitis.

The effective targeting of the p40 subunit of IL-12/IL-23 with the human mAb ustekinumab has resulted in effective treatment of some forms of psoriasis, psoriatic arthritis, and Crohn disease. However, ustekinumab is not effective in MS.

Many studies have implicated TNF in the pathogenesis of the chronic inflammatory diseases, such as RA and Crohn disease. Levels of TNF are highly elevated in the synovial fluid and the serum of patients with RA, as well as in the gastrointestinal mucosa of patients with Crohn disease. This suggests that the proinflammatory effects of TNF might underpin the severe inflammatory symptoms observed in these diseases. Of particular relevance to RA, TNF both inhibits the synthesis of cartilage components, such as proteoglycan, and stimulates bone resorption. These findings prompted the development of specific TNF inhibitors that have demonstrated great promise in the treatment of RA and Crohn disease. The two best-characterized of these inhibitors are monoclonal anti-TNF antibodies (infliximab, adalimumab, and golimumab) and chimeric TNFR2-Fc protein (etanercept). Clinical studies of these compounds have demonstrated that they can induce striking improvement in patients with RA (see Table 9.4). The side effects of TNF antagonism include increased incidence of infection, particularly with *M. tuberculosis,* and a possible increased incidence of cancer.[86] Other TNF-family cytokines have been targeted for therapeutic purposes. Targeting of RANKL with denosumab has been used for the treatment of osteoporosis as well as the bone resorption and hypercalcemia that results from bone metastases in cancer.

Because of the importance of IL-1 in the pathogenesis of fever, it would be expected that agents that inhibit IL-1 would be therapeutically useful. Indeed, IL-1Ra (anakinra), the naturally produced antagonist, has been studied in a variety of settings. It has been found to be somewhat efficacious in the treatment of RA. Anakinra, canakinumab, an anti–IL-1 antibody, as well as rilonacept, a fusion protein containing the extracellular portions of the two IL-1R components IL-1R and AcP, have been more successful in autoinflammatory disorders, particularly those related to overactivity of inflammasome components, such as the cryopyrinopathies. Canakinumab has also been successful in the treatment of more common autoinflammatory conditions, such as juvenile-onset idiopathic arthritis, as well as in the treatment of gout and type II diabetes.[87-89] Similarly, the human mAb canakinumab has entered the clinical arena with overlapping applications, and others are in various stages of clinical development. One of the most exciting new antireceptor antibodies is belimumab, which targets BAFF, a B-cell stimulatory TNF family member. Belimumab is the first licensed drug for the treatment for SLE in more than 50 years, and its mechanism of action is believed to be interference with B-cell survival, differentiation, and autoantibody formation.[90]

Beyond their beneficial effects to patients, the clinical effect of specific cytokine blockade with these agents is the ultimate

TABLE 9.4 Recombinant Cytokines and Biological Agents Currently in Clinical Use or Being Tested for Clinical Application

Name	Target	Phase	Indications
Daclizumab	Interleukin (IL)-2Rα	FDA approved	Transplantation, multiple sclerosis
Basiliximab	IL-2Rα	FDA approved	Transplantation uveitis, ulcerative colitis,
Benralizumab	IL-5R	II	Asthma, chronic obstructive pulmonary disease (COPD)
Reslizumab	IL-5R	II/III	Asthma, inflammation of skin and gastrointestinal tract
Mepolizumab	IL-5	FDA approved	Asthma, nasal polyp
Tocilizumab	IL-6R	FDA approved	Rheumatoid arthritis (RA), juvenile idiopathic arthritis (JIA), Castleman disease, ankylosing spondylitis
Clazakizumab	IL-6	II	RA, psoriatic arthritis
Siltuximab	IL-6	FDA Approved	Castleman disease
Sarilumab	IL-6R	FDA approved	RA Uveitis
Olokizumab	IL-6	III	RA Crohn disease
Sirukinumab	IL-6	III	RA, systemic lupus erythematosus (SLE)
ALX-0061	IL-6		RA, SLE
Oprelvekin	IL-11R	II	Thrombocytopenia, von Willebrand disease
Ustekinumab	IL-12/23 p40	FDA approved	Psoriasis, psoriatic arthritis, Crohn disease, sarcoidosis, palmoplantar pustulosis
Briakinumab	IL-12/23 p40	III	Psoriasis, Crohn disease
Lebrikizumab	IL-13	II	Asthma
Tralokimumab	IL-13	II	Asthma, COPD
Anrukinzumab	IL-13	II	Ulcerative colitis
TNX-650	IL-13	I/II	Hodgkin lymphoma
Brodalumab	IL-17	FDA approved	RA, psoriasis
Ikzekizumab	IL-17	FDA approved	RA, psoriatic arthritis
Bimekizumab	IL-17	II	Psoriatic arthritis, rheumatoid arthritis
BCD-085	IL-17	II	Ankylosing spondylitis; plaque psoriasis
Secukinumab	IL-17	FDA approved	Psoriasis, psoriatic arthritis, ankylosing spondylitis, RA, Crohn disease, multiple sclerosis (MS), xerophthalmia
NNC-114-0005	IL-21	II	Type I diabetes, SLE
Tildrakizumab	IL-23	III	Plaque psoriasis
Risankizumab	IL-23	III	Plaque psoriasis
Guselkumab	IL-23	II	Plaque psoriasis
Anakinra	IL-1	FDA approved	Autoinflammatory syndromes, RA
IL-Trap/Rilonacpet	IL-1	FDA approved	Autoinflammatory syndromes, RA, gout, JIA
Canakinumab	IL-1β	FDA approved	Autoinflammatory syndromes, RA
MABp1	IL-1α	I/II/III	Cancer, cachexia, atherosclerosis, plaque psoriasis, acne vulgaris, type II diabetes
Gevokizumab	IL-1β	III	RA, type I and type II diabetes, giant cell arteritis, Behçet disease, uveitis
NI-0501	Interferon (IFN)-γ	II/III	Hemophagocytic lymphohistiocytosis
Anifrolumab	IFN-β	III	SLE
Etanercept	TNFα	FDA approved	RA, juvenile-onset rheumatoid arthritis (JRA), psoriatic arthritis, plaque psoriasis, ankylosing spondylitis
Infliximab	TNFα	FDA approved	RA, psoriasis, Crohn disease, ankylosing spondylitis, psoriatic arthritis, ulcerative colitis
Adalimumab	TNFα	FDA approved	RA, plaque psoriasis, Crohn disease, ankylosing spondylitis, psoriatic arthritis, ulcerative colitis, JIA
Golimumab	TNFα	FDA approved	RA, ankylosing spondylitis, psoriatic arthritis
Ozoralizumab	TNFα	II	RA
Pegsunercept	TNFα	FDA approved	RA, JRA, psoriatic arthritis, plaque psoriasis, ankylosing spondylitis
Certolizumab	TNFα	FDA approved	RA, JRA, psoriatic arthritis, plaque psoriasis, ankylosing spondylitis
Belimumab	BAFF/BLyS	FDA approved	SLE
Brentuximab vedotin	TNFRSF8 (CD30)	FDA approved	Lymphoma
Denosumab	RANKL	FDA approved	Osteoporosis, RA, hypercalcemia of malignancy, cancer

FDA, US Food and Drug Administration.

test of the pathogenic role of the targeted cytokine. Bringing cytokine blockade into the clinics has helped unravel the complex web of interactions between cytokines in human autoimmune and inflammatory conditions.

ON THE HORIZON

- Although the number of cytokines already seems vast, it is likely that more will be discovered in the future.
- As continued improvement in the imaging of cells and macromolecular complexes improves, it is likely that we will obtain new insights into how cytokines actually signal.
- Improved understanding of regulators like the suppressors of cytokine signaling (SOCS) proteins should offer new therapeutic opportunities.
- Additional therapeutic options for the future may include the use synthetic cytokines and the creation of bispecific antibodies to target more than one cytokine or cytokine receptor at the same time.

CONCLUSIONS AND SUMMARY

Cytokines encompass a wide range of molecules that are essential for communication between cells of the immune system and other nonimmune cells. Although the number of cytokines already seems vast, it is likely that more will be discovered in the future. Considerable progress has been made in defining the *in vivo* functions of various cytokines. Equally impressive have been advances in our understanding how dysregulation of cytokines and cytokine signaling contribute to human disease. Cytokine and anticytokine therapies are being successfully used in the clinic. It is likely that their use will increase with advances in the understanding of the immunobiology of these cytokines.

MULTIPLE-CHOICE QUESTIONS

1. The phenomenon of shared biological activities (cytokine redundancy) between cytokines that belong to the same subfamily reflects which of the following biological properties of type 1 family cytokines?
   - **A.** The cytoplasmic portions of the type I family receptors all contain membrane proximal domains that bind Janus kinases (JAKs).
   - **B.** Type I family cytokines act on all cells to inhibit viral replication, as well as cellular proliferation.
   - **C.** Heterodimeric type I cytokine receptors often use a shared receptor submit in conjunction with a ligand specific subunit.
   - **D.** There can be more than one receptor for each cytokine.

2. Which of the following cytokines promotes allergic responses and inhibits cell-mediated immune responses?
   - **A.** Interleukin-1 (IL-1)
   - **B.** IL-2
   - **C.** IL-4
   - **D.** IL-17

3. Which of the following cytokines is essential for mucocutaneous immunity against *Candida albicans*?
   - **A.** Transforming growth factor-β (TGFβ)
   - **B.** IL-3
   - **C.** IL-6
   - **D.** IL-17

4. Blockade of which of the following cytokines ameliorates rheumatoid arthritis (RA) and endotoxic shock?
   - **A.** IL-7
   - **B.** IL-12
   - **C.** IL-21
   - **D.** Tumor necrosis factor (TNF)

Chemokines and Chemokine Receptors

Philip M. Murphy

INTRODUCTION

Chemokines form a large family composed primarily of small secreted cytokine proteins that coordinate leukocyte trafficking by binding to seven-transmembrane (7TM) domain receptors. Chemokines mediate normal host defense and tissue repair; however, they may also support pathological immune responses, including chronic inflammation, autoimmunity, and cancer. The chemokine system is also a major target for immune system evasion or exploitation by pathogens (e.g., human immunodeficiency virus [HIV] and Plasmodium vivax). Increasingly, additional immunological and nonimmunological chemokine functions are being recognized. The nonimmunological functions can be beneficial, as in embryogenesis, or harmful, as in cancer. WHIM (warts, hypogammaglobulinemia, infections, and myelokathexis) syndrome is the only known mendelian condition caused by mutations in a chemokine or chemokine receptor (the receptor CXCR4). Two chemokine receptor antagonists have been approved by the U.S. Food and Drug Administration (FDA) so far: maraviroc, a CCR5 antagonist, used in the treatment of human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS), and plerixafor, a CXCR4 antagonist, approved for hematopoietic stem cell mobilization for transplantation in cancer. This chapter will expand on these and other basic principles and clinical correlates of chemokine regulation of the immune system.

KEY CONCEPTS

Chemokine and Chemokine Receptors at a Glance

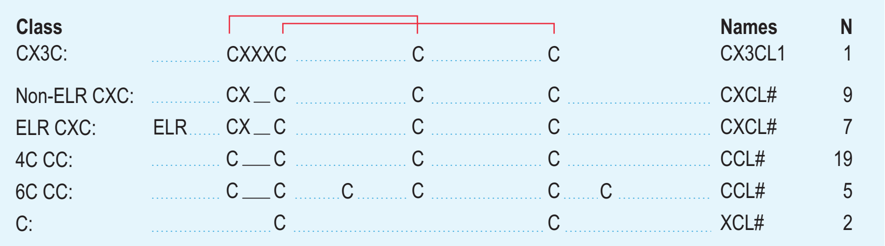
- *Definition:* Chemokines are defined by a common structure, the chemokine fold. Chemokine receptors are defined by a common biochemical function: chemokine binding-dependent cell signaling. Most chemokine receptors catalyze guanine nucleotide exchange on Gi-type G proteins. A small group of atypical receptors signal through an arrestin-dependent pathway.
- *Classification:* Chemokines form four main structural subclasses (C, CC, CXC, and CX3C) and two main immunological subclasses (inflammatory and homeostatic).
- *Evolution:* Chemokines and chemokine receptors arose in vertebrates and have been copied or mimicked by viruses. Chemokines and chemokine receptors rapidly evolve; the repertoires can differ among species and among individuals of the same species.
- *Ligand–receptor promiscuity:* The majority of chemokine receptors pair promiscuously with chemokine ligands, usually restricted to a single chemokine subclass; these typically mediate inflammatory responses.
- *Cell biology:* Chemokines coordinate leukocyte trafficking but can have prominent nontrafficking functions (*e.g.,* lymphocyte proliferation/apoptosis/differentiation/activation, granulocyte degranulation/superoxide production, direct antimicrobial activity), and nonimmunological effects on other cell types (*e.g.,* development, cancer, angiogenesis).
- *Biology:* Chemokines act redundantly or nonredundantly *in vivo,* depending on the context. Host chemokine receptors mediate antimicrobial defense, but certain pathogens (*e.g.,* HIV and *Plasmodium vivax* infection) can exploit chemokine receptors to infect the host. Excessive or inappropriate chemokine expression may pathologically amplify immunologically mediated disease.

MOLECULAR ORGANIZATION OF THE CHEMOKINE SYSTEM

Chemokines are defined by structure rather than function.[1] This reflects the highly conserved nature of their tertiary folded structure that is created by uniformly spaced, disulfide-bonded cysteines (Fig. 10.1). Chemokines contain three β-sheets arranged in the shape of a Greek key, overlaid by a *C*-terminal α-helical domain and flanked by an *N*-terminal domain that lacks order. All chemokines have at least two cysteines, and all but two have at least four. In the four-cysteine group, the first two are either adjacent (CC motif, $n = 24$) or separated by either one amino acid (CXC motif, $n = 16$) or three amino acids (CX3C motif, $n = 1$). Disulfide bonds link C-1 to C-3 and C-2 to C-4. C chemokines ($n = 2$) have only two cysteines, corresponding to C-2 and C-4 in the other groups. Sequence identity is less than 30% for any two chemokines from different groups but ranges between 30% and 99% for any two chemokines from the same group. The group names are used as roots followed by the letter "L" and a number (*e.g.,* CXCL1) in a systematic nomenclature that was established to resolve competing aliases.[2]

Several additional motifs enable subclassification of CC and CXC chemokines. The seven CXC chemokines with glu-leu-arg (ELR) *N*-terminal to C-1 share greater than 40% sequence identity, attract neutrophils, bind the same CXCR2 receptor, and are angiogenic (Table 10.1). CXCL9, CXCL10, and CXCL11 share a receptor (CXCR3) as well as greater than 40% identity, but they are angiostatic.

Two CC subgroups have two additional cysteines. One is in the *C*-terminal domain, and the other can be found either in the *C*-terminal domain or between C-2 and C-3 (Table 10.2). CXCL16 and CX3CL1 cross classes to form a unique multimodular subgroup. Each has a classic chemokine domain, a mucin-like stalk, a transmembrane domain, and a *C*-terminal cytoplasmic module. Each can exist as either a membrane-bound form or a shed form, enabling either direct cell–cell adhesion or chemotaxis, respectively. Chemokine monomer, dimer, and tetramer structures



Class

FIG 10.1 Chemokine Classification and Nomenclature. Chemokine classes are defined by the number and arrangement of conserved cysteines, as shown. Brackets link cysteines that form disulfide bonds. ELR refers to the amino acids glu-leu-arg. X refers to an amino acid other than cysteine. The underscore is a spacer used to optimize the alignment. The *N*- and *C*-termini can vary considerably in length (not illustrated). For molecules with four cysteines, there are approximately 24 amino acids between Cys-2 and Cys-3, and 15 amino acids between Cys-3 and Cys-4. At right are listed the nomenclature system and the number of human chemokines known in each class (N).

TABLE 10.1 Human CXC, CX3C, and C Chemokines

Chemokine	Common Aliases	Main Sources	G Protein–Coupled Receptors	Main Immunological Roles
CXCL1, 2 and 3	GROα, β, and γ	Inducible in most hematopoietic and tissue cells	CXCR2	Neutrophil trafficking
CXCL4	PF4	Preformed in platelets	CXCR3	Procoagulant
CXCL5	ENA-78	Induced in epithelial cells of gut and lung; N, Mo, Plts, EC	CXCR2	Neutrophil trafficking
CXCL6	GCP-2	Induced in lung microvascular EC; Mo; alveolar epithelial cells, mesothelial cells, EC and MΦ	CXCR1, CXCR2	Neutrophil trafficking
CXCL7	NAP-2	Preformed in platelets	CXCR2	Neutrophil trafficking
CXCL8	IL-8	Induced in most cell types	CXCR1, CXCR2	Neutrophil trafficking
CXCL9	Mig	Induced in PMN, MΦ, T cells, astrocytes, microglial cells, hepatocytes, EC, fibroblasts, keratinocytes, thymic stromal cells	CXCR3	Th1 response
CXCL10	IP-10	Induced in ECs, Mo, keratinocytes, respiratory and intestinal epithelial cells, astrocytes, microglia, mesangial cells, smooth muscle cells	CXCR3	Th1 response
CXCL11	I-TAC	ECs, Mo	CXCR3	Th1 response
CXCL12	SDF-1, PBSF	Constitutive in bone marrow stromal cells; most tissues	CXCR4	Myelopoiesis; HPC, neutrophil homing to BM; B lymphopoiesis
CXCL13	BCA-1	Constitutive in follicular HEV of secondary lymphoid tissue	CXCR5	Naïve B- and T-cell homing to follicles; B_1-cell homing to peritoneum; Natural Ab production
CXCL14	BRAK	Constitutive in most tissues, breast and kidney tumors	ND	Macrophage migration
(CXCL15)	(Mouse only)	Constitutive in lung epithelial cells	ND	Neutrophil trafficking
CXCL16	Sexckine	Constitutive in spleen; DCs of the T cell zone	CXCR6	T-cell and DC homing to spleen
CXCL17		Lung, heart, tumor cells	CXCR8	Monocyte and myeloid DC trafficking
CX3CL1	Fractalkine	EC, neurons, Mo, DC	CX3CR1	NK, monocyte, MΦ, and Th1-cell migration
XCL1 and XCL2	Lymphotactin α and β	γδ epidermal T cells, NK, NK-T, activated CD8 and Th1 CD4 T cells	XCR1	$CD62L^{lo}$ T effector cell migration

NA, not applicable; Mo, monocyte; PMN, neutrophil; DC, dendritic cell; EC, endothelial cell; HEV, high endothelial venule; MPC, myeloid progenitor cell; plt, platelet; MΦ, macrophage; GRO, growth-related oncogene; PF4, platelet factor 4; GCP, granulocyte chemoattactant protein; ENA-78, 78 amino acid epithelial cell-derived neutrophil activator; NAP, neutrophil activating protein; IL-8, interleukin-8; Mig, monokine induced by IFN-γ; I-TAC; interferon-inducible T-cell αchemoattractant; SDF, stromal cell-derived factor; BCA, B cell–activating chemokine; BRAK, breast and kidney-associated chemokine.

TABLE 10.2 CC Chemokines

Chemokine	Common Aliases	Sources	Main G Protein–Coupled Receptors	Main Immunological Roles
CCL1	I-309	Inducible in Mo and CD4$^+$ and CD8$^+$ αβ and CD4$^-$CD8$^-$ γδ T cells	CCR8	Th2 response
CCL2	MCP-1	Inducible in Mo, fibroblasts, keratinocytes, EC, PMN, synoviocytes, mesangial cells, astrocytes, lung epithelial cells, and MΦ. Constitutively made in splenic arteriolar lymphatic sheath and medullary region of lymph node, many tumors, and arterial plaque EC	CCR2	Innate immunity Th2 response CD4$^+$ T-cell differentiation
CCL3	MIP-1α LD78α MIP-1αS	Inducible in Mo/MΦ, CD8 T cells, B cells, plts, PMN, Eo, Ba, DC, NK, mast cells, keratinocytes, fibroblasts, mesangial cells, astrocytes, microglial cells, epithelial cells	CCR1, CCR5	Innate immunity Th1 response CD4 T-cell differentiation
CCL3L1	LD78β MIP-1αP	Similar to CCL3	CCR1, CCR5	Probably similar to CCL3
CCL4	MIP-1β	Similar to CCL3	CCR5	Innate immunity Th1 response
CCL5	RANTES	Inducible in EC, T cells, epithelial cells, Mo, fibroblasts, mesangial cells, NK cells Constitutively expressed and stored in plt and Eo granules	CCR1, CCR3, CCR5	Innate immunity Th1 and Th2 response
(CCL6)	Mouse only	Inducible in bone marrow and peritoneal-derived MΦ	CCR1	ND
CCL7	MCP-3	Inducible in Mo, plts, fibroblasts, EC, skin, bronchial epithelial cells, astrocytes	CCR1, CCR2, CCR3, CCR5	Th2 response
CCL8	MCP-2	Inducible in fibroblasts, PMN, astrocytes Constitutively expressed in colon, small intestine, heart, lung, thymus, pancreas, spinal cord, ovary, placenta	CCR8	Th2 response
(CCL9/10)	Mouse only	Constitutively expressed in all mouse organs except brain; highest in lung, liver and thymus Induced in heart and lung	CCR1	ND
CCL11	Eotaxin	Epithelial cells, EC, smooth muscle, cardiac muscle, Eo, dermal fibroblasts, mast cells, MΦ, Reed–Sternberg cells	CCR3	Th2 response Eosinophil trafficking Mast cell trafficking Basophil trafficking, degranulation
(CCL12)	Mouse only	Inducible in lung alveolar MΦ and smooth muscle cells; spinal cord. Constitutive expression in Lymph node and thymic stromal cells	CCR2	Allergic inflammation
CCL13	MCP-4	Inducible in nasal and bronchial epithelial cells; dermal fibroblasts; PBMCs; atherosclerotic plaque EC and MΦ Constitutively expressed in small intestine, colon, thymus, heart, and placenta	CCR1, CCR2, CCR3	Th2 response
CCL14a	HCC-1	Constitutively expressed in most organs; high plasma levels	CCR1, CCR5	ND
CCL14b	HCC-3	Same as CCL14b except absent from skeletal muscle and pancreas	CCR1, CCR5	ND
CCL15	HCC-2; Lkn-1	Inducible in Mo and DC Constitutive RNA expression in liver, gut, heart, and skeletal muscle, adrenal gland and lung leukocytes	CCR1, CCR3	ND
CCL16	HCC-4; LEC	Constitutively expressed in liver, possibly many other organs. Also, Mo, T cells, and NK cells express mRNA	CCR1, CCR2, CCR5	ND
CCL17	TARC	Constitutive in normal DC and Reed-Sternberg cells of Hodgkin disease	CCR4	Th2 response
CCL18	DC-CK1, PARC	Constitutive in Mo/MΦ, germinal center DCs	CCR8	DC attraction of naïve T cells
CCL19	ELC, MIP-3β	Constitutive on interdigitating DCs in secondary lymphoid tissue	CCR7	Naïve and memory T-cell and DCs homing to lymph node
CCL20	LARC MIP-3α	Constitutive in lymph nodes, peripheral blood leukocytes, thymus, and appendix Inducible in PBMC, HUVEC	CCR6	DCs homing to Peyer patch Humoral response
CCL21	SLC, 6Ckine	Constitutive in lymphatic EC, HEV and interdigitating DCs in T areas of 2° lymphoid tissue, thymic medullary epithelial cells and EC	CCR7	Naïve and memory T cells and DCs homing to lymph node
CCL22	MDC	Constitutive in DC and MΦ Inducible in Mo, T, and B cells	CCR4	Th2 response
CCL23	MPIF-1	Constitutive in pancreas and skeletal muscle	CCR1	ND
CCL24	Eotaxin-2	Inducible in Mo	CCR3	Eosinophil migration
CCL25	TECK	Constitutive in thymic stromal cells and small intestine	CCR9	Thymocyte migration Homing of memory T cells to gut
CCL26	Eotaxin-3	Constitutive in heart and ovary Inducible on dermal fibroblasts and EC	CCR3	Th2 response

TABLE 10.2 CC Chemokines—cont'd

Chemokine	Common Aliases	Sources	Main G Protein–Coupled Receptors	Main Immunological Roles
CCL27	CTACK, Eskine	Constitutive in placenta, keratinocytes, testis, and brain	CCR10	Homing of memory and effector T cells to skin
CCL28	MEC	Constitutive in epithelial cells of gut, airway	CCR10	Homing of T cells to mucosal surfaces

NA, not applicable; Mo, monocyte; PMN, polymorphonuclear neutrophil; DC, dendritic cell; EC, endothelial cell; HEV, high endothelial venule; MPC, myeloid progenitor cell; plt, platelet; MΦ, macrophage; MCP, monocyte chemoattractant protein; MIP, macrophage inflammatory protein; RANTES, regulated upon activation normal T cell expressed and secreted; MRP, MIP-related protein; HCC, hemofiltrate CC chemokine; TARC, thymus and activation-related chemokine; PARC, pulmonary and activation-related chemokine; ELC, Epstein-Barr virus-induced receptor ligand chemokine; LARC, liver and activation-related chemokine; SLC, secondary lymphoid tissue chemokine; MDC, macrophage-derived chemokine; MPIF, myeloid progenitor inhibitory factor; TECK, thymus-expressed chemokine; CTACK, cutaneous T-cell-associated chemokine; MEC, mucosa-associated epithelial cell chemokine.

can occur, and complex quaternary structures bound to glycosaminoglycans (GAGs) on the surface of cells may be important for function *in vivo*.[1]

Chemokine Receptors

Chemokine receptors are defined as mediators that activate cellular responses upon binding of chemokines. Twenty-three subtypes of human chemokine receptors have been identified, all of which are members of the seven-transmembrane (7TM) domain superfamily of receptors.[3] They can be divided into two main groups: the G protein–coupled chemotactic chemokine receptors ($n = 19$) and the atypical chemokine receptors ($n = 4$). Chemokine binding, membrane anchoring, and signaling domains for receptors from both groups come from a single polypeptide chain. Structural and biochemical evidence exists that these receptors form homo- and heterodimers.

Some chemokine receptors pair monogamously with their chemokine ligands. Most, however, are promiscuous but restricted to one chemokine structural group (Fig. 10.2). The G protein–coupled receptors are named by ligand group specificity. Each chemokine has a unique receptor specificity profile, and each receptor has a unique chemokine specificity profile. Almost all chemokines are chemotactic agonists, and a few may be agonists at one G protein–coupled chemokine receptor and antagonists at another, in addition to binding to atypical receptors. Differential receptor usage, differential regulation of expression, and biased agonism may all account for nonredundant function observed *in vivo* for chemokines acting at the same G protein–coupled receptor.

Atypical Chemokine System Components

There are three classes of atypical chemokine system components: (1) the atypical 7TM chemokine receptors: as described previously, these bind chemokines promiscuously without signaling or with atypical signaling. These proteins are thought to function as chemokine scavengers but may also facilitate chemokine transcytosis across endothelial barriers;[4] (2) endogenous nonchemokine agonists: these act at chemokine receptors (*e.g.*, β-defensin-2 at CCR6); (3) virally encoded chemokines, 7TM chemokine receptors, structurally unique chemokine-binding proteins (scavengers), and nonchemokine chemokine receptor ligands (agonists or antagonists);[5] examples of the last one include two viral chemokine mimics encoded by HIV: the gp120 and tat proteins, which possess chemokine agonist and antagonist activity, respectively. Viral chemokine elements can function to evade the immune system, recruit new target cells, reprogram gene expression for cell proliferation and angiogenesis, or target cell entry (*e.g.*, HIV gp120).[6] Secreted chemokine-binding proteins have even been identified in tick saliva, which could explain, in part, the lack of inflammation associated with tick bites.[7]

KEY CONCEPTS

Immunological Classification of the Chemokine System

- *Homeostatic system:* Constitutively expressed ligands and receptors. Important in hematopoiesis and immune surveillance. Key receptors: CXCR4 on all leukocytes, especially hematopoietic stem and progenitor cells; CXCR5 on B cells; CCR7 on dendritic cells and T cells; and gut and skin-specific T-cell homing receptors CCR9 and CCR10, respectively.
- *Inflammatory system:* In innate immunity, inducible ligands and constitutively expressed receptors (*e.g.*, neutrophil CXCR2, monocyte/macrophage CCR2 and CX3CR1, eosinophil CCR3, and NK cell CX3CR1). In adaptive immunity, inducible ligands and inducible receptors (*e.g.*, CXCR3, CCR4, and CCR6 on Th1, Th2, and Th17 subsets of CD4 T cells, respectively).

Immunological Classification

Each of the leukocyte subtypes responds to chemokines via a characteristic subset of chemokine receptors. The chemokine system can be subclassified into two main subsystems, *homeostatic* and *inflammatory*, based on receptor expression patterns. Homeostatic chemokines are differentially and constitutively expressed in specific microenvironments within primary and secondary immune organs. They recruit both immature and mature leukocytes via constitutively expressed receptors. Noxious stimuli induce inflammatory chemokines in diverse tissue cells and leukocytes. Inflammatory chemokine receptors are constitutively expressed on myeloid and natural killer (NK) cells but must be induced on activated effector lymphocytes. Dynamic shifts in receptor expression occur during dendritic cell (DC) and NK cell maturation, as well as during lymphocyte maturation, activation, and differentiation.

Inflammatory CXC and CC chemokine genes are found in two main clusters on human chromosomes 4q12-q21 and 17q11-q21, respectively. Conversely, homeostatic chemokine genes have undergone a diaspora resulting in small clusters of genes on multiple chromosomes. Thirteen of the 19 human chemokine receptor genes are clustered at 3p21-23, and *CXCR1* and *CXCR2* are adjacent at 2q34-q35. The chemokine and chemokine receptor repertoire may vary even among closely related species. Gene copy number (*e.g.*, for *CCL3*) and sequence

can vary among individuals of a species. This variation may influence the risk for acquiring certain diseases.

Chemokine Presentation Mechanisms

Chemokines act locally. They appear to be tethered to extracellular matrix proteins or to endothelial cells by binding to glycosaminoglycans or, for CX3CL1 and CXCL16, by transmembrane domains.[1] The tethering cell may have produced the chemokine or else imported it by transcytosis from neighbors. The ligand-binding site includes the receptor *N*-terminus and one or more extracellular loops, which allow docking of the chemokine *N*-loop domain, and multiple 7TM domains, which accept the chemokine's *N*-terminus and are critical for triggering.

Leukocyte Responses to Chemokines

All leukocyte subtypes migrate in response to chemokines. However, each subtype can also respond in additional stereotypical ways. Lymphocytes may proliferate, undergo apoptosis, or release immunoregulatory and cytotoxic factors. Granulocytes may release antimicrobial and inflammatory mediators (*e.g.*, superoxide,

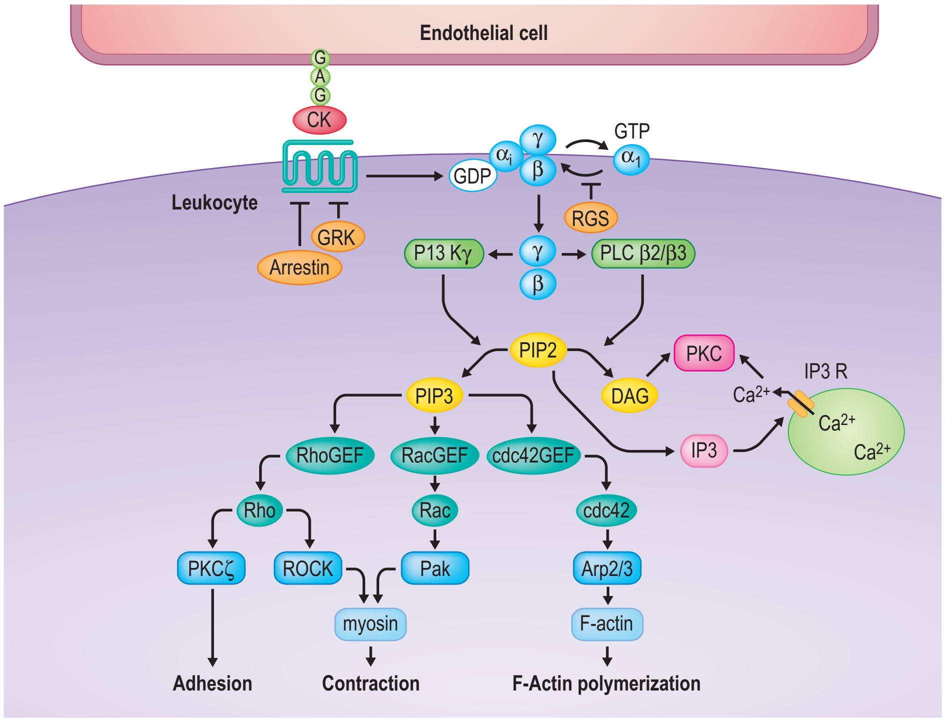

FIG 10.3 **Chemokine Signal Transduction in Chemotaxis.** Depicted are key steps in two of the main pathways induced by most chemokines. The PI3Kγ pathway is particularly important for cell migration. Chemokines are able to activate other pathways as well, including non-Gi-type G proteins, protein tyrosine kinases, and MAP kinases. These pathways influence cell proliferation and activation. The model is modified from the Alliance for Cell Signaling (http://www.signaling-gateway.org). PLC, phospholipase C; PI3K, phosphatidylinositol-3-kinase; RGS, regulator of G protein signaling; DAG, diacylglycerol; IP_3, inositol trisphosphate; PIP, phosphatidylinsol phosphate; GAG, glycosaminoglycan; CK, chemokine; PKC, protein kinase C; GRK, G protein–coupled receptor kinase; GEF, guanine nucleotide exchange factor.

defensins, proteases, histamine, eicosanoids). The mechanism of leukocyte migration can vary, depending on the leukocyte and the environment.[8] The mechanism is best understood for transendothelial migration (Chapter 11).[9] In an initial chemokine-independent step, leukocytes roll on inflamed endothelium in a selectin-dependent manner. Next, chemokines posted on endothelium stimulate rolling leukocytes to express activated β_2 integrins, which mediate firm adhesion via endothelial intercellular adhesion molecules (ICAMs). Leukocytes sense chemokine gradients, polarize, and then become poised to crawl. Motion involves shear-dependent coordinated cytoskeletal remodeling. This includes expansion of the leading edge (lamellipodium), myosin-based contraction at the trailing edge (uropod), release of the uropod from substrate, and membrane lipid movement.[10] Navigation through tissue may require relays of chemokines and adhesion molecules.

CHEMOKINE SIGNALING PATHWAYS

Chemokines trigger G protein–coupled chemokine receptors, mainly heterotrimeric Gi-type G proteins, to act as guanine nucleotide exchange factors (GEFs). Binding either releases guanosine diphosphate (GDP) from or binds guanosine triphosphate (GTP) to the Gi α subunit.[11] This results in G protein dissociation into α and βγ subunits, which, in turn, activates diverse G protein–dependent effectors, including phospholipases A2, C (subtypes β_2 and β_3) and D, phosphatidylinositol-3-kinase γ (PI3Kγ), protein tyrosine kinases (PTKs) and phosphatases, low-molecular-weight guanosine triphosphatases (GTPases), and mitogen-activated protein kinases (Fig. 10.3).

Phospholipase C (PLC) hydrolyzes PI bisphosphate (PIP_2) to form 1,2-diacylglycerol (DAG) and inositol 1,4,5-trisphosphate (IP_3). IP_3 induces Ca^{2+} release from intracellular stores, which acts with 1,2-diacylglycerol (DAG) to activate protein kinase C (PKC). PI3Kγ phosphorylates PIP_2 to form PIP_3, which recruits proteins containing pleckstrin homology (PH) or PHOX (PX) domains to lamellipodium, thereby converting shallow analogue extracellular chemokine gradients into steep digital intracellular effector gradients. Four PH domain-containing targets—Akt, and GEFs for Rac, Rho, and Cdc42—modulate distinct phases of cell movement in various model systems. Rho regulates cell adhesion, chemotaxis, and myosin contraction. Rac and Cdc42 control lamellipodia and filopodia formation, respectively. Downstream targets of Rac include Pak1, which also regulates myosin contraction.

REGULATION OF CHEMOKINE ACTION

Chemokine and chemokine receptor expression can be positively or negatively regulated at the transcriptional level by diverse factors, including proinflammatory cytokines, oxidant stress, viruses, bacterial products (*e.g.,* lipopolysaccharide [LPS] and

N-formyl peptides), cell adhesion, antigen uptake, T-cell costimulation, and diverse transcription factors (*e.g.,* NF-κB). In innate immunity, proinflammatory cytokines, such as interleukin-1 (IL-1), tumor necrosis factor (TNF), and IL-15 induce expression of inflammatory chemokines important for recruitment of myeloid and NK cells. In adaptive immunity, signature cytokines of polarized helper T cells establish positive feedback loops for production of signature chemokines able to specifically recruit these cells. For example, T helper-1 (Th1) cells produce interferon-γ (IFN-γ), which induces expression of CXCL9, CXCL10, and CXCL11, the chemokine agonists specific for the signature Th1 cell chemokine receptor CXCR3. This amplifies Th1 cell recruitment. Similar loops may exist for Th2 cells involving CCL17/CCR4 and IL-4, as well as for Th17 cells involving CCL20/CCR6 and IL-17. IFNs, glucocorticoids, and antiinflammatory cytokines (*e.g.,* IL-10 and transforming growth factor-β [TGF-β]) can inhibit inflammatory chemokine gene expression. Chemokines can also be regulated at the level of messenger ribonucleic acid (mRNA) stability.

A chemokine gene can generate families of proteins varying in activity and potency by alternative splicing and posttranslational modification, especially *N*- and *C*-terminal proteolytic trimming.[12] Proteases can target many chemokines (*e.g.,* CD26 [dipeptidyl peptidase IV] and matrix metalloproteinases [MMPs]), or few or only one (*e.g.,* TACE [the TNF-α–converting enzyme], plasmin, urokinase plasminogen activator, and cathepsin G). Chemokine action can be blocked by atypical chemokine receptors (*e.g.,* ACKR1), endogenous receptor antagonists, receptor decoys, and autoantibodies. Cytokines may also convert a signaling receptor into a decoy (*e.g.,* IL-10 inactivates CCR2 on monocytes).

CHEMOKINE REGULATION OF HEMATOPOIESIS

Bone Marrow

Most chemokines that modulate hematopoietic progenitor cell (HPC) proliferation *ex vivo* act early during hematopoiesis and are inhibitory. CXCL12, the most abundant chemokine in bone marrow, is an important exception. CXCL12 signaling through its receptor CXCR4 is critical for bone marrow myelopoiesis and B-cell lymphopoiesis. CXCR2 and CXCR4 both regulate neutrophil egress from bone marrow, and CXCR4 is also critical for mobilization of hematopoietic stem cells (HSCs) and HPCs from bone marrow.[13] A second CXCL12 receptor, ACKR3 (previously known as CXCR7), does not regulate hematopoiesis, but interestingly it is an essential factor responsible for cardiac valve development apparently due to its ability to bind the nonchemokine ligand adrenomedullin. ACKR3 also regulates marginal zone B-cell positioning in the spleen. CCR2 is important for monocyte release from bone marrow.

Thymus

During development, T cells must migrate from the thymic cortex to the medulla (Chapter 8). Chemokines and chemokine receptors are differentially expressed in thymus and coordinate migration.[14] CCR9 and its ligand, CCL25, may be important, since competitive transplantation of CCR9$^{-/-}$ bone marrow is less efficient than normal marrow at repopulating the thymus of lethally irradiated Rag-1$^{-/-}$ mice.

CCL25 is expressed by medullary DCs and both cortical and medullary epithelial cells. CCR9 is expressed on the majority of immature CD4$^+$CD8$^+$ thymocytes but is downregulated during transition to the CD4$^+$ or CD8$^+$ single-positive stage (Fig. 10.4). Just before thymic egress, thymocytes become CCR9 negative and upregulate L-selectin. Transition from CD4$^+$CD8$^+$ thymocytes in the cortex to CD4$^+$ or CD8$^+$ single-positive thymocytes in the medulla is associated with upregulation of CCR4 and CCR7, receptors for CCL22, and CCL19 and CCL21, respectively, which are expressed in the medullary stroma. Accordingly, these chemokines attract thymocytes between the late cortical and medullary stages of development *in vitro.* Neutralization studies suggest that egress of newly formed T cells from the fetal thymus to the circulation is mediated by CCL19, which is selectively localized on endothelial cells of medullary venules and acts at CCR7 on mature thymocytes.

Tissue

Once myeloid cells are released from bone marrow, they undergo specific trafficking itineraries and in some cases become resident in tissue. This is regulated, in part, by specific chemokines. For example, CXCL14 is important for macrophage positioning in the lung, and CCL11 and its receptor CCR3 for eosinophils in the spleen and the gastrointestinal tract. CCR6 regulates positioning of immature myeloid CD11c$^+$CD11b$^+$ DCs in the subepithelial dome of Peyer patches. CX3CR1 regulates localization of myeloid DCs in Peyer patches and may be important for antigen sampling from the intestine.

CHEMOKINE REGULATION OF THE IMMUNE RESPONSE

The innate and adaptive immune systems are deployed separately but are assembled, in part, by specific sets of chemokines and chemokine receptors (see Fig. 10.4).[15]

Innate Immunity

Platelet-Derived Chemokines

Made primarily during platelet development, stored in platelet α granules, and rapidly released during platelet degranulation, CXCL4 and CXCL7 are among the first chemokines to appear at sites of tissue injury and infection. When there is hemorrhage and vascular damage, chemokine concentrations can reach elevated levels.[16] CXCL7 can function as an immediate-early mediator of neutrophil recruitment released from platelets at sites of inflammation. Although it is not a prominent leukocyte chemoattractant and does not induce degranulation of neutrophil lysosomal enzymes, CXCL4 is able to induce neutrophil secondary granule exocytosis and release of matrix-degrading enzymes, which may facilitate neutrophil penetration of infected or injured tissues.

CXCL8 and CXCR2

All seven ELR$^+$ CXC chemokines preferentially recruit neutrophils *in vitro* by binding to CXCR2. Two of these, CXCL6 and CXCL8, are also potent agonists at CXCR1, which is coexpressed at similar levels on neutrophils.[17] These seven chemokines are rapidly inducible but may differ biologically because of temporal and spatial differences in expression. These differences provide a mechanism for the graded navigation of neutrophils through tissue. Blocking studies in multiple animal models have demonstrated the importance of CXCL8 and CXCR2 in neutrophil accumulation in response to infectious and noninfectious stimuli. Intradermal injection of CXCL8 in humans causes rapid (<30 min) and selective accumulation of large numbers of

FIG 10.4 Chemokine Receptor Control of Leukocyte Trafficking. Shown are routes among primary and secondary immune organs and the periphery, leukocyte subtypes trafficking on those routes and some of the chemokine receptors that appear to be most important in regulating each route. Tn, naïve T cells; Tp, precursor T cells; Tm, memory T cells; TEM, effector memory T cells; TCM, central memory T cells; TFH, T-follicular helper cells; iDC, immature dendritic cells; N, neutrophil; Eo, eosinophil; MΦ, macrophage; Mo, monocyte; NK, natural killer cell; PC, plasma cell; HSC, hematopoietic stem cell; GC, germinal center. The model is based primarily on studies of mice where the relevant gene has been inactivated by gene targeting.

neutrophils in perivascular regions of skin without causing edema.

Tissue-specific transgenic overexpression of mouse CXCL8 paralogues KC and MIP-2 suggests that *in vivo* these factors may recruit cells, but not independently activate cytotoxic mechanisms. In a human blister model, endogenous CXCL8 peaks at ~24 hours, whereas C5a and leukotriene B4, which also recruit neutrophils, appear earlier. Thus the primary role of CXCL8 may be to amplify early inflammatory responses initiated by immediate-early chemoattractants, such as leukotriene B4.[18] CXCL1, -2, -3, -7, and 8 have also been reported to induce basophil chemotaxis and histamine release *in vitro*, which, together with other factors, such as complement-derived anaphylatoxins, promote vasodilatation during the early stages of the innate immune response.

Monocyte recruitment typically follows neutrophil accumulation with delayed kinetics. Recruitment can be mediated by multiple inflammatory CC receptors and CX3CR1. CCR2 and CX3CR1 are particularly important and define two monocyte subsets, $CX3CR1^{hi}CCR2^{-}$ and $CX3CR1^{lo}CCR2^{+}$, which are referred to as "resident" and "inflammatory" monocytes because of their distinct trafficking characteristics.[19]

Natural Killer Cells

Human NK cell subsets express unique repertoires of chemokine receptors.[20] The $CD56^{dim}CD16^{+}$ subset, which is associated with high cytotoxic capacity and low cytokine production, expresses primarily CXCR1 and CX3CR1. The minor $CD56^{bright}CD16^{dim}$ subset, which produces large amounts of cytokines but has low killing capacity, preferentially expresses CCR7. The exact profile of chemokine receptor expression can be modulated by adherence and stimulation *ex vivo* with IL-2. Cognate chemokines chemoattract NK cells and promote degranulation and killing.

The importance of chemokines in NK cell function *in vivo* is evident in mouse cytomegalovirus (MCMV) infection, a cause of hepatitis. MCMV induces CCL3 production in the liver, and this is required for recruitment of NK cells. NK cells are the major source of IFN-γ in this model. IFN-γ induces CXCL9, which is required for protection. Thus a cytokine–chemokine–cytokine cascade is required for NK cell–mediated host defense against this pathogen.

Dendritic Cells and Transition to the Adaptive Immune Response

Transition from innate to adaptive phases of the immune response involves antigen uptake by antigen-presenting cells (APCs), especially DCs, mediated by Fc and complement phagocytic receptors, as well as pattern recognition receptors (PRRs), including DC-SIGN and Toll-like receptors (TLRs) (Chapter 3). Both TLR2 and TLR4 signaling induce expression of CCL3, CCL4, and CCL5. However, TLR2 selectively induces CXCL8, whereas TLR4 selectively induces CXCL10. CXCL8 increases neutrophil migration to the site, whereas CXCL10 enhances NK cell or Th1 effector T-cell trafficking. Pathogens can skew the nature and magnitude of the immune response in a specific direction by means of specific pattern recognition receptor (PRR) ligands.

The chemokine receptors expressed on DCs vary, depending on the nature of the inflammatory stimulus and type. For example, blood-derived plasmacytoid and myeloid DCs express a similar repertoire of inflammatory chemoattractant receptors, but they are functional only on myeloid DCs. CCL3, CCL4, and CCL5 may be particularly important for recruiting additional mononuclear phagocytes and DCs to sites of infection. This can amplify the late stage of the innate immune response. In the extreme, this can devolve into endotoxic shock. Consistent with this idea, genetic disruption of the CCL3/CCL4/CCL5 receptor CCR5 renders mice relatively resistant to LPS-induced endotoxemia.

Adaptive Immunity

Afferent Trafficking to Secondary Lymphoid Tissue

The homeostatic receptors CXCR5 and CCR7 and their ligands are major regulators of the immune response. They act at the level of B and T lymphocytes and DCs trafficking to and within secondary lymphoid tissue.[21,22] DC maturation in peripheral tissues is associated with downregulation of inflammatory receptors, which is important for recruitment, migration, and retention in the periphery, and reciprocal upregulation of CCR7, which mediates mature DC migration to draining lymph nodes. Inflammatory receptors, such as CCR2, may also contribute to afferent trafficking. CCR7 is also a major lymph node trafficking receptor for naïve T cells and can mediate activated T-cell exit from inflamed tissue.

The CCR7 ligand CCL21 is constitutively expressed on afferent lymphatic endothelium, high endothelial venules (HEVs), stromal cells, and interdigitating DCs in the T zones of the lymph node, Peyer patch, mucosa-associated lymphoreticular tissue, and spleen.[8] It is not expressed in B-cell zones or sinuses. CCL19, another CCR7 ligand, is also restricted to the T-cell zone and is expressed on interdigitating DCs.

CCR7$^{-/-}$ mice and the *plt* mouse, which is naturally deficient in CCL19 and a CCL21 isoform expressed in secondary lymphoid organs, have similar phenotypes: atrophic T-cell zones populated by a paucity of naïve T cells. This and the failure of activated DCs to migrate to the lymph node from the skin of these mice explain why contact sensitivity, delayed type hypersensitivity, and antibody production are severely impaired. However, lymph node trafficking is not completely abolished in these mice, which may develop autoimmune phenomena.

CXCR5 is expressed on all peripheral blood and lymph node B cells as well as on some T cells. Its ligand, CXCL13, is expressed constitutively on follicular HEVs and controls trafficking of CXCR5 positive B and T cells from blood into the follicles. In *CXCR5*$^{-/-}$ mice, B cells do not migrate to the lymph node, Peyer patches are abnormal, and inguinal lymph nodes are absent. CXCL13 is also required for B1 cell homing, natural antibody production, and body cavity immunity. *CXCR5*$^{-/-}$ mice still can produce antibody, perhaps, in part, because B cells and follicular DCs can form ectopic germinal centers within T-cell zones of the periarteriolar lymphocyte sheath of spleen.

Migration Within Lymph Node Microenvironments

CXCR5 is expressed on a majority of memory CD4 T cells in the follicles of inflamed tonsils. T-follicular helper cells (T_{FH}), a CD57$^+$ subset of CXCR5$^+$ T cells, lack CCR7, which licenses them to move from the T zone following activation to the follicles where they provide help for B-cell maturation and antibody production. Reciprocally, B cells activated by antigen in the follicles upregulate CCR7 and move toward the T-cell zone. Thus B–T interaction can be facilitated by the reciprocal movement of these cells, which may be influenced by the balance of chemokines made in adjacent lymphoid zones.[23] CXCR4 signaling is also important in naïve and memory B-cell trafficking to germinal centers. CCR5 ligands can guide naïve CD8 T cells to sites of CD4 T cell–DC interaction in lymph nodes.

Efferent Trafficking

Naïve lymphocytes that do not encounter antigen continue to recirculate between blood and secondary lymphoid tissue without acquiring any tissue-specific homing properties. Most antigen-stimulated T cells die by apoptosis. The survivors can be divided into functionally distinct subsets marked by characteristic patterns of chemokine receptor expression. In general, the trafficking properties of these cells are not well understood.

Among CD4 T cells, three memory subsets and two main effector subsets have been proposed. The memory subsets include T_{FH} cells described above as well as effector memory cells (T_{EM}), central memory cells (T_{CM}), and tissue resident memory cells (T_{RM}). T_{EM} do not express L-selectin or CCR7. They traffic through peripheral tissues as immune surveillance cells, rapidly releasing cytokines in response to activation by recall antigens. T_{CM} cells express CCR7 and lymph node homing receptors. They traffic between blood and secondary lymphoid organs but are not polarized and lack immediate effector function. Instead, they efficiently interact with DCs in the lymph node and differentiate into effector cells upon secondary stimulation. Highly heterogeneous, multifunctional human T_{EM} cells are produced early in differentiation and may become stable resting cells.[24]

Upon antigen activation, the classic effector CD4 T-cell subsets, Th1, Th2, and Th17, downregulate CCR7 and upregulate inflammatory chemokine receptors. Exit from lymph node via efferent lymphatics is mediated by additional mechanisms, including S1P1 (sphingosine 1 phosphate type 1 receptor) signaling, which can be blocked by the drug FTY720. *In vivo,* Th1 cells more frequently express CXCR3, CXCR6, CCR2, CCR5, and CX3CR1 than do Th2 cells, and the pattern of receptor expression is a function of maturation and age.[25] In contrast, Th2 cells more frequently express CCR3, CCR4, and CCR8 than do Th1 cells.

CXCR3 expression has been most consistently associated with Th1 immune responses and Th1-associated diseases. Its agonists CXCL9-11 are highly induced by IFN-γ but not IL-4. "Th1 chemokines" help maintain Th1 dominance through their ability to block CCR3. Similarly, in Th2 immunity, IL-4 and IL-13 made at inflamed sites in the periphery induce production of CCL7, CCL11 and other CCR3 ligands, the CCR4 ligands CCL17 and CCL22, and the CCR8 ligands CCL1 and, in the mouse, CCL8. CCR3 is expressed on a subset of Th2 lymphocytes as well as on eosinophils and basophils, the three major cell types associated with Th2-type allergic inflammation. Th2 cells are also associated with CCR4 expression. Arrival of Th2 cells amplifies a positive feedback loop through secretion of additional IL-4. CCL7 and CCL11 can block Th1 responses by antagonizing CCR2, CXCR3, and CCR5. Th17 cells are all found within the CCR6$^+$ subset of CD4 T cells.[26] There may also be a positive feedback loop for IL-17 induction of the CCR6 ligand CCL20 as a mechanism to recruit additional Th17 cells to inflamed sites.

Tissue-Specific Lymphocyte Homing

Cutaneous lymphocyte-associated antigen (CLA$^+$) T lymphocytes, which home to skin, preferentially express CCR4 and CCR10.[24] The CCR4 ligand CCL22 is made by resident dermal macrophages and DCs, whereas the CCR10 ligand CCL27 is made by keratinocytes. Blocking both these pathways, but not either one alone, has been reported to inhibit lymphocyte recruitment to skin in a delayed-type hypersensitivity model. This implies that these two molecules act redundantly as well as independently of inflammatory chemokines.

Homing to the small intestine is determined, in part, by T-lymphocyte expression of the integrin $\alpha_4\beta_7$ and CCR9.[27] The $\alpha_4\beta_7$ ligand MAdCAM-1 and the CCR9 ligand CCL25 colocalize on normal as well as on inflamed endothelium of the small intestine. Most T cells in the intraepithelial and lamina propria zones of the small intestine express CCR9. These cells, which are mainly TCR$\gamma\delta^+$ or TCR$\alpha\beta^+$CD8$\alpha\beta^+$, are reduced in the small intestine from *CCR9*$^{-/-}$ mice.

As B cells differentiate into plasma cells, they downregulate CXCR5 and CCR7 and exit the lymph node. B immunoblasts expressing immunoglobulin G (IgG) coordinately upregulate CXCR4, which promotes homing to bone marrow, whereas B immunoblasts expressing IgA specifically migrate to mucosal sites. Like gut-homing T cells, B immunoblasts that home to the small intestine express $\alpha_4\beta_7$ integrin and CCR9 and respond to CCL25.

Our understanding of the chemokine-dependent mechanisms for leukocyte subset trafficking in most tissues remains rudimentary. There are hundreds of subsets that need to be evaluated in both healthy tissues and disease states. At stake is the potential identification of important new targets for therapeutic development of specific, safe, and effective mechanism-based drugs in human disease.

CHEMOKINES AND DISEASE

There is a vast amount of literature addressing the presence and potential clinical relevance of chemokines in human disease. This section provides only a sampling of this work. Diseases for which evidence is strongest for a clear role of chemokines in pathogenesis in humans are highlighted. In some cases, understanding the role of chemokines has led to specific therapeutic interventions.

Opposite Effects of CCR5 in HIV and West Nile Virus Infection

HIV envelope glycoprotein gp120 mediates fusion of viral envelope with the target cell membrane by binding to CD4 and a specific chemokine receptor, which is referred to in this context as an HIV coreceptor.[6] CCR5 and CXCR4, the most important HIV coreceptors, have been shown to be physically associated with CD4 and gp120. HIV viruses are classified into three main subtypes by preferred chemokine receptor usage: X4 strains, which use CXCR4 for entry; R5 strains, which use CCR5; and R5X4 strains, which can use either coreceptor. Coreceptor preference is the main determinant of distinct cytotropisms between primary macrophages and cultured T-cell lines that have been observed for these strains.

The importance of CCR5 in clinical HIV/AIDS is revealed most clearly by *CCR5Δ32,* a nonfunctional allele that occurs in ~20% of North American Caucasians. Homozygotes are highly resistant to R5 HIV, the main transmitting strain, and HIV-infected heterozygotes have slower disease progression. Homozygotes appear healthy, as do unstressed CCR5 knockout mice. This has led to the development and the US Food and Drug Administration (FDA) approval of the specific CCR5 antagonist maraviroc for treatment of patients with HIV/AIDS.[28] The clinical importance of CCR5 in HIV disease is also illustrated by the outcome of an HIV$^+$ patient from Germany who had leukemia and fortuitously received bone marrow transplantation from a *CCR5Δ32* homozygote after cytoreductive therapy for leukemia. Remarkably, this patient has remained well, with undetectable viral load without antiretroviral therapy, suggesting a functional "cure."[29] This has spurred on efforts to develop zinc finger nuclease, CRISPR (clustered regularly interspersed short palindromic repeats), and other genetic methods to inactivate the *CCR5* gene as a cure strategy in infected patients. Positive preliminary results have been reported for a CCR5 zinc finger nuclease.

CLINICAL RELEVANCE

Examples of Chemokine and Chemokine Receptor Determinants of Human Disease

- *WHIM syndrome:* Mendelian combined immunodeficiency disorder caused by gain-of-function mutations in *CXCR4*
- Plasmodium vivax *malaria:* Protection conferred by a nonfunctional promoter variant in ACKR1/Duffy that abrogates expression of the receptor on red blood cells preventing use of the receptor by the parasite for cell entry
- *HIV infection:* Protection from cell entry by the virus conferred by homozygous mutation *CCR5Δ32*
- *AIDS disease progression rate:* Slowed by heterozygous *CCR5Δ32*
- *West Nile virus disease:* Increased risk with homozygous *CCR5Δ32*
- *Kaposi's sarcoma:* Human herpesvirus 8 vGPCR
- *Age-related macular degeneration:* Increased risk with *CX3CR1 M280* allele
- *Cardiovascular disease:* Decreased risk with *CX3CR1 M280* allele
- *Autoimmune heparin-induced thrombocytopenia:* Caused by CXCL4 autoantibodies
- *Chronic renal allograft rejection:* Reduced risk with homozygous *CCR5Δ32*
- *Rheumatoid arthritis:* Reduced risk with *CCR5Δ32*
- *Eosinophilic esophagitis:* Associated with CCL26 variant

CLINICAL RELEVANCE

FDA-Approved Drugs Targeting the Chemokine System

- *Maraviroc:* CCR5 antagonist for human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) that works by blocking HIV target cell entry
- *Plerixafor:* CXCR4 antagonist indicated together with granulocyte–colony-stimulating factor (G-CSF) for hematopoietic stem cell (HSC) mobilization in autologous stem cell transplantation of patients with multiple myeloma and non-Hodgkin lymphoma receiving cytoreductive therapy

CCR5 is also important in the pathogenesis of West Nile virus (WNV) infection, but in this case, it plays a protective role.[30] The mechanism appears to be increased antiviral defense by increasing recruitment of CCR5$^+$ leukocytes to the brain. Theoretically, therefore CCR5 blocking agents could increase the risk of WNV disease in infected individuals, particularly in the setting of HIV/AIDS, where the immune system is already compromised.

Malaria

Plasmodium vivax also uses a chemokine receptor for target cell entry.[31] The parasite ligand, named the *Plasmodium vivax* Duffy Binding Protein (PvDBP), is expressed in micronemes of merozoites and binds to the *N*-terminal domain of ACKR1 (originally known as Duffy and later as DARC [Duffy Antigen Receptor for Chemokines]) on erythrocytes via a cysteine-rich domain. This interaction is required for junction formation during invasion, but not for initial binding or parasite orientation. *P. vivax*-malaria is rare in sub-Saharan Africa because of genetic deficiency in ACKR1/Duffy caused by a single nucleotide substitution in the gene promoter (–46 C) affecting an erythroid-specific GATA-1 site. Fixation of the mutation in Africa presumably occurred because of positive selective pressure from malaria. ACKR1/Duffy deficiency in humans and in *Ackr1* knockout mice is not associated with any known health problems. ACKR1/Duffy is an obvious drug target, but to date, no candidates have been reported.

WHIM Syndrome

Truncating mutations in the *C*-tail of CXCR4 that increase receptor signaling are the cause of most cases of WHIM syndrome, a rare disease characterized by *w*arts, *h*ypogammaglobulinemia, *i*nfection, and *m*yelokathexis (neutropenia without maturation arrest).[32] Myelokathexis and infection can be explained by exaggeration of the normal bone marrow retention function of CXCR4 for myeloid cells, inhibiting their egress to blood. The exact mechanism underlying the selective predisposition to human papillomavirus infection is unknown. Dialing down the pathologically increased CXCR4 activity with a specific CXCR4 antagonist is a direct and rational strategy for treatment of patients with WHIM syndrome. In this regard, clinical trials are in progress to repurpose plerixafor (Mozobil, AMD3100), a CXCR4 antagonist approved by the FDA for use with granulocyte colony-stimulating factor (G-CSF) to mobilize HSCs for autologous transplantation in patients with multiple myeloma or lymphoma undergoing cytoreductive therapy.[33,34]

Remarkably, a patient who was spontaneously cured of WHIM syndrome by chromothripsis (chromosome shattering) on chromosome 2, which harbors the *CXCR4* gene, has been identified.[35] Chromothripsis is a newly described and uncommon example of genomic instability first described in cancer. The chromothriptic event in the patient apparently occurred in a single HSC that not only survived and lost the WHIM allele (but not the normal allele of *CXCR4*) but also acquired a selective advantage that allowed it to repopulate bone marrow, resulting in correction of panleukopenia and clinical cure. This fortuitous experiment of nature has been recapitulated in experimental mice, indicating directly that CXCR4 haploinsufficiency promotes HSC engraftment and therefore may have been an important or even the sole mechanism of cure in the patient. Together, these findings point to a potential genetic cure strategy for WHIM syndrome that might also be applied more broadly as an adjuvant to aid engraftment of gene-corrected cells in other genetic diseases of blood.

Atherosclerosis

Macrophages are the dominant leukocytes present in atherosclerotic lesions and are associated with the presence of macrophage-targeted chemokines, such as CCL2, CCL5, and CX3CL1.[36] *Ccl2*$^{-/-}$, *Ccr2*$^{-/-}$, *Cx3cl1*$^{-/-}$, and *Cx3cr1*$^{-/-}$ mice on the atherogenic *ApoE*$^{-/-}$ genetic background demonstrate smaller lesions and reduced accumulation of macrophages in the vessel wall. Adoptive transfer studies with bone marrow from *Cxcr2*$^{-/-}$ mice have also revealed a role for CXCR2 in promoting atherosclerosis in mouse models, apparently by promoting monocyte adhesion to early atherosclerotic endothelium through interaction with its mouse ligand KC and activation of the VLA-4/VCAM-1 adhesion system.

The CX3CR1 genetic variant CX3CR1-M280, which lacks normal CX3CL1-dependent adhesive function under conditions of physiological flow, has been associated with reduced risk of atherosclerotic vascular disease in humans. Mechanistic studies suggest that CX3CL1 on coronary artery smooth muscle cells anchors macrophages via CX3CR1.

ON THE HORIZON

The Viral Chemokine System

Studies of the viral chemokine system can yield insight into the role of chemokines in immunoregulation. Viral chemokine elements may also have applications as therapeutic agents.

Structural Classification

- Chemokines (*e.g.,* HHV8 vMIP-I, II, and III)
- 7TM chemokine receptors (*e.g.,* HCMV US28, HHV8 vGPCR)
- Chemokine-binding proteins (*e.g.,* γHV68 vCKBP-III)
- Chemokine mimics (*e.g.,* HIV gp120)

Functional Classification

- Cell entry factors (*e.g.,* HIV gp120)
- Leukocyte chemoattractants (*e.g.,* HHV8 vMIP-II)
- Immune evasion
  - Chemokine scavengers (*e.g.,* γHV68 vCKBP-III)
  - Chemokine receptor antagonists (*e.g.,* MCV MC148-R)
- Angiogenic factors (*e.g.,* HHV8 vGPCR)
- Growth factors (*e.g.,* HHV8 vGPCR)
  - In mice, overexpression of this viral chemokine receptor induces Kaposi's sarcoma (KS)-like lesions.

Kaposi's Sarcoma

HHV8 is an example of a virus laden with genes encoding pirated chemokines and chemokine receptors. It encodes three CC chemokines, vMIP-I, -II, and -III, as well as a constitutively active CC/CXC chemokine receptor named vGPCR, encoded by ORF74. All of these factors are angiogenic and may contribute to the pathogenesis of Kaposi's sarcoma (KS), a highly vascular multicentric nonclonal tumor caused by HHV8, typically in the setting of immunosuppression, such as in HIV/AIDS. Consistent with this, vGPCR induces KS-like tumors when expressed in transgenic mice. The mechanism may involve activation of NF-κB and induction of angiogenic factors and proinflammatory cytokines. This virus appears to have converted a hijacked receptor, probably CXCR2, into a regulator of gene expression.[37]

Autoimmunity

Two human diseases in which chemokines act as autoantigens for autoantibodies have been identified. The first, heparin-induced thrombocytopenia (HIT), is the only human autoimmune disease directly linked mechanistically to chemokines.[38] An established risk factor for thromboembolic complications of heparin therapy, HIT occurs in 1–5% of patients treated with heparin and is the result of autoantibodies that bind specifically to CXCL4-heparin complexes in plasma. The second, autoimmune myositis, is associated with autoantibodies to histidyl transfer RNA (tRNA) synthetase, a protein synthesis factor that is also able to induce DC chemotaxis, apparently by acting as an agonist at CCR5. Its exact importance in promoting inflammation in myositis has not been established.

In general, T cell–dependent autoimmune diseases in human, such as psoriasis, multiple sclerosis (MS), rheumatoid arthritis (RA), and type 1 diabetes mellitus, are associated with inflammatory chemokines and tissue infiltration by T lymphocytes and monocytes expressing inflammatory chemokine receptors. In a mouse model of immune complex–induced arthritis, the specific contributions of Ccr1, Cxcr2, Blt1 (a leukotriene B4 receptor), and the C5a receptor have been dissected in detail in joint venules at the level of adhesion and transendothelial migration. A dominant negative antagonist of CCL2 inhibits arthritis in the MRL-*lpr* mouse model of RA, suggesting a potential role for CCL2 and CCR2. Met-RANTES, a chemically modified variant of CCL5 that blocks CCR1, CCR3, and CCR5, was shown to be beneficial in a collagen-induced arthritis model in DBA/I mice.

The relative importance of these in human disease is not known. Drugs targeting CCR1 have failed in clinical trials in RA. Likewise, although a gene association meta-analysis suggested a protective effect for *CCR5Δ32* in RA, the CCR5 antagonist maraviroc was ineffective in a clinical trial in patients with RA.

Paradoxically, in some cases, blocking of chemokine receptors can lead to increased inflammation, as shown for CCR1 and CCR2 in mouse models of nephrotoxic nephritis and glomerulonephritis. This is associated with increased renal recruitment of CD4 and CD8 T cells, macrophages, and enhanced Th1 immune responses. The mechanism remains unclear.

Acute Neutrophil-Mediated Inflammatory Disorders

Many neutrophil-mediated human diseases, including psoriasis, gout, acute glomerulonephritis, acute respiratory distress syndrome, RA, and ischemia reperfusion injury, have been associated with the presence of CXCL8. Systemic administration of neutralizing anti-CXCL8 antibodies is protective in diverse models of neutrophil-mediated acute inflammation in the rabbit (skin, airway, pleura, glomeruli), providing proof-of-concept that CXCL8 is a nonredundant mediator of innate immunity and acute pathological inflammation in these settings. CXCR2 knockout mice are less susceptible to acute urate crystal-induced gouty synovitis. In addition, SB-265610, a nonpeptide small molecule antagonist with exquisite selectivity for CXCR2, prevents neutrophil accumulation in the lungs of hyperoxia-exposed newborn rats. Together, these results identify CXCL8 and its receptors as candidate drug targets for diseases mediated by acute neutrophilic inflammation. CXCR2 knockout mice also have shown delayed wound healing. Interestingly, studies of *Candida albicans* and *Pseudomonas aeruginosa* infection in mice have suggested that the highly related neutrophil receptor Cxcr1 does not mediate neutrophil recruitment into infected sites but is, instead, involved in activation of antimicrobial effector mechanisms.

Transplant Rejection

In the case of transplant rejection, the advantage over other animal models of human disease is that in both human and animal situations, the time of antigenic challenge is precisely known. The most extensive analysis of the role of chemokines in transplant rejection has been carried out in an major histocompatibility complex (MHC) class I/II-mismatched cardiac allograft rejection model in the mouse, which is mediated by a Th1 immune response. Similar sets of inflammatory chemokines are found in the mouse model as in human disease and appear in a strict temporal sequence.

Analysis of knockout mice has demonstrated that multiple chemokine receptors contribute to rejection in this model but that there is a marked rank order: Cxcr3 > > Ccr5 > Ccr1 = Cx3cr1 = Ccr2. Most impressively, rejection and graft arteriosclerosis do not occur if the recipient mouse, treated with a brief, subtherapeutic course of cyclosporine, is *Cxcr3*$^{-/-}$ or if the donor heart is *Cxcl10*$^{-/-}$. This identifies the CXCR3/CXCL10 axis as a potential drug target. Neutralization of Cxcl9, a Cxcr3 ligand that appears later than Cxcl10, can also prolong cardiac allograft survival.

In humans, CCR5 may be important in chronic kidney allograft rejection, since individuals homozygous for *CCR5Δ32* are underrepresented among patients with this outcome in a large German kidney transplantation cohort.

Allergic Airway and Intestinal Disease

Chemokine receptors associated with asthma include CXCR2, CCR3, CCR4, and CCR8.[39] CCR3 is present on eosinophils, basophils, mast cells, and some Th2 T cells. CCR4 and CCR8 identify airway T cells of allergen-challenged patients with atopic asthma.

Ccr8 knockout mice have reduced allergic airway inflammation in response to three different Th2-polarizing antigens: *Schistosoma mansoni* soluble egg antigen, ovalbumin, and cockroach antigen.

A role for the CCR3 axis in asthma has been supported by Ccl11 neutralization in the guinea pig and *Ccr3* gene knockout in the mouse. The effect of *Ccr3* knockout depends dramatically on the specific method of sensitization and challenge because of complex and opposite effects on eosinophil and mast cell trafficking. Thus *Ccr3*$^{-/-}$ mice sensitized intraperitoneally have reduced eosinophil extravasation into the lung but increased mast cell homing to the trachea. The net result is a paradoxical increase in airway responsiveness to cholinergic stimulation. Mast cell mobilization is not seen after epicutaneous sensitization, and these animals have reduced airway eosinophilia on challenge and no increase in airway hyperresponsiveness.

Ccr6$^{-/-}$ mice have decreased allergic airway inflammation in response to sensitization and challenge with cockroach antigen, which is consistent with the induction of its ligand Ccl20 in this model. *Ccr6*$^{-/-}$ mice are also protected from a mouse model of psoriasis, which is related to Ccr6 expression on monocytes and IL-17 expression in γδ T cells. Eosinophilic esophagitis has been associated with a CCL26 variant. Although there is no CCL26 homologue in the mouse, other mouse CCR3 ligands have been implicated in a mouse model of this disease.

CCR9 is an attractive drug target in Crohn's disease because of its important role in T-cell homing to gut; however, a CCR9 antagonist entered into clinical trials in this disease did not meet the primary endpoint for efficacy.

Cancer

Many chemokines and leukocyte subtypes have been detected *in situ* in tumors, and cancer cells have been shown to produce chemokines and express chemokine receptors. However, the role played by endogenous tumor-associated chemokines in recruiting tumor-infiltrating lymphocytes and tumor-associated macrophages and in promoting an antitumor immune response has not been clearly delineated. On the contrary, there are data from mouse models suggesting that the overall effect may be to promote tumorigenesis through additional effects on cell growth, angiogenesis, apoptosis, immune evasion, and metastasis.[39] Controlling the balance of angiogenic and angiostatic chemokines may be particularly important. Chemokine receptors on tumor cells have been shown to directly mediate chemokine-dependent proliferation. In Japan, a monoclonal antibody mogamulizumab, which blocks CCR4, has been approved for the treatment of adult T-cell leukemia or lymphoma, which expresses this receptor at high levels.

THERAPEUTIC APPLICATIONS

Chemokines and Chemokine Receptors as Targets for Drug Development

Efforts to develop chemokine blocking agents over the past 20 years have so far led to FDA approval of two drugs: maraviroc, targeting CCR5 as a viral entry factor in HIV/AIDS; and plerixafor, targeting CXCR4 in HSC mobilization from bone marrow for transplantation in cancer patients (see above).[28,33] Chemokine receptors are the first cytokine receptors for which potent, selective nonpeptide small molecule antagonists have been identified that work *in vivo*. Targeting host determinants, as in the case of CCR5 in HIV/AIDS, is a new approach in the development of antimicrobial agents. Other candidate disease indications are ACKR1/Duffy in *P. vivax* malaria; CXCR4 in WHIM syndrome; CXCR2 in acute neutrophil-mediated inflammation; CXCR3 and CCR2 in Th1-driven disease; CCR2 and CX3CR1 in atherosclerosis; CCR3 and possibly CCR4 and CCR8 in Th2 diseases, such as asthma; CCR9 in inflammatory bowel disease; and CCR6 in Th17 diseases, such as psoriasis.

Potent and selective nonpeptide small molecule antagonists of chemokine receptors, including CXCR2, CXCR3, CXCR4, CCR1, CCR2, CCR3, CCR5, and CCR9 have been reported.[40] These molecules share a nitrogen-rich core and appear to block ligand binding by acting at a conserved allosteric site analogous to the retinal-binding site in the transmembrane region of rhodopsin. Although small molecules taken as pills are the main goal, other blocking strategies are also under consideration, such as (1) ribozymes; (2) modified chemokines (*e.g.,* amino-terminally modified versions of CCL5); (3) intrakines, which are modified forms of chemokines delivered by gene therapy that remain in the endoplasmic reticulum and block surface expression of newly synthesized receptors; (4) monoclonal antibodies; and (5) specific gene editing, using the zinc finger nucleases, TALENs and CRISPR/Cas9.

The fact that viral and tick antichemokines typically block multiple chemokines acting at multiple receptors suggests that the most clinically effective chemokine-targeted antiinflammatory strategy may need to provide broad-spectrum coverage. In this regard, viral and tick antichemokines themselves may have a place therapeutically, although issues of antigenicity may be limiting for chronic inflammatory disease applications.

Chemokines as Biological Response Modifiers

Both inflammatory and homeostatic chemokines are being evaluated for therapeutic potential as biological response modifiers, acting mainly as immunomodulators or as regulators of angiogenesis. Studies, to date have not revealed major problems with toxicity, and efficacy has been noted in models of cancer, inflammation, and infection. Clinical trials in cancer and stem cell protection have shown disappointing results. Chemokines are being developed as vaccine adjuvants as well. Chemokine gene administration has also been shown to induce neutralizing antibody against the encoded chemokine, which is able to block immune responses and to alleviate experimental allergic encephalomyelitis and arthritis in rodent models.

Many chemokines, when delivered pharmacologically as recombinant proteins, by plasmid DNA, or in transfected tumor cells, are able to induce immunologically mediated antitumor effects in mouse models and could be clinically useful. Mechanisms may differ, depending on the model, but may involve recruitment of monocytes, NK cells, and cytotoxic CD8 T cells to tumor. Chemokines could also be useful as adjuvants in tumor antigen vaccines. Chemokine–tumor antigen fusion proteins represent a novel variation of this approach, facilitating uptake of tumor antigens by APCs via the normal process of ligand–receptor internalization. Non-ELR CXC chemokines, such as CXCL4, also exert antitumor effects through angiostatic mechanisms. As a final point, the use of chemokine-based immunotoxins to target disease cell–associated chemokine receptors, including cells infected with viral chemokine receptors, is quite conceivable.

CONCLUSION

The chemokine system occupies a central place in immunoregulation and is an attractive source of potential drug targets for any disease with an innate or adaptive immune component. A basic outline of how the system works has been established by using mouse models, and there has been tangible progress in the application of this knowledge in clinical practice. Two major pioneering successes, CCR5 inhibition in HIV/AIDS and CXCR4 inhibition for HSC mobilization, have demonstrated the feasibility of targeting the chemokine system therapeutically in humans. However, both are eccentric indications that address unusual, niche roles of chemokine receptors. Satisfactory treatments for chronic immune-mediated diseases remain a major unmet medical need, and in this context, the chemokine system offers many drug targets, as well as difficult challenges for the future.

MULTIPLE-CHOICE QUESTIONS

1. The major signal transduction pathway triggered by chemokines includes:
   - **A.** Pertussis toxin sensitive heterotrimeric Gi proteins
   - **B.** Phospholipase C β
   - **C.** Diacylglycerol
   - **D.** Phosphoinositide 3 kinase
   - **E.** All of the above

2. Chemokine receptors are:
   - **A.** Rhodopsin-like G protein–coupled receptors
   - **B.** Localized in the nucleus
   - **C.** Encoded by certain bacterial species
   - **D.** Used by intracellular bacteria for cell entry

3. The chemokine system includes:
   - **A.** Chemokines
   - **B.** Chemokine receptors
   - **C.** Seven-transmembrane (7TM) domain chemokine-binding proteins
   - **D.** Chemokine-binding proteins that lack both chemokine and 7TM structure
   - **E.** All of the above

4. The chemokine system is involved in the pathogenesis of which of the following diseases?
   - **A.** WHIM syndrome
   - **B.** HIV/AIDS
   - **C.** Malaria
   - **D.** All of the above

5. The major homeostatic chemokine receptors include:
   - **A.** CCR7
   - **B.** CXCR3
   - **C.** CCR6
   - **D.** CCR1

Lymphocyte Adhesion and Trafficking

Sirpa Jalkanen, Marko Salmi

EARLY LYMPHOCYTE PRECURSOR TRAFFICKING TO THE PRIMARY LYMPHOID ORGANS

Lymphocyte trafficking begins at an early stage of human ontogeny when lymphocyte precursor cells first appear and migrate into the primary lymphoid organs.[1-3] The multipotent hematopoietic progenitor and stem cells from the yolk sac and from the aorta–gonad–mesonephros migrate via the circulation to the liver and the spleen, which are important organs that support lymphocyte production in the embryo (Chapters 2, 7), and then into bone marrow. Thereafter, the developmental maturation of B cells takes place solely in bone marrow. T cells, in contrast, require an additional migratory event, which involves the entry of marrow-derived T-cell progenitors into the thymus (Chapter 8).[4] These early T-cell progenitors enter the thymus via the vessels in the cortical region. Concomitant with their differentiation and maturation via positive and negative selection, they pass from the cortex into the medulla.

MIGRATION OF NAIVE MATURE LYMPHOCYTES FROM BLOOD TO THE SECONDARY LYMPHOID ORGANS

After completing their initial course of development, newly arisen naïve B and T cells exit the primary lymphoid organs, travel through blood, and extravasate selectively to the secondary lymphoid organs.[2,5,6] These include peripheral lymph nodes, organized lymphoid tissues of the gut (*e.g.,* Peyer patches and the appendix), and the spleen (Chapter 2). In lymph nodes, most lymphocyte trafficking from blood to tissues takes place in specialized postcapillary venules. The endothelial cells of the venule exhibit a characteristic high cuboidal morphology that has given them their name: high endothelial venules (HEVs). The protrusion of the surface of these endothelial cells into the vascular lumen promotes the interaction of leukocytes in the relatively low-shear venular part of the circulatory system with the endothelial surface membrane (Fig. 11.1). HEVs carry many unique adhesion molecules that enable the capture of passing lymphocytes. They also have special intercellular connections that facilitate penetration of the vessel walls by these emigrating lymphocytes. It has been estimated that more than 50% of incoming lymphocytes make transient contacts with the vascular lining in the lymph nodes and that as many as one passing cell in four adheres to the endothelium and then extravasates into the tissue.

KEY CONCEPTS

Lymphocyte Recirculation

- Lymphocytes recirculate continuously between blood and lymphoid organs.
- 80% of lymphocytes enter the lymph nodes via specialized vessels called high endothelial venules (HEVs).
- The remaining lymphocytes enter the lymph nodes together with dendritic cells (DCs) and antigens via afferent lymphatics.
- Lymphocytes leave the lymph nodes via efferent lymphatics.
- Lymphocyte recirculation allows the lymphocytes to meet their cognate antigens and other leukocyte subsets to evoke an efficient immune response.

Antigens gather into these secondary lymphoid organs by a different route. Most antigens in the periphery can be taken up by dendritic cells (DCs) (Chapter 6), which subsequently migrate into the secondary lymphoid organs via the afferent lymphatics.[2] These afferent lymph channels open into the subcapsular sinus of the lymph node. Individual DCs subsequently penetrate the lymphatic endothelium and migrate into the stroma. Unbound, or free, antigens that are being carried via the afferent lymphatics through the body can diffuse into these secondary lymphoid organs, and then they can be captured by the professional antigen-presenting cells (APCs) of the lymph nodes. Lymph nodes thus serve as traps for the immune system, collecting lymphocytes from blood and antigens from lymph (Fig. 11.2). In these organs, lymphocytes percolate through the tissue in search of their cognate antigens.[2,7] If a given lymphocyte does not find its antigen, it will leave the organ by entering the efferent lymphatics that drain the medullary sinuses and is then transported via a major lymphatic trunk, such as the thoracic duct, back into the large systemic veins. After reentering the circulation, the cell can randomly gain access to another lymph node, where it has another chance to extravasate into tissue and find its cognate antigen. One round of recirculation from blood to the lymph node stroma, to a lymphatic vessel, and then back to blood takes about 1 day. Naïve lymphocytes continue recirculating until they either find their cognate antigen or die.

ACTIVATED LYMPHOCYTES DISPLAY SELECTIVE TISSUE HOMING PATTERNS

In a secondary lymphoid organ, a successful encounter between a lymphocyte and its cognate antigen leads to the proliferation

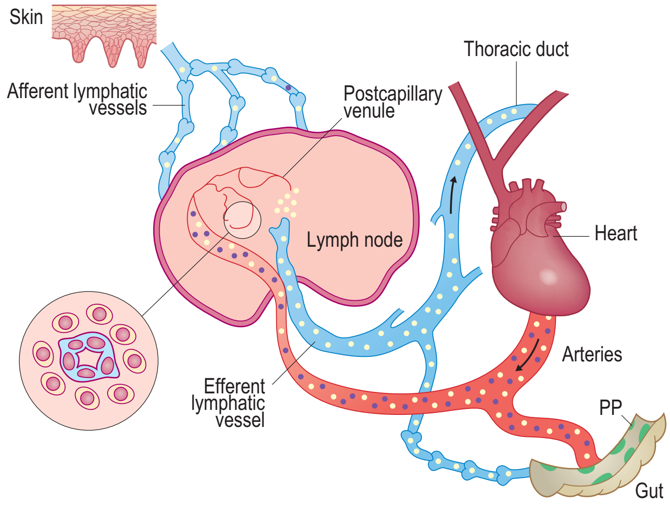

FIG 11.1 Lymphocyte Recirculation Routes Under Physiological Conditions. A low level of continuous antigenic transport into lymphoid organs takes place via the afferent lymphatics draining the skin and epithelium of the gut. Bloodborne lymphocytes enter the organized lymphatic tissues (lymph nodes and Peyer patches [PP]) from the circulation via the arterial tree, flow through the capillary bed, and then extravasate in the postcapillary high endothelial venules (HEVs). The extravasated lymphocytes percolate through the tissue parenchyma, enter the lymphatic vessels, and are then carried via the efferent lymphatics back to the systemic circulation. (Most of the venous circulation has been omitted from the figure.) Inset: an HEV. (From Salmi M, Jalkanen S. How do lymphocytes know where to go: current concepts and enigmas of lymphocyte homing. Adv Immunol 1997;64:139, with permission from Elsevier.)

of the cell within the organ and the maturation of its progeny.[2,6,7] Simultaneously, a process called *imprinting* leads to a profound change in the subsequent pattern of migration of the antigen-responsive cell. During the imprinting, local DCs give educational clues, such as vitamin A and D metabolites, to the lymphocytes. These lead to changes in the chemoattractant and adhesion receptor repertoire of the lymphocytes.[8] Although these responding cells leave the node via the lymphatics and are carried back to the systemic circulation, unlike naïve cells, they no longer migrate randomly to any lymphoid tissue. Instead, imprinting primes cells to preferentially seek the peripheral tissues in which the inciting antigen was originally ingested by the DC. In this way, selective homing of lymphocytes according to their previous history allows the organism to focus the immune response to the tissues where the effector cells can do the most good.

Among activated T cells, distinct pools of short-lived T effector cells, long-lived central memory T cells, effector memory T cells, and tissue resident memory T cells can be distinguished.[6,9] The different profile of adhesion molecule and chemokine receptor expression allows central memory T cells to continue migration through lymph nodes, whereas effector memory T cells are dispersed to patrol the peripheral tissues. In contrast, tissue resident lymphocytes, including tissue resident memory T cells, intraepithelial lymphocytes, γδ T cells, and innate lymphoid cells, mostly remain sessile in barrier tissues without the pattern of constant recirculation that is typical of the other lymphocyte subpopulations.

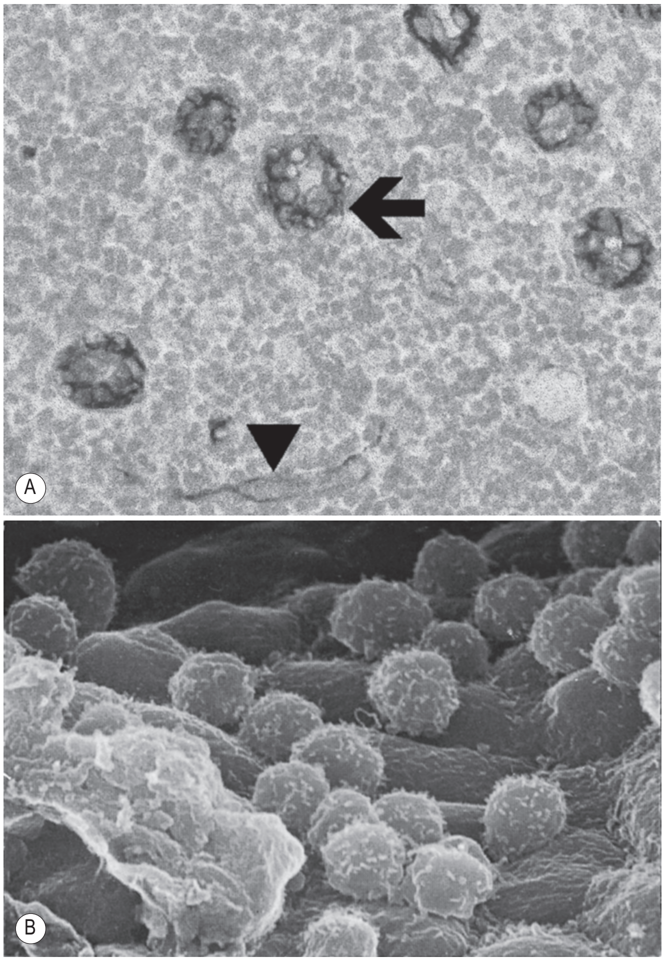

FIG 11.2 Characteristic Features of High Endothelial Venules (HEVs). (A) In this immunoperoxidase staining with anti-CD31 antibody, six HEVs are seen with typical plump endothelial cells. One HEV is identified with an arrow; a vessel with flat endothelium is also seen in this Figure *(arrowhead)*. (B) In this scanning electron micrograph lymphocytes are adhering to the HEV.

Under normal conditions, two distinct routes of lymphocyte recirculation can be discerned.[2,6] One targets lymphoid cells to the peripheral lymph nodes, and the second targets them to gut-associated lymphoreticular tissues (GALT; Chapter 20). Although the common gut-associated lymphoreticular system has long been considered to include both the respiratory and genitourinary tracts, differences in the fine specificity of lymphocyte homing between these targets do exist.

DISTINCT RECIRCULATION ROUTES IN THE SPLEEN

The spleen holds a unique place in the panoply of secondary lymphoid tissues.[10] It contains more lymphocytes than all of the peripheral lymph nodes combined, and the number of lymphocytes recirculating through it daily is the equivalent of the total pool of circulating lymphocytes. In the spleen, which lacks HEVs, many lymphocytes enter the tissue through the marginal zone sinuses, where macrophage-like cells may play an important role. Once in the splenic parenchyma, T cells accumulate in the regions surrounding the central arteriole in the white pulp, a location known as the *periarteriolar sheath*. B cells are scattered in the corona that surrounds these T-cell areas. Most splenic lymphocytes leave the spleen via the splenic vein. The mechanisms that control the entry and exit of lymphocytes from the spleen remain incompletely understood but include chemokines, oxysterols, and sphingosine 1 phosphate.

KEY CONCEPTS

Adhesion Molecules in Inflammation

- Adhesion molecules are important in directing leukocyte traffic to sites of inflammation.
- Numerous inflammatory mediators upregulate and/or induce expression of several endothelial cell adhesion molecules.
- Harmful inflammation can be prevented and cured by blocking the function of adhesion molecules.

INFLAMMATION-INDUCED CHANGES IN LEUKOCYTE TRAFFICKING

During an acute inflammatory response to an antigenic insult, leukocytes can migrate into all nonlymphoid. The inflammation-induced leukocyte migration takes place in characteristic waves.[11] First, the polymorphonuclear leukocytes rapidly (typically within 1–4 hours) infiltrate into the inflammatory focus. They are then followed by mononuclear cells (monocytes and lymphocytes). In a primary challenge, it may take 3 days or more before antigen-specific immunoblasts are seen at the peripheral site of inflammation. However, a secondary response by memory lymphocytes typically has a much shorter lag period. Different CD4 T-helper subpopulations, including Th1, Th2, Th17, and regulatory T cells (Tregs; Chapters 8, 16, and 18), CD8 T-cytotoxic cells (Chapter 17), and B cells (Chapter 7) can all enter the inflamed tissue by using basically the same mechanisms. However, the ratio of these populations and the individual molecules employed can vary.[6,12] Successful resolution of an inflammatory reaction is also dependent on a coordinated program involving specialized proresolving lipid mediators (lipoxins, resolvins, protectins, and maresins), proteins (annexin A1), purines (adenosine), and gaseous mediators (*e.g.*, hydrogen sulfide), all of which serve to halt the inflammatory cell recruitment and to initiate multiple antiinflammatory, tissue-repairing mechanisms.[13]

The normal vascular endothelium in nonlymphoid tissues has a flat, inactive morphology. With inflammation, a series of events renders postcapillary venules in these tissues capable of binding lymphocytes. The most important changes result from the proadhesive effects of a multitude of proinflammatory cytokines that are released by a variety of cell types after being subjected to inflammatory stimuli.[11] If inflammation becomes chronic, marked histological manifestations become apparent in the affected nonlymphoid tissues.[14] Most notably, the venules in these chronically inflamed tissues acquire many of the characteristics of HEVs. Immigrating lymphocytes can form lymphoid follicles that resemble those seen in lymph nodes. These alterations have consequences for lymphocyte recirculation pathways. For example, inflamed skin displays characteristics of lymphocyte homing that are clearly distinct from those of either mucosal or peripheral lymph node systems.[8,15]

MOLECULAR MECHANISMS INVOLVED IN LEUKOCYTE EXTRAVASATION FROM BLOOD INTO TISSUES

The Adhesion Cascade

Dynamic interactions between leukocytes and endothelial cells can be observed both *in vitro* and *in vivo*. For example, leukocyte adhesion can be followed *in vivo* in experimental animals and even in human tissues by intravital microscopy (Fig. 11.3). Leukocyte–endothelial cell interaction during the extravasation cascade can be divided into a series of phases, or steps, that all leukocyte subtypes, including lymphocytes, are thought to follow (Fig. 11.4).[2,6,11,16]

First, the leukocytes marginate out of the main bloodstream and begin to tether and roll on the endothelial cell surface. This step is mediated primarily by selectins and their mucin-like counterreceptors. This slow-velocity movement culminates in an activation phase, during which leukocyte chemokine receptors transmit activation signals by recognizing their chemokine ligands presented on the endothelial cell surface. This leads to avidity and/or affinity changes in leukocyte integrins, which bind leukocytes firmly to their immunoglobulin superfamily ligands on endothelial cells. Leukocytes then begin to crawl on the endothelium. After finding a proper place, they transmigrate through the endothelium. This transmigration process begins with interactions between leukocyte integrins, their counterreceptors, and other molecules. This step is followed by complex signaling events that lead to protein phosphorylation and dynamic clustering of the cytoskeleton.

Leukocytes transmigrate between endothelial cells at the endothelial cell junction, which opens transiently and subsequently closes by localized stimuli.[16] This process requires proteinases, such as matrix metalloproteinase-2 (MMP-2), which is induced in T cells upon adhesion to endothelial cells, as well as other repair mechanisms that are currently not well known. This subsequently closes the path of transmigration. Interestingly, leukocytes can also migrate through endothelial cells in a subtype-specific fashion. For example, polymorphonuclear leukocytes prefer entering via the interendothelial junctions, whereas nonactivated lymphocytes may choose the transcellular route.[11,16]

KEY CONCEPTS

Leukocyte–Endothelial Cell Interactions

- Leukocytes interact with the vessel wall in a multistep fashion, using several leukocyte surface molecules that recognize their counterreceptors on endothelial cells.
- Selectins mediate the rolling and tethering of leukocytes on the vessel wall.
- Chemokines and their receptors activate leukocyte integrins.
- Only activated integrins are able to mediate firm adhesion between leukocytes and endothelium.
- The transmigration of leukocytes into the tissues requires proteinases and repair mechanisms.

Certain endothelial molecules involved in the adhesion cascade show organ-specific expression patterns. Analogously, leukocyte-associated homing molecules display subtype-specific expression profiles. Only those leukocytes that have the proper set of molecules on their surface can enter a particular tissue because

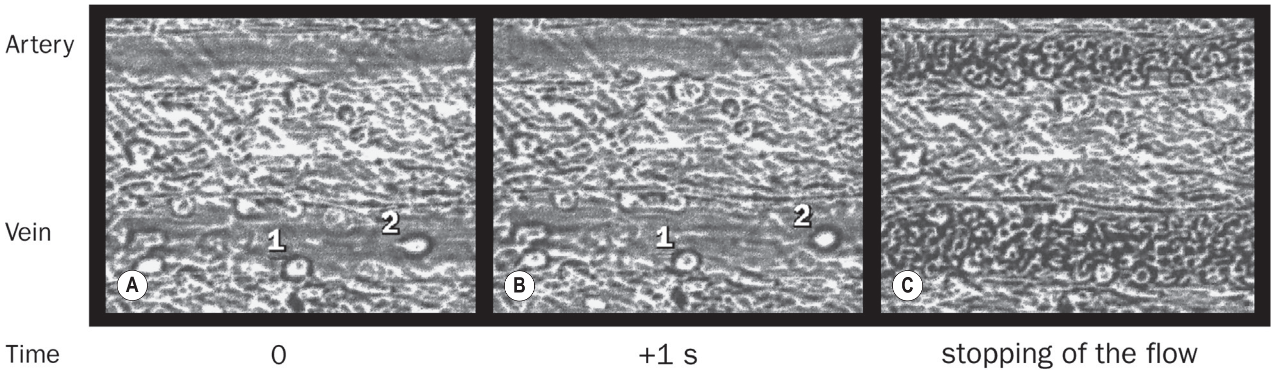

FIG 11.3 Intravital Microscopy of Mesenteric Vessels. In these video frames taken at indicated intervals from the same field, a vein, an artery, leukocytes, and the transparent mesenteric membrane are seen. Within the vein, rolling and adherent leukocytes are visible, whereas no such cells are seen in the artery. Leukocyte 1 is attached to the vessel wall and leukocyte 2 is slowly rolling. Compare the locations of these cells in A and B to stationary leukocytes outside the vessels. Leukocyte 1 is at the same location in both panels, whereas leukocyte 2 has moved a distance corresponding to roughly the length of its diameter. Under normal conditions, freely flowing cells move so fast that they cannot be visualized. However, in panel C, the flow has been transiently stopped. Under this static condition, the large number of hematopoietic cells (mainly erythrocytes) traveling within the bloodstream can be seen. (Courtesy of S. Tohka, University of Turku, Finland.)

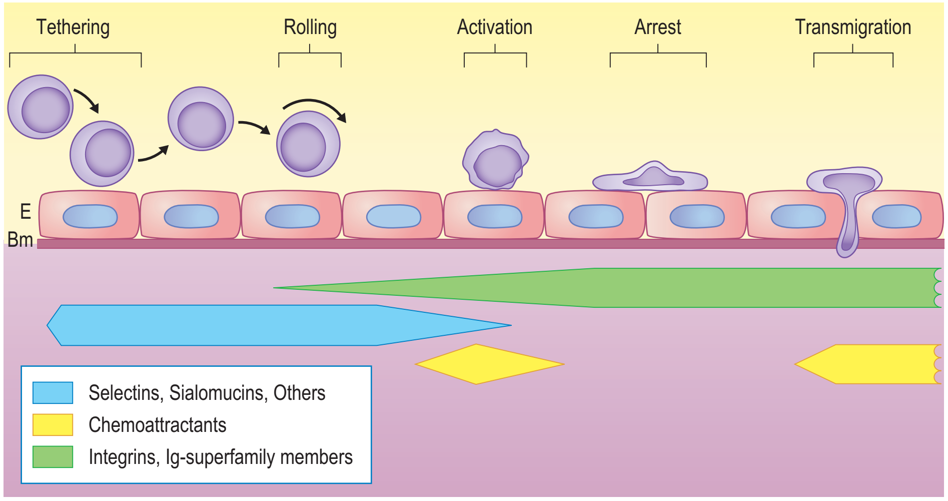

FIG 11.4 The Multistep Cascade of Lymphocyte Extravasation. The bloodborne cell makes transient initial contacts with endothelial cells (tethering), which leads to the cell rolling along the vascular lining. If the cell becomes activated, it can subsequently adhere firmly to the endothelial cells (arrest). The adherent cell can then penetrate through the endothelial cell cytoplasm (transcellular migration) or seek for interendothelial junctions (crawling). It can then migrate between two endothelial cells (paracellular migration) and finally penetrate the basement membrane to enter the tissue. The contribution of major superfamilies of adhesion-associated molecules at each step is depicted below. E, endothelial layer; Bm, basement membrane.

the entering leukocyte must find a correct endothelial partner molecule at each step of the adhesion cascade. Thus leukocyte–endothelial cell interactions take place in a well-coordinated multistep fashion, in which every step must be properly executed before the leukocyte can be guided into the tissue. The multistep nature of the leukocyte adhesion cascade is reminiscent of the cascades involved in blood clotting and complement-mediated killing.

Receptors and Their Ligands in Leukocyte–Endothelial Cell Interaction

Various molecules belonging to several molecular families are expressed on both leukocyte and endothelial cell surfaces and participate in the complex extravasation process.[16] Most of these molecules exert their function in successive, but overlapping, phases of the adhesion cascade. In addition, proper functioning

of multiple intracellular signaling molecules is needed for execution of successful extravasation.[2,16] In the following section, only the best-known surface molecules in this process are discussed (Fig. 11.5).

Selectins and Their Ligands

Three members of the selectin family mediate leukocyte trafficking. L-selectin is expressed on several leukocyte subpopulations. E-selectin is expressed on the endothelium, and P-selectin is expressed on both platelets and the endothelium. An important structural feature of selectins is the presence of a terminal lectin domain that is used to bind to their counterreceptors. The counterreceptor is typically decorated by a sialyl Lewis X (sLeX) carbohydrate, which is a prototype recognition domain for selectins in general.[17] The interaction between selectins and their counterreceptors is transient and weak, which allows leukocytes to form and break contacts with the endothelium effectively during tethering and rolling under shear stress.

L-selectin preferentially mediates lymphocyte migration to the peripheral lymph nodes. However, it also participates in the homing of lymphocytes to organized MALT (*e.g.*, Peyer patches) (Chapter 20). L-selectin is also an important contributor to the process of leukocyte trafficking to sites of inflammation. Peripheral lymph node addressins (PNAds) are the best-characterized counterreceptors for L-selectin. This group consists of at least six different molecules that are decorated with a sulfated and fucosylated sLeX, which serves as a recognition motif for L-selectin. PNAds include glycosylation-dependent cell adhesion molecule-1 (GlyCAM-1), CD34, podocalyxin, endomucin, nepmucin, and mucosal addressin cell adhesion molecule-1 (MAdCAM-1). MAdCAM-1 is decorated with recognition epitopes for L-selectin on HEVs in the organized lymphoid areas of the gut, but not on the flat-walled vessels in the lamina propria.

The importance of posttranslational carbohydrate modifications for the function of selectin ligands has been well demonstrated in knockout mice deficient in fucosyl, glucosaminyl, galactosyl, sialyl, or sulfotransferases. For example, mice with a targeted disruption of fucosyltransferase VII (Fuc-TVII) are unable to glycosylate L-selectin ligands appropriately. These mice exhibit severe defects in lymphocyte homing and in the extravasation of leukocytes to sites of inflammation. In contrast, core 2 β 1,6-N-acetylglucosaminyltransferase (C2 β GlcNAcT) knockout mice that have deficient glycosylation of their P- and E-selectin ligands demonstrate normal lymphocyte homing to lymph nodes, but impaired leukocyte trafficking to sites of inflammation. Interestingly, L-selectin also facilitates entry of leukocytes into tissues by mediating leukocyte tethering and rolling of endothelium-bound leukocytes by binding to P-selectin glycoprotein ligand-1 (PSGL-1).

E-selectin and P-selectin are inflammation-inducible molecules. Within minutes, P-selectin can be translocated from intracellular storage granules onto the endothelial cell surface, where it binds to its leukocyte receptor, PSGL-1 (see Fig. 11.5). P-selectin and PSGL-1 mediate rolling at early time points during inflammation. Platelet P-selectin can facilitate lymphocyte entry into tissues because it can simultaneously bind to PNAd on the endothelium and PSGL-1 on lymphocytes. E-selectin upregulation requires new protein synthesis. It is maximally expressed about 4 hours after induction of inflammation. E-selectin is needed for slow rolling of leukocytes. It also has an affinity toward PSGL-1, as well as a specific glycoform of PSGL-1, cutaneous lymphocyte antigen (CLA). CLA specifically directs lymphocyte trafficking to inflamed skin. In addition to PSGL-1, E-selectin has more private leukocyte receptors, CD44 and E-selectin ligand-1 (ESL-1) (see Fig. 11.5).[17] Mice deficient in both E- and P-selectins have more drastic defects in their rolling and leukocyte migration to sites of inflammation than could have been anticipated from mice deficient in only one of the two selectins. This suggests that E- and P-selectins have overlapping functions and can compensate for each other.

Chemokines and Their Receptors

Chemotactic cytokines and their receptors (Chapter 10) are grouped into four different families based on their primary protein structure. The families are defined by a cysteine signature motif—CXC, CC, C, and CX3C—where C is a cysteine, and X any amino acid residue.[18] Most chemokines are small, soluble heparin-binding chemoattractants. The relevant chemokines for leukocyte extravasation are presented to bloodborne lymphocytes by proteoglycan molecules present on endothelial cell surfaces. During the adhesion cascade, they activate integrins by signaling via serpentine receptors, which are pertussis toxin sensitive and G-protein linked.[19]

Different leukocyte subsets bear their own distinct sets of receptors, which enable them to respond to chemokines presented on the vascular endothelium as well as within tissues. For example, CCL21 and CCL19 are preferentially expressed by HEVs that are found in the interfollicular areas within a lymph node. They preferentially attract T cells bearing the CCR7 receptor and thus draw T lymphocytes from blood and into these areas. Fractalkine, a CX3C chemokine, can be produced in either a soluble or a membrane-anchored form. It can be found on the HEVs in peripheral lymph nodes and has potent chemoattractant activity for T cells. The major attractants for B cells are CXCL12 and CXCL13.

Although many chemokines are present in different organs in the body, some selectivity in their expression can guide tissue-selective leukocyte trafficking. For example, CCL25 attracts CCR9-positive lymphocytes to the small intestine, and CCL17 and CCL22 attract CCR4-bearing lymphocytes to the skin. Chemokines can form heteromeric complexes to activate chemokine receptors. For example, CXCL13 can enhance triggering of CCR7 by CCL19 and CCL21. Conversely, formation of chemokine complexes may protect a chemokine from degradation.[18]

Integrins and Their Immunoglobulin Superfamily Ligands

Integrins are a large family of heterodimeric molecules consisting of an α and a β chain.[2] Traditionally, they are thought to mediate firm adhesion between leukocytes and endothelial cells. However, in specific low-shear conditions, they can also participate in rolling. For leukocyte trafficking, the most important integrins are $\alpha_4\beta_7$, leukocyte function–associated antigen-1 (LFA-1), and $\alpha_4\beta_1$.

$\alpha_4\beta_7$ is a principal homing receptor for lymphocyte trafficking to mucosa-associated lymphatic tissues. It binds to MAdCAM-1 on HEVs in organized mucosal lymphatic tissues, such as Peyer's patch and the appendix, and to flat-walled venules in the lamina propria. α4-integrin can also pair with a β_1 chain to form $\alpha4\beta_1$ dimers, which are utilized by lymphocytes primarily in inflammatory conditions. It binds to vascular cell adhesion molecule-1 (VCAM-1) on the endothelium and has been proven central in mediating lymphocyte trafficking into the brain in multiple sclerosis.

LFA-1 (CD11a/CD18) is a member of the group of leukocyte integrins that contain a unique α chain (CD11 a, b, c, and d) but share a common β chain (β_2/CD18). LFA-1 is present on practically all leukocyte subsets. It interacts with its counterreceptors, intercellular adhesion molecules (ICAM-1 and ICAM-2), on the endothelial cell surface (see Fig. 11.5). ICAM-1 is upregulated at sites of inflammation, whereas ICAM-2 is constitutively present on the vascular endothelium. To be functional, LFA-1 must be activated. Activation of LFA-1 is thought to be primarily a product of chemokine signaling. Alternative activation pathways include triggering through glycosyl-phosphatidylinositol (GPI)–linked molecules and CD44, as well as through other costimulatory lymphocyte surface molecules.[20] LFA-1–dependent pathways display no significant organ specificity in their function.

Mac-1 (CD11b/CD18) is also involved in leukocyte migration, although its contribution is overshadowed by LFA-1. Like LFA-1, Mac-1 uses ICAM-1 and ICAM-2 as its ligands (see Fig. 11.5). Both VCAM-1 and ICAM-1 also play an important role in initiating transmigration, as they mediate the signals to endothelial cells that are needed to change their shape and other properties in order to allow leukocyte entrance.[20]

Other Homing-Associated Molecules

Several other molecules belonging to various molecular families also participate in the adhesion cascade. CD44 is a multifunctional proteoglycan found on a large variety of different cell types.[21] Using endothelial hyaluronan as its ligand, it mediates lymphocyte rolling. It can form bimolecular complexes with $\alpha_4\beta_1$ that strengthen leukocyte–endothelial cell interaction. *In vivo* inhibition studies using function-blocking antibodies indicate that CD44 plays an important role in directing lymphocyte trafficking to sites of inflammation (*e.g.*, skin and joints).

CD31, a member of the immunoglobulin superfamily, is found on many subsets of lymphocytes as well as in the continuous endothelium of all vessel types. It is expressed primarily at the intercellular junctions and is involved in a stimulus-specific manner in transmigration, especially through the endothelial basement membrane. Other molecules involved in the transmigration process are CD99 and junctional adhesion molecules A and C, which are expressed on both leukocytes and endothelial cells. These molecules interact sequentially in a homotypic fashion during diapedesis. Endothelial JAM-A can also use LFA-1, JAM-C can utilize Mac-1, and JAM-B can use $\alpha_4\beta_1$ as leukocyte ligands.

The role of ecto-enzymes in the adhesion cascade has been recently recognized.[22,23] Vascular adhesion protein-1 (VAP-1), CD73, and CD38 have well-established roles in leukocyte trafficking. Because of their enzymatic properties, they can rapidly modify adhesive interactions and modulate the microenvironment. VAP-1 is a homodimeric sialoglycoprotein, which, under conditions of inflammation, is rapidly translocated onto the endothelial cell surface. It mediates early phases of leukocyte interaction with the endothelium, as well as transmigration. Besides its adhesive function, it also possesses an amine oxidase activity that can produce potent immunomodulators, such as hydrogen peroxide (H_2O_2) and aldehyde as end products.

CD73 is present both on a subpopulation of lymphocytes and on the endothelium. It is an ecto-nucleotidase. The main product of its enzymatic activity in dephosphorylation of adenosine monophosphate (AMP) is adenosine, which is highly anti-inflammatory in nature. Endothelial CD73 may also have a counterreceptor on the lymphocyte surface because lymphocyte binding to the endothelium inhibits the enzymatic activity of CD73. This facilitates the extravasation process of the lymphocyte. The importance of CD73 in dampening inflammation is clearly seen in mice deficient in CD73, as they are highly susceptible to inflammatory injuries as a result of leaky vasculature.

CD38, an adenosine diphosphate (ADP)–ribosyl cyclase, is expressed on most lymphoid cells and can use CD31 as its endothelial cell ligand. It regulates calcium fluxes and the sensitivity of leukocytes to chemokine signals via its enzymatic activity.

INTRAORGAN LYMPHOCYTE LOCALIZATION

Following its extravasation from the blood vessels, a lymphocyte needs to interact with several matrix molecules, such as fibronectin, laminin, and collagens. Adhesive interactions between a lymphocyte and the extracellular matrix molecules are largely mediated by β_1 integrins, although lymphocytes can also use CD44 to interact with fibronectin and collagens. The directional movement and the final localization of a lymphocyte within the tissues are controlled by chemokines.[24] Modern two-photon imaging has provided detailed information about the kinetics and directionality of lymphocyte movement in living tissues.[7]

Besides directing the entry of T cells into tissues, CCL21 and CCL19 also determine the final destination of the T lymphocyte within lymph nodes, the spleen, and Peyer's patches. CCL19 and CCL21 produced by stromal cells in the T cell areas within lymphoid tissues guide the T lymphocyte into the interfollicular space. In an analogous manner, CXCL13, the B cell–attracting chemokine-1, is produced by a subset of follicular DCs found in the secondary lymphoid organs. It attracts B cells possessing CXCR5 to the light zone of the follicles. CXCL12, in contrast, guides CXCR4 positive B cells to the dark zone (Fig. 11.6).

The correct localization of a lymphocyte and an APC within the lymph node is a prerequisite for an optimal immune response.

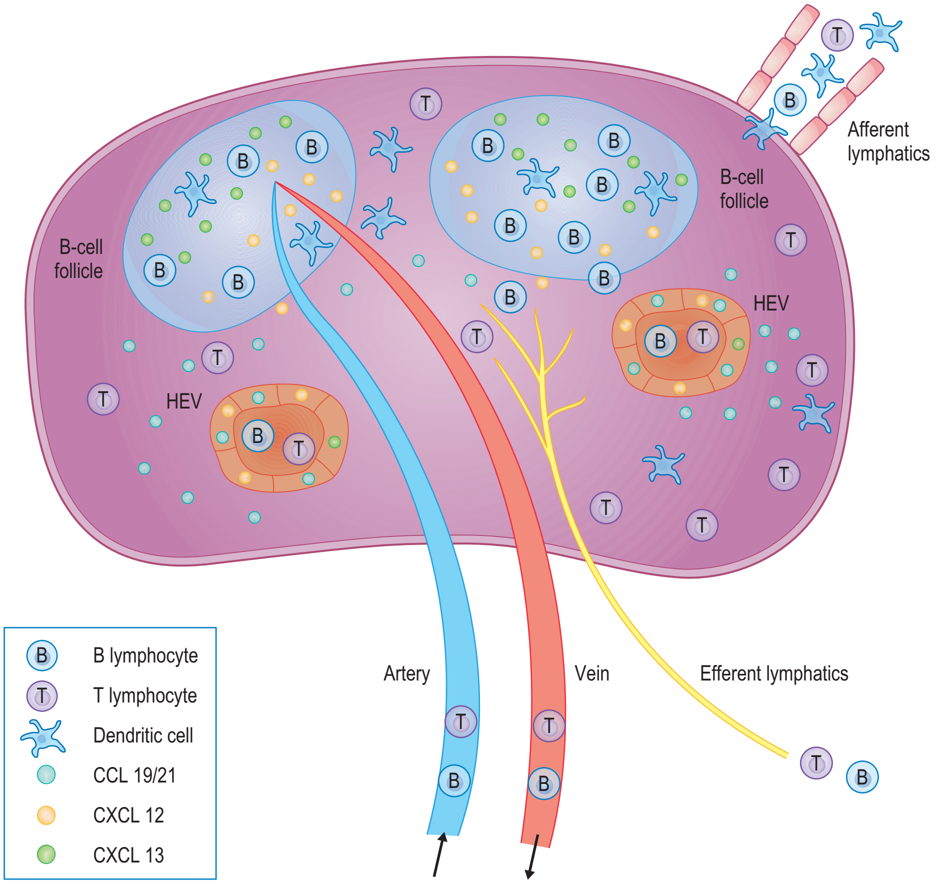

FIG 11.6 The Role of Chemokines in Entrance and Intraorgan Localization of Lymphocytes. CCL19 and CCL21 are involved in T-lymphocyte entrance into the lymph node via the high endothelial venules (HEVs). They also guide migration of T cells to the interfollicular areas within the node. In contrast, CXCL12 and CXCL13 attract B lymphocytes on the vessel wall and direct their movement to the follicles.

For example, B-cell collaboration with T cells is ensured by the upregulation of CXCR5 expression on a subpopulation of T cells and the upregulation of CCR7 on certain B cells. This promotes the movement of these cells to the B- and T-cell zone boundary.

The importance of CCL21 and CCL19 in lymphocyte trafficking is demonstrated by a spontaneous mutant mouse strain, plt, which has reduced expression of these chemokines. In these mice, both lymphocyte entry via HEVs and the organization of T-cell areas within lymph nodes are defective. This phenotype is recapitulated in CCR7-knockout mice. CCL21/CCL19 and CXCL12/CXCL13 are currently the best-known determinants of lymphocyte localization within lymphoid tissues, although several other chemokines are needed for optimal encounters among various cell populations to create a crisp immune response. In addition to chemokines, other attractants (*e.g.,* oxysterols) guide lymphocytes within the nodes. For example, Epstein-Barr virus induced genes in B cells (EBI2) have a strong migratory response to 7α,25-dihydroxycholesterol, promoting B-cell positioning to the lymphoid follicles.[25]

CELL TRAFFICKING WITHIN LYMPHATICS

Although leukocyte trafficking within the lymphatics is an essential part of the recirculation process and the immune response in general, the molecular mechanisms that regulate this tightly controlled and cell type–selective migration remain poorly understood. It is known that CCL21 on the lymphatic endothelium attracts CCR7-positive lymphocytes into the afferent lymphatics and hence to the draining lymph nodes.[26] Adhesion molecules, such as the macrophage mannose receptor and the common lymphatic endothelial and vascular endothelial receptor-1 (Clever-1, also known as "Stabilin-1" and "FEEL-1"), also mediate lymphocyte migration into the lymphatics. Lymphocytes adhere to lymphatic vessels via these molecules in *in vitro* assays, and inhibition and/or lack of these molecules impair lymphocyte trafficking within the lymphatics *in vivo.* Both macrophage mannose receptor and Clever-1 are present on the afferent and the efferent lymphatics and, thus, are able to control both incoming and outgoing lymphocyte traffic in lymph nodes.[27,28]

Sphingosine 1 phosphate receptor 1 (S1P1), which is expressed in many different cell types, also participates in the entry of lymphocytes into the afferent lymphatics and the exit of lymphocytes from lymph nodes into the efferent lymphatics. Although its absence leads to defects in vascular development and embryonic lethality, studies of conditional knockout mice have shown that lymphocytes lacking S1P1 can enter lymph nodes normally. However, they are not able to exit from lymph nodes into the efferent lymphatics. Additional studies indicate that S1P1 may control lymphocyte trafficking by regulating endothelial permeability and/or suppressing lymphocyte chemotaxis in S1P gradients and be a useful target for drug development in many diseases.[29]

CLINICAL IMPLICATIONS

Leukocyte trafficking plays a pivotal role in the pathogenesis of all infectious and inflammatory diseases.[16] Trafficking is essential for mounting a proper immune response against an invading microbe. However, in many other cases, inappropriate leukocyte migration also causes tissue destruction. Here, we have chosen a few representative examples to illustrate some of the general principles.

TABLE 11.1 Clinical Features of Immunodeficient Patients With Abnormalities in Homing-Associated Molecules

	LAD I	LAD II	LAD III
Clinical Manifestation			
Recurrent bacterial infections	+++	+	+++
Neutrophilia	Yes	Yes	Yes
Developmental abnormalities	No	Yes	No
Laboratory Findings			
CD18 expression	Marked decrease or absence	Normal	Normal
sLex expression	Normal	Absent	Normal
Neutrophil rolling	Normal	Marked decrease	Normal
Neutrophil firm adherence	Marked decrease	Mild decrease	Marked decrease
Primary detect	CD18	FUCT1	KINDLIN3

Immunodeficiencies

Various genetic defects in leukocyte trafficking have been identified during the past two decades among a multitude of other immunodeficiencies.[30] Leukocytes from patients with Wiskott-Aldrich syndrome (WAS) show reduced migration to the chemokines CCL2, CCL3, and CXCL12 as a result of a mutation in the gene encoding an intracellular WAS protein that is responsible for proper cytoskeletal organization of the hematopoietic cells. Mutations of CXCR4 in patients with WHIM (warts, hypogammaglobulinemia, infections, and myelokathexis) lead to an enhanced chemotactic response to CXCL12 expressed on the bone marrow endothelium and leukocyte accumulation in bone marrow. A single case of inherited dysfunction of E-selectin has also been reported. The patient had recurrent infections but did not demonstrate neutrophilia. She could not synthesize E-selectin on the endothelium, although her serum level of soluble E-selectin had increased.[31]

Three different forms of adhesion defect in integrins lead to poor or total lack of homing of certain leukocyte populations.[32] Their typical features are listed in Table 11.1. These diseases are extremely rare, but they offer a perfect recapitulation in human of the basic principles of leukocyte trafficking that was first deciphered in animal models.

LAD I

Patients with leukocyte adhesion defect-1 (LAD-1) have defects in the synthesis, pairing, or expression of β_2 integrins.[33] The severe form leads to a drastic reduction or absence of CD11a/CD18 (LFA-1), CD11b/CD18 (Mac-1), CD11c/CD18, and CD11d/CD18. Although patients with LAD-1 exhibit neutrophilia, they suffer from severe recurrent bacterial infections as a result of defects in leukocyte extravasation into sites of inflammation. These patients usually die young. Patients suffering from a milder form of LAD-1 (<10% of normal β_2 integrins) demonstrate impairment in leukocyte migration and suffer from frequent infections as well, but they usually survive until adulthood. In these patients, lymphocyte migration to inflammatory sites is close to normal, probably because lymphocytes can utilize the VLA-4–VCAM-1 pathway to compensate for the lack of β_2 integrins. LAD-1 variants with modestly reduced β_2 integrin expression have been associated with mutations that create heterodimers but do not bind ligands. In all types of LAD I, granulocytes typically show normal rolling, but failure to arrest on endothelial cells.

LAD II

Patients with LAD II suffer from several abnormalities, including recurrent infections, neutrophilia, impaired pus formation, mental retardation, growth defects, and deficiency in H blood group antigen.[33] The cause of the disease is impaired transport of guanosine diphosphate (GDP)–fucose from the cytoplasm to the Golgi lumen as a result of mutations in a GDP–fucose transporter. The defect leads to impaired fucose modification of selectin ligands, most notably that of PSGL-1. Consequently, these patents demonstrate a marked decrease in leukocyte rolling under flow conditions. Interestingly, some patients respond to treatment with oral fucose.

LAD III

The third LAD syndrome involves defective inside-out signaling of β_1, β_2, and β_3 integrins.[33] In the leukocytes of these patients, activation of multiple leukocyte integrins, including LFA-1 and VLA-4, by chemokine-triggered, G protein–coupled signals is genetically defective. Concurrent defects in platelet integrins lead to a bleeding diathesis. LAD III is caused by mutated Kindlin3, which is a major cytoplasmic activator of integrins.

Autoimmune or Inflammatory Diseases

Multiple Sclerosis

Migration of lymphocytes through the blood–brain barrier into the central nervous system (CNS) is a key pathogenic event that occurs during the development of multiple sclerosis (MS) and its widely used animal model, experimental allergic encephalomyelitis (EAE)[34] (Chapter 66). Under normal conditions, lymphocytes only patrol outside of the CNS parenchyma in the leptomeningeal and perivascular compartments. Naïve lymphocytes inefficiently bind to endothelial cells in meningeal microvessels without a rolling step using α_4 integrin and then extravasate through the fenestrated choroid vessels using P-selectin and CCR6. Upon inflammation, meningeal and choroid vessels become more adhesive, and the endothelial cells within the CNS parenchyma start to express ICAM-1 and VCAM-1. These alterations allow effector lymphocytes, which have primarily been activated in the cervical lymph nodes that ultimately drain the CNS-derived antigens, to penetrate the blood–brain barrier and enter the CNS parenchyma.

In vivo animal studies have shown that the disease course can be dramatically altered by blocking the function of leukocyte α_4 integrin.[34] This treatment is able to prevent the disease and even reverse the paralytic disease and lymphocytic infiltrations in the brain. Antibodies against $\alpha_4\beta_1$ integrin show this remarkable efficacy even if started a month after onset of the clinical disease. Certain EAE models can also be blocked by targeting the α_4 integrin ligand VCAM-1 or by blocking the function of CD44. In contrast, inhibition of many other adhesion molecules, such as L-selectin, PSGL-1, and E- and P-selectins, fails to yield a consistent effect on EAE. It should also be noted that although $\alpha_4\beta_1$ integrin is very important for lymphocyte homing to brain, it is not a brain-specific destination. It is also involved in leukocyte trafficking to other organs, such as the pancreas and the gut.

Inflammatory Bowel Diseases

As described above, effector lymphocytes activated in the inductive sites (Peyer's patches and mesenteric lymph node) of the intestine selectively migrate to the effector sites of the gut (mainly the lamina propria).[35] The key tissue-specific adhesion code for the intestinal entry is $\alpha_4\beta_7$ integrin on lymphocytes and its endothelial counterreceptor MAdCAM-1. Although the canonical CCR9-CCL25 interaction is important for attracting T and B lymphocytes to the small intestine, the critical chemotactic receptors for the entry into the large intestine are GPR15 (on T cells except for Tregs) and CCR10 (on plasmablasts).

In humans, the homing of regulatory T cells to the colon is GPR15 independent. This creates pathways by which the trafficking of proinflammatory versus antiinflammatory lymphocyte subtypes in the large bowel can be altered. In inflammatory bowel disease (IBD), the expression of MAdCAM-1 is upregulated in the vessels of lamina propria, together with other vascular adhesins, such as VCAM-1 and ICAM-1. Increased expression of CCL20 in the IBD mucosa enhances the recruitment of both T and B cells to the inflamed gut through ligation of CCR6. Successful pharmacological and genetic targeting of these key gut-selective lymphocyte trafficking alleviates inflammation in multiple animal models of IBD.

ON THE HORIZON

Adhesion Molecules as Targets for Novel Diagnostic and Therapeutic Agents

- Use of adhesion molecules as targets for the diagnosis of immune deficiencies, inflammatory disorders, and cancers.
- Use of adhesion molecules as targets for imaging inflammatory responses.
- Use of adhesion modulating therapies and other manipulations of lymphocyte trafficking, including small molecules, to treat infections, immune deficiencies, autoimmune disorders, transplant rejection, ischemia-reperfusion injuries, and cancers.

Cancer

Immunoevasion is one of the main hallmarks of cancer, and insufficient lymphocyte trafficking to solid tumors contributes to tumor progression. In the neoangiogenic vessels of tumors, immature and disorganized endothelial cells often express insufficient amounts of adhesion and attraction molecules.[36] Moreover, tumor-derived factors often render the local endothelial cells unresponsive to inflammatory cytokines. Nevertheless, chronic inflammation in tumors can induce the formation of HEV-like vessels, which show augmented expression of trafficking molecules.

Lymphocyte migration can be harnessed to improve the outcome of cellular immunotherapy for cancer.[36] Infusion of activated or genetically modified effector T cells, and cytotoxic CD8 T cells in particular, would benefit from a more effective targeting of the cells into the tumor. Homing of CAR-T cells to the tumors could be enhanced by transduction with adhesion molecules and chemokine receptors, possibly with simultaneous induction of tumor vessel normalization. However, anti-adhesive therapies targeting inappropriate accumulation of Tregs in the tumor would also enhance anti-cancer immune responses.

THERAPEUTIC PRINCIPLES

- Proadhesive strategies have been mainly developed using gene therapy.
- Inappropriate inflammation associated with many diseases can be dampened by antiadhesive therapeutics.
- Function blocking monoclonal antibodies (mAbs) are effective antiadhesive molecules.
- Cell migration can also be blocked by ligand and receptor analogues, small-molecule inhibitors, and genetic means (*e.g.,* RNA interference).

Adhesion Molecules as Diagnostic Targets

Immunodeficiency Disorders

In classic LAD I deficiency, a definitive diagnosis can be established by flow-cytometric analysis of immunofluorescent-stained CD18 integrin on blood leukocytes.[32] In individuals without the deficiency, practically all peripheral blood lymphocytes are CD18 positive. In severe cases of LAD I deficiency, there is a complete absence of this adhesion molecule, whereas in moderate deficiency about 1–10% of control levels is seen. LAD II can be diagnosed with commercially available antibodies by documenting a lack of fucosylated adhesion molecules (*e.g.,* abnormal expression of sLeX on blood leukocytes). Diagnosis of LAD III requires activation of cells, the use of monoclonal antibodies (mAbs) that recognize specific activation epitopes, or functional assays.

Soluble Adhesion Molecules

Most adhesion molecules are found in soluble forms in body fluids. They can be generated by alternative splicing of messenger RNA (mRNA) with deletion of transmembrane anchors, by proteolytic cleavage of cell-bound proteins by various sheddases (proteases), or by cleavage of the GPI linkage. Either of the soluble forms can function as molecular sinks, competing for their specific ligand(s) with the membrane-bound forms. Alternatively, they can trigger biological responses by interacting with their ligand-bearing cells.

The availability of commercial kits for measuring the levels of soluble adhesion molecules has led to numerous reports describing an increase or a decrease of certain adhesion molecules in different diseases. In most cases, there appears to be little or no additional diagnostic or predictive value derived from the use of these tests compared with more traditional parameters of inflammatory activity. Therefore at present, the indications for measurements of soluble adhesion molecules, or chemokines, in inflammatory diseases and cancers remain to be defined.

Imaging

The use of neutrophil scans or radioactively labeled nonspecific molecules to localize inflammatory foci is not satisfactory in terms of timing, expense, biohazards, specificity, or sensitivity. Hence, there have been trials to radioactively or nonradioactively label mAbs that recognize endothelial adhesion molecules, infuse them intravenously, and monitor their accumulation by appropriate imaging devices. Inflammation-inducible molecules, such as E-selectin and MAdCAM-1, have been used as target antigens. In the case of radioactively labeled E-selectin antibodies, the utility of this approach has been verified in patients.

CLINICAL PEARLS

- Blocking of α_4 integrin with natalizumab ameliorates disease activity in multiple sclerosis (MS) and in Crohn disease.
- Blocking of α_4/β_7 with vedolizumab is an effective treatment for inflammatory bowel disease (IBD).

Therapeutic Applications of Adhesion Modulating Therapies

Pro- and anti-adhesive therapies have long been an obvious pharmaceutical goal in the field of leukocyte trafficking. Inflammation-promoting strategies would be beneficial for treating many immune deficiencies, persistent infections, or cancers. Proadhesive control of lymphocyte traffic would benefit specific areas, such as vaccine development and bone marrow cell transplantation. In practice, lymphocyte recirculation routes are already being empirically exploited, for example, by varying the anatomical site (skin vs. intestine) of vaccination to optimize the immunization response. Anti-adhesive therapy, on the other hand, can be seen as a form of treatment applicable to all disease categories that involve an inflammatory component. In addition, it could provide novel precision drugs individually tailored for treating organ-specific inflammatory disorders, which would be predicted to diminish the problems of generalized immunosuppression.

Antibodies and Small-Molecular Drugs

A number of specific antagonists of adhesion molecules have been developed.[37] Function-blocking mAbs against adhesion molecules and chemokines have often been the drug candidates used for proof-of-principle experiments. In parallel, recombinant ligand or receptor analogs have been developed. Ultimately, knowledge of the structure of the adhesion molecules has allowed the design of rational, small-molecular drugs, such as those affecting the conformational state of leukocyte integrins. Possibilities to modulate mRNA expression of adhesion molecules through antisense oligonucleotides and RNA interference have added another potential tool to the pharmaceutical armamentarium.

Adhesion-Modulating Drugs in Clinical Use

Although all these forms of therapy have been enormously successful in a panoply of animal models, transfer to the clinic has been difficult. However, a small number of very potent drugs targeting adhesion molecules have been introduced.

The first two selective adhesion molecule (SAM) inhibitors were natalizumab and efalizumab. The way for natalizumab, a humanized anti-α_4 integrin antibody, was paved by the excellent results of α_4–blocking in EAE (see above). In patients with relapsing MS, a monthly intravenous injection of natalizumab leads to a significant reduction in the numbers of new lesions, numbers of relapses, and the risk of sustained disability.[34] The beneficial effects of natalizumab treatment are evident also in patients who do not respond to interferon- (IFN-β) therapy. Because natalizumab also inhibits $\alpha_4\beta_7$, the gut homing receptor, natalizumab also alleviates inflammation in the gut, and it has been shown to be effective in patients with Crohn disease.[35]

Efalizumab, a humanized, function-blocking antibody directed against CD11a, was the second antiintegrin antibody to enter clinical application. It showed good efficacy in patients with plaque psoriasis, but it was withdrawn from the market because of an increased risk of an opportunistic infection (see below).

The most recent clinically approved selective modulator of an adhesion molecule is vedolizumab.[35] It is a humanized mAb that binds to a combinatorial epitope in α_4/β_7 integrin but does not interact with α_4/β_1 and α_E/β_7 integrins. This makes vedolizumab a remarkably selective inhibitor of lymphocyte homing to the intestine. It has been approved for the treatment of both ulcerative colitis and Crohn disease. An mAb, etrolizumab, which targets the β_7 integrin (thus blocking both α_4/β_7 and α_E/β_7, but not α_4/β_1), which may induce remission in ulcerative colitis, and an anti-MAdCAM-1 antibody that appears to be effective in ulcerative colitis, but not in Crohn disease, are in early-phase clinical trials.[38]

The most feared adverse effect of natalizumab and efalizumab treatment is the possible reactivation of polyoma John Cunningham (JC) virus, which leads to the development of potentially fatal progressive multifocal leukoencephalopathy (PML).[39] Up to 1% of natalizumab-treated patients develop PML in the high-risk groups, and more than 700 cases of PML have been recorded among natalizumab-treated patients. However, the benefits of this therapy in MS still outweigh the risks. With good risk stratification and vigilance, the drug has maintained its status as a very effective biological treatment option for MS. Efalizumab, in contrast, was voluntarily withdrawn from the market in 2009 upon emergence of PML in the treated patients. Theoretically, α_4/β_7 blocking should not interfere with lymphocyte surveillance functions in the CNS, and in line with this, no PML cases have been reported among vedolizumab-treated patients. Mild adverse effects with SAM therapy include an expected increase in susceptibility to infections and injection site reactions. However, apart from the risk of PML with natalizumab, both natalizumab and vedolizumab seem to have a good overall safety profile.

Lymphocyte migration can also be targeted therapeutically by modulating lymphocyte exit from the lymph nodes.[40] Fingolimod/FTY720 causes S1P receptor internalization and degradation. Consequently, it is a functional antagonist of SIP receptors 1, 3, 4, and 5. It inhibits lymphocyte egress from the lymphoid organs. It may selectively retain CCR7-positive T cells, including central memory T cells, which may be particularly important for the pathogenesis of brain inflammation, while sparing CCR7-negative effector memory cells. It has been approved by the US Food and Drug Administration (FDA) as the first-line treatment for relapsing MS, and it is the first orally active disease-modifying drug for this immunological disease. More selective S1P receptor 1 antagonists, such as ozanimod, have shown preliminary efficacy in IBD. Although used in certain clinical indications, targeting of chemokine/chemokine receptors for manipulating lymphocyte migration has not yet proceeded to clinical applications.

MULTIPLE-CHOICE QUESTIONS

1. In the peripheral lymph nodes:
   A. All lymphocytes enter the tissue through high endothelial venules
   B. Activated B lymphocytes exit the tissue by migrating to the subcapsular sinus and afferent lymphatics
   C. Chemokines immobilized on the high endothelial venules are crucial for triggering firm adhesion of bloodborne lymphocytes
   D. Effector T lymphocytes are imprinted to home selectively to gut

2. During the multistep adhesion, cascade lymphocytes:
   A. Use integrins mainly for tethering
   B. Enter the spleen from the red pulp via capillary endothelium
   C. Solely transmigrate through the endothelial cell cytoplasm by a transcytotic process
   D. Mainly utilize selectins for the rolling step

3. Which one of the following therapies modulating lymphocyte traffic is not currently used in clinics?
   A. Functional antagonists of sphingosine 1 phosphate receptors in reducing lymphocyte traffic to brain in multiple sclerosis
   B. Agonists of L-selectin in enhancing lymphocyte homing to spleen in sepsis
   C. Function-blocking antibody against α in alleviating multiple sclerosis
   D. Function-blocking antibody against $\alpha_4\beta_7$ integrin in reducing intestinal homing in inflammatory bowel disease

T-Cell Activation and Tolerance

Erik J. Peterson, Jonathan S. Maltzman

Activation of T lymphocytes during an immune response triggers a series of programmed gene regulation, proliferation, differentiation, and effector functions. These T-cell functions coordinate with other leukocytes to permit the immune system to react against foreign antigens without initiating self-reactivity or autoimmunity. Each of these functions is fully dependent on environmental cues that are recognized by cell surface receptors and are then translated through biochemical alterations within the cell. This chapter discusses signal transduction through one of the most studied of these receptors, the antigen-specific T-cell receptor (TCR) complex. It addresses the mechanisms whereby signals propagated through the TCR combine with those from costimulatory receptors to produce either productive activation or immune tolerance. It also discusses how abnormal TCR signaling, and imbalanced signaling through costimulatory or coinhibitor molecules, can contribute to T-cell dysfunction and disease (Table 12.1). Targeting these molecular pathways has resulted in several clinically relevant drugs currently used to treat autoimmunity, transplant rejection, and cancer.

CLINICAL RELEVANCE

- Dysfunction or deficiency of T-cell signaling proteins (induced or spontaneous) has been causally linked to several disease states in animal or human models. Molecules wherein mutations may lead to immune deficiency or dysregulation include:
  - CD45
  - LCK
  - ZAP-70
  - SLP-76
  - LAT
  - IL-2R γ chain
  - Mst1
- Molecules wherein mutations may lead to lymphocyte hyperproliferation include:
  - CTLA-4
  - SHP-1
  - CD95/CD95 ligand
  - SAP
  - CBL/CBL-b
  - ZAP-70
  - LYP
  - DGK

THE T-CELL ANTIGEN RECEPTOR COMPLEX

The TCR complex consists of a ligand-binding TCR α/β or γ/δ heterodimer (Chapter 4) in association with the CD3/ζ chain complex, which provides transmembrane signal transduction capability.[1] Specificity of the TCR for antigen resides exclusively within the highly polymorphic, clonotypic, ligand-binding α/β or γ/δ heterodimers. Although many of the biochemical events leading to α/β and γ/δ T-cell activation are similar, α/β T cells exhibit a broader spectrum of antigen reactivity and are thought to participate in a wider range of specific immune responses. This chapter focuses on α/β T cells.

The α/β TCR specifically recognizes short peptide ligands bound to major histocompatibility complex (MHC) antigens (Chapter 5) on the surface of antigen-presenting cells (APCs) (Chapter 6). Coreceptor molecules expressed on subsets of α/β T cells determine whether the TCR recognizes class I or class II MHC. CD4 T cells are stimulated by processed exogenous antigen presented by class II MHC molecules on the surface of professional APCs. CD8 T cells respond to peptides synthesized by APCs and presented by class I molecules. CD4 and CD8 associate with MHC class II and class I molecules, respectively, to stabilize the tripartite interaction between the TCR, antigen, and MHC, which increases the effectiveness of TCR engagement.

Although the α/β chains of the TCR contain all of the information necessary for antigen/MHC binding, these proteins are not sufficient to initiate the intracellular biochemical events that signal antigen recognition. Instead, signal transduction is accomplished by noncovalently associated CD3 and TCRζ polypeptides, which include several pairs of transmembrane hetero- or homodimers (Fig. 12.1). Each CD3 and ζ chain derives signaling capacity from the presence of one or more cytoplasmic regions known as *immunoreceptor tyrosine-based activation motifs* (ITAMs).[2]

KEY CONCEPTS

Protein Tyrosine Kinase Activation

T-cell receptor engagement activates several families of protein tyrosine kinases, which are required for propagation of second messenger-instigated intracellular signaling:

- Src family: LCK, FYN
- Syk family: ZAP-70
- Tec family: ITK, RLK

Activation of Protein Tyrosine Kinases by the TCR and the Role of the ITAMs

Among the earliest of the biochemical events following engagement of the TCR is the activation of LCK and FYN, two members of the SRC family of protein tyrosine kinases (PTKs).[2] Along with all SRC family PTKs, LCK and FYN share features critical

TABLE 12.1 Phenotypes Associated With Deficient Function of Selected T-Cell Signaling Molecules

		PHENOTYPE	
Molecule	**Affected Signaling Event**	**Mouse**	**Human**
TCR Signaling			
CD3 γ	TCR expression	$B^{+}T^{+}NK^{+}$ SCID	$B^{+}T^{+}NK^{+}$ SCID
CD3 ε	TCR expression	$B^{+}T^{-}NK^{+}$ SCID	$B^{+}T^{+/-}NK^{+}$ SCID
CD3 δ	TCR expression	$B^{+}T^{-}NK^{+}$ SCID	$B^{+}T^{-}NK^{+}$ SCID
CD3 ζ	TCR expression, TCR-mediated PTK activation	$B^{+}T^{+}NK^{+}$ SCID	$B^{+}T^{+}NK^{+}$ SCID
ZAP-70	TCR-mediated PTK activation	$B^{+}T^{+/-}NK^{+}$ SCID. TCRαβ T cells are absent, but TCRγδ T cells survive. Arthritis occurs in some inbred strains	$B^{+}T^{+/-}NK^{+}$ SCID. CD8 T cell lymphopenia. Overexpressed in some hematological malignancies
LCK	TCR-mediated PTK activation	$B^{+}T^{+/-}NK^{+}$ SCID. Impaired thymopoiesis and proliferation	$B^{+}T^{+}NK^{+}$ SCID. CD4 lymphopenia, absent CD28 expression on CD8 T cells, and hypogammaglobulinemia
CD45	Maintenance of SRC family PTK in "open" conformation	$B^{+}T^{+/-}NK^{+}$ SCID. Impaired thymopoiesis	$B^{+}T^{+/-}NK^{+}$ SCID. Impaired thymopoiesis, decreased cytotoxic T-cell responses, progressive hypogammaglobulinemia, genetic polymorphisms may correlate with increased prevalence of autoimmune disease
SAP	SHP-2 binding to SLAM	Increased susceptibility to lymphocytic choriomeningitis virus, reduced IgE production, NKT cell deficiency	X-linked lymphoproliferative disease (XLP) with B-cell hyperresponsiveness, NKT cell deficiency
WASP	Actin polymerization	Decreased T-cell proliferation and interleukin-2 (IL-2) production	Wiscott-Aldrich syndrome (immunodeficiency, atopic dermatitis, thrombocytopenia, bloody diarrhea)
CBL/CBL-b*	E3 ubiquitin ligase. Recruitment of CrKL/C3G inhibitory complex	Hyperproliferative T cells*	Proto-oncogene for leukemia
LAT	Coupling PTK activation to downstream signals	$B^{+}T^{-}NK^{+}$ SCID. Absolute block in thymopoiesis	
SLP-76	Coupling PTK activation to downstream signals	$B^{+}T^{-}NK^{+}$ SCID. Absolute block in thymopoiesis. Defect in vascular/lymphatic development	
ITK/RLK	Amplification of proximal PTK signals. Activation of PLC-γ1	Defective Th2 immune responses	
CTLA-4	Inhibition of CD28-mediated costimulation	Fatal lymphoproliferative disease with myocarditis, pancreatitis	Allelic variants associated with autoimmunity, including Hashimoto thyroiditis, Graves disease, and systemic lupus erythematosus
SHP-1	Downregulation of PTK activity	Autoimmunity, inflammatory lung disease. "Moth-eaten" mice	
LYP (Lymphoid phosphatase; *PTPn22* gene product)	Attenuation of LCK activity	Augmented TCR-stimulated IL-2 production and proliferation	Allelic variants are associated with increased risk of rheumatoid arthritis, systemic lupus erythematosus, type 1 diabetes mellitus
DGKζ	Downregulation of DAG-dependent Ras activation	Impaired T-cell anergy induction	
Mst1 (STK4)	Suppression of Akt, phosphorylation of FoxO transcription factor	Inefficient thymic egress; impaired positive selection; impaired Treg development and function	Recurrent infections; progressive loss of peripheral CD4 T cells; autoimmune hemolytic anemia
IL-2R Signaling			
γc	Coupling IL-2 binding to JAK activation	$B^{+}T^{-}NK^{-}$ SCID	$B^{+}T^{-}NK^{-}$ SCID, X-linked SCID
JAK3	Phosphorylation of STAT proteins	$B^{+}T^{-}NK^{-}$ SCID	$B^{+}T^{-}NK^{-}$ SCID

γc, common γ-chain (IL2Rγ); IgE, immunoglobulin E; NK, natural killer; SCID, severe combined immunodeficiency; TCR, T-cell receptor.

*CBL and CBL-b are closely related; CBL-b-deficient mice develop autoimmune features and more severe lymphoproliferative disease compared with mice lacking CBL.

for their function (Fig. 12.2). These include an amino-terminal myristoylation sequence that directs membrane localization, a SRC homology 3 (SH3) domain that permits associations with other proteins containing regions rich in proline residues, a SRC homology 2 (SH2) domain that dictates interactions with proteins phosphorylated on tyrosine residues, a catalytic region, and a carboxyl-terminal tyrosine residue. The precise mechanism whereby LCK and FYN are stimulated by the TCR is not clear, but both have been shown to associate physically with TCR CD3 components and/or coreceptors CD4 and CD8.

SRC family PTK enzymatic function is regulated, in part, by the state of tyrosine phosphorylation of the kinase. When the

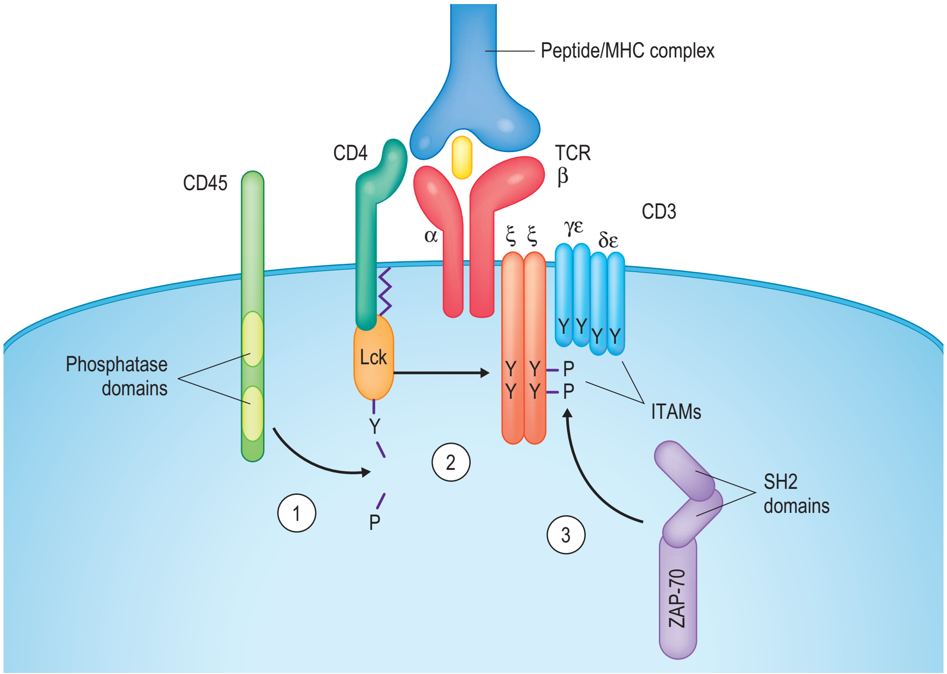

FIG 12.1 Biochemical Events in Early T-Cell Receptor (TCR) Signaling. The tyrosine phosphatase CD45 dephosphorylates the negative regulatory tyrosine residue on the CD4-associated protein tyrosine kinase (PTK) LCK, maintaining LCK in an activatable conformation (1). Engagement of the TCR α/β heterodimer and the CD4 (or CD8) coreceptors by major histocompatibility complex (MHC)–bound peptide antigen brings activated LCK into proximity with immunoreceptor tyrosine-based activation motif (ITAM)-bearing CD3 chains. LCK phosphorylates the CD3ζ chain within ITAMs (2). The phosphorylated CD3ζ-chain ITAMs interact with the tandem SH2 domains of the cytoplasmic PTK ZAP-70 (3), permitting activation of ZAP-70 and phosphorylation of downstream substrates.

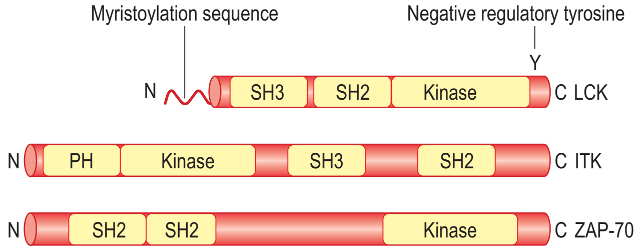

FIG 12.2 Domain Organization of T-Cell Receptor (TCR)-Stimulated Protein Tyrosine Kinases (PTKs). Comparative schematic representation of members of three families of PTKs required for T cell-activating signals. In addition to catalytic domains, LCK (SRC family), ITK (TEC family), and ZAP-70 (SYK family) each contain regions responsible for mediating protein–protein interactions, including SH3 and SH2 domains. SH3, Src homology 3; SH2, Src homology 2; PH, pleckstrin homology.

conserved carboxyl-terminal tyrosine residue is phosphorylated, SRC family PTKs adopt a "closed" conformation that is the product of an intramolecular interaction between that phosphotyrosine and the SH2 domain (Fig. 12.3). This intramolecular interaction inhibits the enzymatic activity of the PTK, limiting subsequent tyrosine phosphorylation–dependent signaling events. Phosphorylation of the carboxyl-terminal tyrosine (Y505 in LCK and Y527 in FYN) is dynamically regulated.[3] Phosphate is transferred to this residue by the cytoplasmic PTK CSK and is removed by the transmembrane protein tyrosine phosphatase CD45.

Phenotypes of CD45-deficient cells in mice and humans highlight the critical regulatory importance of the carboxyl-terminal tyrosine in SRC family PTKs.[4] TCR signal transduction in cell lines lacking CD45 is blocked at the most proximal step, and mice that have been genetically modified to lack CD45 expression exhibit profound defects in thymocyte development and subsequent T-cell activation. CD45 deficiency in humans results in a T^-, B^+, NK^+ severe combined immunodeficiency (SCID) (Chapter 35). These outcomes correlate with markedly impaired LCK enzymatic activity and hyperphosphorylation of Y505, the regulatory tyrosine.

Following TCR engagement and PTK activation, numerous cellular substrates become tyrosine-phosphorylated, including the CD3 and ζ-chain ITAMs (see Fig. 12.1). In resting T cells, key tyrosine residues within the ITAMs are embedded within the hydrophobic core of the plasma membrane lipid bilayer. Upon TCR triggering, conformational changes induced within the CD3 cytoplasmic tails result in enhanced tyrosine accessibility to the action of SRC family kinases.[2] ITAM phosphorylation creates a docking site for another cytosolic PTK, ζ-associated phosphoprotein of 70 kilodaltons (kDa) (ZAP-70). ZAP-70, a member of the SYK family PTKs, contains a catalytic domain that is located carboxyl-terminal to two tandem SH2 domains (see Fig. 12.2). The ZAP-70 SH2 domains have affinity for

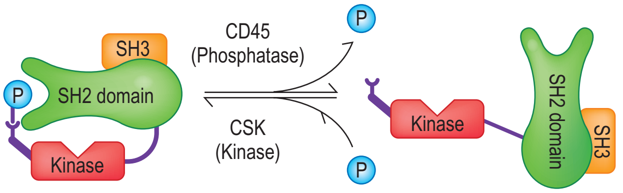

FIG 12.3 Model for Dynamic Regulation of LCK by Intramolecular Interaction Between an SH2 Domain and Phosphotyrosine. The transmembrane phosphatase CD45 dephosphorylates tyrosine 505 in the carboxyl-terminus of the SRC family protein tyrosine kinase (PTK) LCK. CD45 activity maintains LCK in an "open" conformation, permitting LCK kinase domain access to intracellular substrates. CSK activity opposes that of CD45; phosphorylation of tyrosine 505 results in an intramolecular interaction between the SH2 domain and phosphotyrosine. Inhibition of LCK kinase activity correlates with the "closed" conformation *(left).*

phosphotyrosine present within ITAMs. Thus inducible phosphorylation of the CD3 and ζ-chain ITAMs results in the formation of docking sites that mediate recruitment of ZAP-70. Upon recruitment to TCR, ZAP-70 enzymatic activity is increased as a result of phosphorylation by LCK as well as autophosphorylation. The net result of these phosphorylations is conversion of the TCR from an enzymatically inactive ligand-binding complex to a potent PTK.

LCK, FYN, and ZAP-70 are critically important for both thymocyte development and mature T-cell activation. Jurkat T cells (a human leukemic cell line) deficient in expression of either LCK or ZAP-70 cannot be activated via the TCR. Mice deficient in Zap-70 or Lck, but not in Fyn, exhibit a significant yet incomplete block in early T-cell development. The pre-TCR (a complex present on immature thymocytes that includes signaling components thought to be similar to the TCR on mature T cells) appears to require Src and Syk family PTKs to transduce signals. ZAP-70 deficiency and abnormal LCK function in humans create a T^-, B^+, NK^+ SCID.[5]

In addition to SRC and SYK family PTKs, TCR engagement results in the activation of a third family of cytosolic PTKs, the Tec family, which includes TEC, ITK, and RLK.[6] Tec PTKs contain SH2, SH3, and catalytic domains, as well as pleckstrin homology (PH) domains that mediate interactions with membrane-localized phospholipids (see Fig. 12.2). PH domains permit recruitment of Tec family kinases to the plasma membrane, where they can phosphorylate important substrates. Activation of Tec family members is dependent on the prior activation of SRC and SYK family PTKs. ITK positively regulates antigen receptor signaling through recruitment and activation of the lipid modulator PLCγ to a "signalosome" nucleated by the cytoplasmic adaptor protein SLP-76 (see below). The importance of normal ITK signaling was recently shown in humans, where homozygous mutation led to immunodeficiency resulting in death from Epstein-Barr virus (EBV)–associated lymphoproliferation.

Tec family kinases are thought to modulate TCR signal strength. Mice deficient in Tec kinases display variable partial defects in thymocyte development and peripheral T-cell maturation. T cells deficient in Tec PTKs display alterations in actin polymerization and cytoskeletal polarization, which promote recruitment of adhesion-related proteins, including β_2 integrins and signaling mediators, such as Vav, to membrane regions important for propagating activation signals. The importance of normal ITK signaling was recently shown in humans, where homozygous mutation led to immunodeficiency resulting in death from EBV-associated lymphoproliferation.

KEY CONCEPTS

TCR Signaling Pathways

T-cell receptor engagement leads to the initiation of signaling cascades, including:
- PLCγ1 activation
  - Calcium flux
  - DAG formation
- RAS/MAPK
- NF- κB
- PI3K

Second Messenger Cascades Downstream of the TCR-Stimulated PTKs

TCR engagement incurs numerous biochemical changes that are dependent on the activation of ZAP-70 and its association with the CD3 and ζ-chain ITAMs. One intermediate event in TCR signaling is activation of the membrane-associated enzyme phospholipase Cγ1 (PLCγ1) (Fig. 12.4).[7] PLCγ1 is phosphorylated by multiple TCR-dependent PTKs, including both ZAP-70 and members of the Tec family. TCR-stimulated tyrosine phosphorylation alone is not sufficient to activate PLCγ1; relocalization of the enzyme into adaptor-protein nucleated complexes probably plays a critical role.

Activated PLCγ1 catalyzes the hydrolysis of phosphatidylinositol-4,5-bisphosphate (PIP2), a minor plasma membrane phospholipid. PIP_2 hydrolysis gives rise to two second messengers, the soluble sugar inositol 1,4,5-trisphosphate (IP_3) and the lipid diacylglycerol (DAG). IP_3 binding to a cognate receptor on endoplasmic reticulum (ER) results in the release of calcium from this organelle. Consequent IP_3-mediated reductions in calcium ER concentrations are sensed by STIM1, an EF-hand domain–containing protein localized in the ER membrane.[8] In turn, STIM1 aggregation activates store-operated calcium entry channels, including the transmembrane protein ORAI. Marked calcium influx from the extracellular milieu attends calcium channel activation. Intracellular calcium serves as a second messenger that activates calcineurin, a serine/threonine phosphatase. Substrates of calcineurin include members of the nuclear factor of activated T cells (NFATs) family. In resting T cells, NFAT proteins are phosphorylated and reside in the cytosol. Activated calcineurin dephosphorylates NFAT, allowing it to translocate to the nucleus and bind the response elements in the promoters of genes important for T-cell activation.

Knowledge of the calcineurin pathway has been exploited clinically. The compounds cyclosporine and tacrolimus are mainstays in the prevention of human solid-organ transplant rejection (Chapter 81) and are also used, albeit not commonly, to treat T cell–driven autoimmune diseases (Chapter 87). Both cyclosporine and tacrolimus interfere with calcineurin-dependent T-cell activation, but via distinct mechanisms.

The other major product of PIP_2 hydrolysis, DAG, functions as second messenger to a parallel cascade of TCR signaling intermediates, including protein kinase D (PKD), Ras guanyl nucleotide releasing proteins (RasGRPs), and members of the protein kinase C (PKC) family of serine/threonine kinases.[9] PKD cooperates with PKC-dependent signals to activate high-affinity

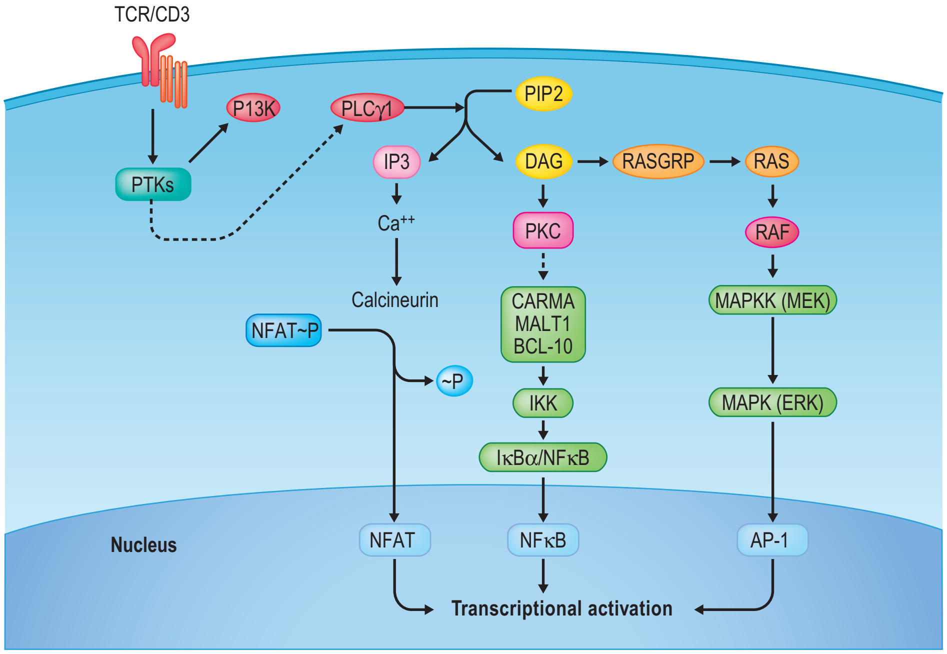

FIG 12.4 Signaling Pathways Activated by T-Cell Receptor (TCR) Engagement. TCR ligation results in activation of protein tyrosine kinases (PTKs), such as LCK and ZAP-70. Phospholipase Cγ1 (PLCγ1) becomes phosphorylated and activated by PTKs, including ITK. Hydrolysis of phosphatidyl inositol bisphosphate (PIP_2) by PLCγ1 releases diacylglycerol (DAG) and inositol trisphosphate (IP_3). IP_3 stimulates an increase in intracellular calcium concentration, which activates the phosphatase calcineurin. Calcineurin dephosphorylates NFAT, thereby signaling NFAT translocation to the nucleus. The formation of DAG leads to activation of RAS-GRP1 GEF activity and RAS activation. Active RAS binds and stimulates the kinase RAF1, initiating a cascade of serine/threonine kinases (MAPK cascade) leading to phosphorylation and nuclear translocation of the ERK kinases. DAG formation also results in activation of the CARMA/BCL-1/MALT1 complex leading to phosphorylation of IκB kinase (IKK). Active IKK phosphorylates IκB-α, leading to IκB-α degradation and release of NF-κB to the nucleus. TCR-activated PI3K catalyzes formation of PIP3 from membrane-associated PIP_2; the phosphatase PTEN antagonizes PIP_3 formation. PIP_3 binds to the Akt lipid-binding pleckstrin homology domain, a required element in Akt activation. Active Akt both promotes the PKC-CARMA-NFκB pathway and blocks FoxO-dependent transcriptional regulation. Transcription factors NFAT, NFκB, and those activated by the MAPK pathway cooperate to upregulate transcription of genes, such as *IL-2,* critical for T-cell activation.

binding capacity and clustering of integrins, a family of molecules that mediate TCR signal-augmented cell binding to adhesion molecules on APCs.[10] RasGRP mediates activation of the Ras cascade. Deletion of RasGRP1 leads to severe defects in thymocyte development in mice, highlighting the importance of the RasGRP pathway in TCR signaling. PKC is essential for full activation of the Ras/ERK and NF-κB cascades (see below) that are required to mount a TCR-stimulated gene transcriptional program and drive cellular activation.

In T lymphocytes, RasGRP1 is one of two distinct guanine exchange factors (GEFs) that mediate exchange of guanosine triphosphate (GTP) for guanosine diphosphate (GDP) bound to RAS.[11] The other, parallel-acting factor, Son of Sevenless (SOS), is recruited to the plasma membrane through its interaction with the GRB2 adaptor protein. Activation via the GRB2-SOS pathway acts as a digital “on–off” switch, whereas RasGRP1-mediated activation can be envisioned as an analog rheostat, leading to varying degrees of downstream signal, depending on the strength of upstream stimulus.[11] RAS activity is tightly regulated. RAS activity may be curbed through the hydrolysis of RAS-bound GTP to GDP, either through the intrinsic guanosine triphosphatase (GTPase) activity of RAS or through the recruitment of GTPase-activating proteins (GAPs) to the active RAS molecule.

Active RAS recruits the serine-threonine kinase RAF to the plasma membrane, initiating a phosphorylation cascade. Active RAF, in turn, phosphorylates MEK, which phosphorylates extracellular signal-regulated kinase (ERK), which undergoes nuclear translocation. Upon entry into the nucleus, ERK can phosphorylate and activate several transcription factors that are critical for TCR-induced transactivation of cytokines and other activation genes. Studies in cell lines and in genetically altered mice attest to the central importance of RAS activation for T-cell function. Jurkat T cells expressing inhibitory mutant forms of RAS fail to produce interleukin-2 (IL-2) following TCR engagement. In contrast, Jurkat cells expressing an activated form of RAS produce IL-2 much more readily than do wild-type cells. Similarly, mice transgenic for activating Ras mutants show alterations in thymocyte development and demonstrate a partially stimulated state in the absence of antigen binding.

TCR stimulation also triggers a cascade headed by phosphatidylinositol 3′-hydroxyl kinase (PI3K) (see Fig. 12.4).[12] PI3Ks are composed of two noncovalently bound subunits; the p85 regulatory subunit activates the kinase activity of the p110 catalytic subunit. PI3K phosphorylates phosphoinositides, which play an important role in the regulation of several downstream serine/threonine kinases, including protein kinase B (PKB) (Akt). One central function of Akt is promotion of the NFκB pathway downstream of PLCγ1- and DAG-driven PKC. Although TCR engagement alone can stimulate some degree of PI3K function, full activity of the lipid kinase requires costimulation of the T cell through receptors, such as CD28 (see below). The outcomes of PI3K and Akt signaling play essential diverse roles in T-cell development, differentiation, and effector function, most of which maximize effector T-cell activation responses. These include suppressing the induction of Foxp3-expressing regulatory T cells (Tregs); suppressing expression of proapoptotic molecules, including Bim or Bad, and of cell cycle inhibitors; and promoting T-cell survival via metabolic processes, including glucose uptake and glycolysis. The importance of this pathway is suggested by the efficacy of PI3K inhibitors in animal models of T cell–driven autoimmunity and in current clinical trials in human hematologic malignancies.[13]

TCR cross-linking also leads to activation of the serine-threonine kinase PKC-θ. PKC activation ultimately engenders nuclear translocation of members of the nuclear factor-κB (NFκB) family of transcription factors (see Fig. 12.4).[14] In the basal state, NFκB family members are sequestered in the T-cell cytoplasm through interaction with inhibitors of NFκB (IκB). TCR stimulation results in the formation of a multimolecular activating complex composed of CARMA1, BCL-10, and MALT1 (CBM). The assembly of the complex lies upstream of signals leading to activation of IκB kinases (IKKs), which phosphorylate and degrade IκB. Transient IκB degradation frees NFκB for translocation to the nucleus. Defects in T-cell activation and survival result from deficiencies in CBM proteins.

INTEGRATION OF SECOND-MESSENGER PATHWAYS BY ADAPTOR PROTEINS

Identification and characterization of adapter proteins has provided insight into how intracellular signaling pathways are initiated by TCR cross-linking.[15,16] Adaptors lack enzymatic or transcriptional regulatory activity. Instead, they possess modular domains responsible for subcellular relocalization and intermolecular interactions. Both constitutive and induced intermolecular interactions mediated by adaptor molecules can promote TCR signal transduction.

Adaptor proteins commonly contain modular domains that exhibit affinity for phosphorylated tyrosine residues (Fig. 12.5A). Such regions include the SH2 and phosphotyrosine-binding (PTB) domains, which recognize phosphorylated tyrosine residues within particular sequence contexts. PTB domains obtain their specificity based on residues amino-terminal to the key phosphotyrosine, whereas SH2 domains recognize sequence motifs carboxyl-terminal to phosphotyrosine. Other adaptor domains include SH3 modules, which bind proline-rich regions, WW regions responsible for interactions with proline/tyrosine or proline/leucine motifs, and PH domains that have specificity for phospholipids.

Several hematopoietic-specific adaptors play essential roles in T-cell development, in coordinating the signals necessary for mature T-cell activation, and in the process of terminating T-cell responses. Two examples are linker of activated T cells (LAT) and SH2 domain-containing leukocyte phosphoprotein of 76 kDa (SLP-76). Both LAT and SLP-76 were identified during efforts to characterize the substrates of the PTKs stimulated by TCR engagement.

LAT is a 36-kDa integral membrane protein that contains numerous tyrosine residues within its cytoplasmic tail (see Fig. 12.5A).[16] Tyrosines exist within specific sequence motifs needed to bind the SH2 domains of other T-cell signaling molecules. In stimulated T cells, LAT inducibly associates with the SH2 domains of GRB2, GADS (Grb2 family member), PLCγ1, and the regulatory (p85) subunit of PI3K. It is likely that these induced intermolecular interactions are critical for communicating TCR engagement to downstream second-messenger cascades. The importance of LAT for T-cell activation was suggested by the signaling phenotype of LAT-deficient variants of the Jurkat T-cell leukemic line. Engagement of the TCR on these cells fails to result in signaling events downstream of ZAP-70 activation. Furthermore, Lat plays an essential role in T-cell development, as Lat-deficient mice have significantly decreased numbers of thymocytes. Thymocytes that remain in $Lat^{-/-}$ mice are arrested at an early stage of development and cannot give rise to any peripheral T cells.

Using similar approaches, it was shown that the adapter SLP-76 is absolutely required for both T-cell development and signaling via the mature TCR.[7] SLP-76 contains an amino-terminal region with tyrosine phosphorylation sites, a central proline-rich domain, and a carboxyl-terminal SH2 domain. Unlike LAT, SLP-76 does not possess a transmembrane domain. By means of its proline-rich region, SLP-76 constitutively associates with the adaptor GADS. Through its SH2 domain, SLP-76 can inducibly interact with other tyrosine-phosphorylated adaptors, such as HPK-1 and ADAP. Following tyrosine phosphorylation, SLP-76 inducibly binds other SH2-domain-containing proteins (*e.g.,* VAV, an exchange factor for the RAC GTP-binding protein; NCK, an adaptor protein; and the Tec family kinase ITK). In mutant T-cell lines lacking SLP-76, the PLCγ1 and RAS/MAPK signaling cascades are not activated by TCR ligation, despite normal TCR-stimulated activation of Zap-70. Mice deficient in SLP-76 show a complete block in early thymocyte development. Each of the SLP-76 domains appears critical for its function, as the overexpression of mutant variants of SLP-76 is unable to restore TCR signaling efficiency fully in either Jurkat T cells or SLP-76-deficient mice.

One model for how SLP-76 and LAT functionally interact holds that each contributes multiple molecular interactions to a larger “signalosome” complex at the plasma membrane (see Fig. 12.5B).[16] Following TCR engagement, the two adaptors associate with each other, bridged by GADS and PLCγ1. Formation of this complex brings Itk into proximity of PLCγ1, resulting in its phosphorylation and activation and leading to the generation of IP3 and DAG, as described above.

Other adapter proteins play important roles in restraining TCR-mediated signal transduction events, frequently by dictating subcellular localization of regulatory enzymes. For example, in the absence of TCR stimulation, the transmembrane adaptor PAG binds to the cytoplasmic PTK CSK, bringing it to the plasma membrane.[17] Membrane-localized CSK phosphorylates the regulatory tyrosine of LCK, thus keeping LCK inactive in resting T cells.

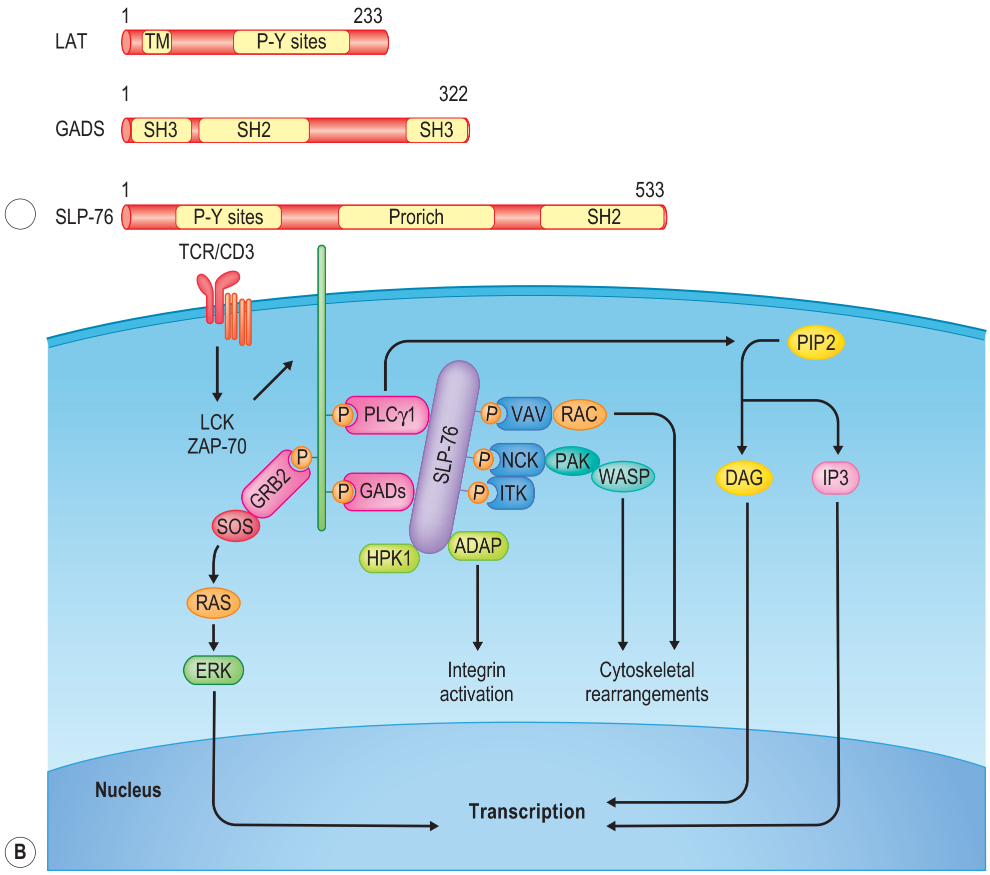

FIG 12.5 Model for Adaptor Protein-Mediated Coupling of the T-Cell Receptor (TCR) to Phospholipase Cγ1 (PLCγ1) Activation. (A) Structural schematics of three adaptors implicated in plasma membrane proximal biochemical events. SH3 domains mediate association with proline-rich regions; SH2 domains associate with phosphorylated tyrosine residues. (B) LAT and SLP-76 are among the substrates of the TCR-activated protein tyrosine kinases (PTKs). When tyrosine residues within the LAT cytoplasmic tail are phosphorylated, GADS binds to LAT through the GADS SH2 domain. Recruitment of GADS results in relocalization of SLP-76, as the proline-rich region of SLP-76 mediates constitutive association with the SH3 domain of GADS. Tyrosine-phosphorylated SLP-76, in turn, becomes associated with ITK via the ITK SH2 domain. ITK is thus brought into proximity with membrane-localized substrates, including PLCγ1. Activation of PLCγ1 leads to hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2) and activation of transcription factors, such as nuclear factor-κB (NFκB), activating protein 1 (AP-1), and nuclear factor of activated T cells (NFAT). SH2 domain containing leukocyte phosphoprotein of 76 kDa (SLP-76) also recruits several other signaling molecules, such as VAV, NCK, HPK1, and ADAP, thereby regulating changes in the actin cytoskeleton and adhesion. Phosphorylation of linker of activated T cells (LAT) also leads to recruitment of Grb2/SOS and an additional pathway for RAS activation. TM, transmembrane domain; P-Y, sites for phosphorylation of tyrosine; pro-rich, proline-rich regions.

Coreceptors Transduce Signals That Are Integrated With TCR Signals

T-cell proliferation and the initiation of effector function require that the T cell must receive signals in addition to the TCR via other cell surface receptors.[18] This requirement for multiple signals allows the T cell to be extremely sensitive to TCR binding while protecting against the inappropriate activation of potentially dangerous effector cells. Because T cells respond to antigens presented on APCs, stimulation under physiological conditions involves the potential engagement of multiple coreceptors on the T cell by cognate ligands on the APCs. Some coreceptors may function to increase the avidity of T cells for interacting APCs. However, many coreceptors exhibit intrinsic signal-transducing capacity. Some signal independently of the TCR; others intersect with TCR-driven signaling machinery. Additionally, coreceptors may function as recruiters of cytoplasmic signaling molecules, including adaptor proteins, as described above.

The most intensively studied coreceptors are CD4 and CD8 (Chapter 4). CD4 or CD8 expression on peripheral T cells define subsets that respond to MHC class II- or class I-bound peptide antigens, respectively (Chapter 6). Either CD4 or CD8 can contribute to enhanced TCR signal strength because they each associate with LCK.[19] This constitutive interaction, which occurs via specific residues within the CD4 and CD8 cytoplasmic domains, localizes a key effector enzyme to the TCR complex.

Counterbalanced Costimulatory and Coinhibitory Signals Determine T-Cell Response Thresholds

As stated earlier, productive T-cell stimulation results from a composite of TCR cross-linking and costimulatory signals. Non-TCR activating signals are transduced via a functional family of T-cell coreceptor proteins termed *costimulatory molecules.* An additional array of coreceptors termed *coinhibitors* serve to dampen or restrict potential for TCR-induced cellular activation and balance the stimulation-promoting effects of costimulatory molecules. Although functionally divergent, costimulatory and coinhibitory molecules share structural features, such as immunoglobulin (Ig)–like extracellular domains. Key costimulatory receptors possessing Ig-like domains include CD28 and ICOS (inducible costimulator); coinhibitory counterparts include CTLA-4 (cytotoxic T lymphocyte antigen-4), PD-1 (programmed death 1), and BTLA (B- and T-lymphocyte attenuator).[20] Increased understanding of both activation-promoting and activation-restraining coreceptors has recently been exploited to substantial effect in management of human autoimmune and malignant diseases.

The best-characterized T-cell costimulatory molecule is CD28, a constitutively expressed homodimeric transmembrane glycoprotein.[18,20] CD28 binds to two ligands expressed on APCs: B7.1 (CD80) and B7.2 (CD86). Ligation of CD28 in isolation has little effect on T-cell activation; however, when CD28 is engaged along with the TCR, many TCR signals are augmented. Indeed, concomitant CD28 and TCR engagement is required for activation of naïve T cells.

CD28 ligation engages several signal transduction pathways implicated in T-cell activation. CD28 contains no intrinsic enzymatic activity, but tyrosine residues within its cytoplasmic tail become inducibly phosphorylated during T-cell activation. These phosphorylated tyrosines recruit several signal-transducing molecules possessing SH2 domains, including GRB2 and the regulatory p85 subunit of PI3K. TCR- and CD28-dependent coactivation of PI3K leads to transactivation of the prosurvival genes *BCL-2* and *BCL-XL.* Via GRB2 association, CD28 engages an NF-κB-dependent survival program dependent on PKCθ and the GEF VAV1. CD28-driven activation of the GTP-binding protein RAS-related C3 botulinum toxin substrate 1 (RAC1) is crucial for the protein kinase activity of c-JUN N-terminal kinase (JNK), which, in turn, plays an important role in CD28-dependent T-cell cytokine production and apoptosis resistance.

Costimulation with CD28 agonists dramatically augments TCR-driven IL-2 production, both by increasing transcription of the *IL-2* gene and by stabilizing its messenger RNA (mRNA).[21,22] Notably, if the TCR is engaged in the absence of CD28 costimulation, activation does not occur. Rather, isolated TCR engagement leads either to T-cell death by apoptosis (Chapter 13) or to a state of unresponsiveness known as *anergy* (see below). CD28 is required not only for T-cell priming during infection but is also important for protective secondary T-cell responses during microbial challenge.[23] Significant nonredundant roles for CD28 have also recently been described in the Treg subset of CD4 T cells. In animals lacking CD28 specifically in Treg, splenomegaly, lung inflammation, and accumulation of activated CD4 T cells occur.[24] These findings suggest that the survival- and activation-promoting function of CD28 costimulation is important for balanced homeostasis of Treg and effector CD4 T-cell subsets. On balance, inhibition of CD28 ligation by CD80/CD86 results in decreased immune responses. Blockade of CD28 costimulation using CTLA4-Ig fusion proteins (abatacept; belatacept) can significantly ameliorate synovial inflammation in rheumatoid arthritis and restrain lymphocyte-driven rejection responses in transplanted kidneys, respectively.

Another Ig domain-containing costimulatory molecule, ICOS is induced on the T-cell surface following combined TCR and CD28 stimulation.[18] ICOS interaction with APC-expressed ICOS-L is required for development of T-follicular helper (Tfh) cells, a subset of CD4 cells required for germinal center formation and B-cell antibody class switching. In murine models of rheumatoid arthritis and multiple sclerosis, ICOS antibody blockade results in reduced Tfh and germinal center formation, associated with suppression of autoimmune responses. ICOS deficiency associates with human common variable immune deficiency (CVID) (Chapter 34), further suggesting that ICOS plays an important role promoting T-cell dependent humoral immunity.

The CTLA4 coinhibitory molecule shares at least two features with CD28: membership in the Ig domain–containing superfamily; and high-affinity binding capacity for APC-expressed ligands CD80 and CD86. Unlike CD28, CTLA4 expression is inducible in conventional CD4 T cells. However, CTLA4 is present constitutively on Treg cells. Experimental data support both T cell–intrinsic and cell-extrinsic mechanisms by which CTLA4 can limit immune responses. Ligation of CTLA4 induces a biochemical cascade, including the activation of PP2A and SHP-2 phosphatases.[24] In conventional T cells, CTLA4 functions to antagonize the TCR “stop signal,” whereby T cells are induced to pause and maintain lengthy physical contact with antigen-bearing dendritic cells (DCs).[18] Moreover, using a CTLA4-dependent process, Treg are thought to limit access of conventional T cells to CD80/CD86 by downregulating these ligands on APCs. Monoclonal, antagonist anti-CTLA4 antibodies have been employed in patients with cancer an attempt to release the CTLA4-driven “negative checkpoint” on T-cell function thought to be impairing natural antitumor T-cell responses. A CTLA4 antagonist was approved by the US Food and Drug Administration (FDA) in 2011; its use has resulted in sometimes dramatic tumor regression and durable remissions in patients with advanced metastatic melanoma and other malignancies.

Like CTLA4, the coinhibitor PD-1 is an Ig domain-containing surface receptor negative regulator of T-cell activation, likely through attenuation of TCR-driven PI3K and Akt. Ligation of PD-1 by cognate ligand PDL-1 (also known as B7-H1) results in recruitment of phosphatases, such as SHP2, to motifs within the PD-1 cytoplasmic tail. Phosphatase-associated PD-1 interacts with TCR microclusters, resulting in dephosphorylation of apical TCR signaling mediators, including ZAP-70 and CD3ζ, thus dampening TCR signal strength. At a cellular level, PD-1 enforces T-cell unresponsiveness by inhibiting TCR-mediated “stop signals” that promote stable, prolonged contact between T cells and APCs. Disruption of PD-1 in mice results in autoantibody formation and glomerulonephritis. In chronic viral infections, CD8 T cells display a hyporesponsive “exhausted” phenotype associated with elevated surface expression of PD-1.[26]

Antibody blockade of PD-1/PDL-1 interactions results in restoration of effector functions in exhausted T cells, suggesting that PD-1 manipulation could benefit patients with viral infections. However, the therapeutic potential of PD-1 has been most dramatically realized in the field of tumor immunotherapy.[27] In many malignancies, both CD4 and CD8 T cells accumulate within the tumor stroma. Tumor-infiltrating lymphocytes (TILs) are characterized by high expression of PD-1 and other coinhibitory molecules; tumor-expressed ligands for these molecules are thought to enforce a state of reduced cytolytic or cytokine-secreting functions. Monoclonal anti-PD1 and anti-PDL1 antagonist antibodies have recently been employed in an attempt to reinvigorate TIL antitumor capacity. PD1/PDL1 blockade has sometimes resulted in dramatic tumor regressions and responses, in responses of diverse tumors ranging from metastatic melanoma to non–small cell lung carcinoma, to lymphoma. Other T-cell coinhibitors, including Lag3 and BTLA, remain under active investigation as potential therapeutic targets.[27]

A second large class of costimulatory molecules includes members of the tumor necrosis factor receptor (TNFR) family.[18] Costimulatory TNFR family members include OX40 (CD134), 4-1BB (CD137), herpesvirus entry mediator (HVEM), CD30, and glucocorticoid-induced TNF receptor (GITR). Cytoplasmic domains within these type I transmembrane proteins contain sequences that recruit a family of adaptor molecules known as TNF receptor–associated factors (TRAFs). Antigen receptor costimulation functions for both CD4 and CD8 T cells have been described for each member of this family. With regard to positive regulation of T-cell signaling, a well-characterized member of this group is OX40.[28] OX40 is upregulated on activated CD4 T cells after CD3/CD28 stimulation. Trimerization of OX40 induced by engagement of APC-expressed OX40L leads to recruitment of TRAF2, TRAF3, and TRAF5. TRAF complexes control activation of a survival-enhancing NF-κB pathway. OX40 deficiency leads to defects in CD4 T cell proliferation, reduced survival of effector memory T cells, and impaired formation of effective responses to secondary T-cell stimulation with antigen. Antibody-mediated blockade of OX40-OX40L results in reduced induction of experimental autoimmune encephalitis (EAE) and collagen-induced arthritis.

Knowledge of basic signaling components utilized by TCR and costimulatory molecules has been exploited in the generation of chimeric antigen receptors (CARs). These engineered molecules possess an antigen-specific extracellular region (often a single-chain variable fragment), a transmembrane domain, and cytosolic signaling machinery from CD3 ζ-chain fused to a region from a costimulatory molecule (*e.g.,* CD28, OX40, 4-1BB) cytosolic region. Cross-linking of these CARs thus may provide both signal 1 (TCR) and signal 2 (costimulation). T cells modified to express CD19-specific CARs have recently been successful in treating B-cell malignancies and are being developed for use in other malignancies.

Spatial and Temporal Distribution of TCR Signaling Proteins

Recent methodological advances in live cell imaging and engineering of lipid bilayers that mimic physiological antigen-presenting surfaces have permitted exciting insights into the temporal–spatial relationships between signaling molecules. Following TCR engagement, a highly organized interface termed the *immunological synapse* (IS) forms between the T cell and the APC (Chapter 6). Within the IS, a number of transmembrane and cytoplasmic proteins are coordinately polarized and form a structure called the *supramolecular activation cluster* (SMAC).[29] The SMAC is composed of concentric rings with a central region (cSMAC) enriched in TCR and CD3/ζ. The more peripheral ring (pSMAC) is enriched for the integrin leukocyte function–associated antigen-1 (LFA-1). Inhibitory signaling molecules, such as the transmembrane phosphatase CD45, are excluded from the SMAC. These observations initially suggested that formation of the SMAC is required for signal initiation. The subsequent finding of a paucity of active signaling molecules located in the SMAC has led to alternative models in which the SMAC is involved in directed cytokine secretion or in signal termination.

Efficient formation of the T cell IS is heavily dependent on nucleation-promoting factors, such as Wiskott-Aldrich syndrome protein (WASP), which promotes reorganization of the actin cytoskeleton.[29] Complexes composed of TCR, active kinases, and adaptor molecules, termed *microclusters,* form at the immune synapse within seconds following TCR engagement.[30] TCR microclusters are dynamically regulated in space and time. Within 2 to 3 minutes of formation, microclusters migrate along polymerized actin from the periphery to the center of the IS, where dephosphorylation and dissociation of the components occur. Sustained TCR signaling depends on constant re-formation of microclusters containing SLP-76 and ZAP-70 at the periphery of the central zone. Costimulatory signals generated by CD28 or the integrin very late antigen-4 (VLA-4) can alter the dynamics of microcluster formation and movement and enhance T-cell activation. The functions of either the SMAC or the microclusters in TCR signal initiation and termination remain incompletely understood.

KEY CONCEPTS

Mechanisms of Tolerance: Central and Peripheral

- Central
  - Clonal deletion/AIRE
- Peripheral
  - Immune privilege
  - Anergy
  - Regulation

TOLERANCE

Tolerance is an inherent property of the immune system that governs the ability to respond against foreign antigens (nonself) without attacking the host (self). In normal hosts, tolerance protects against autoimmune tissue injury. The concept of immune tolerance predated understanding of the cellular and molecular bases for the phenomenon. Owen's experiments in cattle showed that a shared blood supply during development led to lifelong immune tolerance.[31] Billingham et al. expanded upon the concept of tolerance establishment in 1953 by showing that *in utero* inoculation with foreign tissue resulted in tolerance to foreign skin grafts later in life.[32] Layered and complementary mechanisms of immune system tolerance have developed to calibrate immune responsiveness with maintenance of maximum capacity for protective activation. The remainder of this chapter discusses critical roles played by T cells in the establishment and maintenance of tolerance.

Establishment of immune tolerance to self may occur either during T-lymphocyte development or after maturation in tissues.[33] *Central tolerance* refers to active deletion that is induced during development of T cells in the thymus (Chapter 8). Despite the presence of mechanisms that promote expression of a full repertoire of self-peptides (see below) in the thymus, establishment of central tolerance alone is inadequate to prevent tissue-damaging autoimmune responses. In healthy vertebrate hosts, a small percentage of the T cells that normally develop and emigrate from the thymus carry autoreactive TCR. Control of such "escaped" autoreactive cells in secondary lymphoid organs and tissues is achieved through a series of extrathymic processes; these are referred to in aggregate as *peripheral tolerance.*

Central Tolerance/Clonal Deletion

Techniques that allow "fate mapping" of clonal populations during T-cell development have opened windows into the molecular mechanisms of the thymic process of clonal deletion.[34,35] Monoclonal antibodies specific for Vβ17 TCR variable regions allow tracking of developing thymocytes that react with endogenous retrovirus-derived "self" peptides. Such peptides form the dominant antigens for Vβ17-bearing thymocytes. In the normal murine thymus, immature Vβ17-expressing $CD4^+CD8^+$ (double-positive [DP]) thymocytes are present, but the fraction of Vβ17-expressing cells in the mature CD4 single-positive (CD4SP) or CD8SP compartments declines precipitously. The paucity of Vβ17-expressing mature thymocytes thus suggests that clonal deletion can occur at the transition from DP to SP.

TCR transgenic mice expressing a single specificity TCR potentiated additional investigation into central tolerance. Mice bearing transgenic TCRs reactive with a Y chromosome–encoded antigen (H-Y) are among the oldest models of clonal deletion. Massive deletion of developing thymocytes results in small thymi in self-antigen–expressing (male) mice; only a small number of DP thymocytes avoid the apoptotic cell death induced by TCR engagement. In contrast, transgenic T cells develop normally in littermate female mice that lack H-Y antigen. Additional TCR transgenic models of central tolerance have shown that autoreactive thymocyte deletion can occur before, during, or after the DP stage.

Deletion for self-reactivity implies that the extent of autoreactivity of the developing thymocytes is systematically calibrated. A currently favored model is one that employs strength of signal as determined by a combination of TCR affinity and costimulation to assess the extent of self-reactivity.[36] Signals that exceed an intensity threshold lead to clonal deletion of cells bearing that TCR. This model is supported by data from animals in which the signaling machinery has been genetically altered to increase or decrease TCR signal intensity. For example, an increase in the number of TCR-associated ITAMs (presumably leading to increases in downstream signals) enhances clonal deletion in a TCR transgenic system.[37]

For clonal deletion to establish comprehensive self-tolerance, T cells must come into contact with all potential self-antigens during thymocyte maturation. It is easy to recognize how deletion of cells reactive to MHC and other widely expressed protein products can occur in the thymus. However, there are also self-antigens whose expression is restricted to a specific tissue or developmental time point.

The complex mechanisms whereby clonal deletion of developing thymocytes reactive with tissue-restricted antigens (TRAs)—expressed only in the pancreas or testes, for example—occurs are beginning to be unraveled. Some evidence supports the possibility that all TRAs are transported to the thymus by APCs, such as migratory DCs.[36] Another, non–mutually exclusive model holds that subsets of thymus-resident APCs may "ectopically" express TRAs. The leading candidate for controlling TRA expression within medullary thymic epithelial cells (mTECs) is the transcription factor AIRE (autoimmune regulator).[38] AIRE expression ectopically drives mTEC to express peptides from open reading frames representing TRA. Self-reactive developing T cells are thus exposed to TRAs in the thymus and are deleted. AIRE-deficient humans and mice develop autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APS-1 or APECED in humans; Chapter 35), emphasizing the role of central tolerance in preventing T cell–mediated autoimmune disease.

Isolated TRA presentation by mTEC is unlikely to fully account for successful clonal deletion, given the relative rarity of mTEC in thymic stroma and the abundance of autoreactive thymocytes. One potential mechanism for enhancing exposure of autoreactive cells to deleting TRA-driven signals is antigen presentation by additional thymic stromal cells. A recent observation that intercellular transfer of TRA between mTEC and thymic-resident or migrant DCs readily occurs supports this model.[36]

Peripheral Mechanisms of Tolerance

Clonal deletion, like all biological processes, is imperfect. Given the potential for autoimmune tissue damage should central tolerance mechanisms fail (as exemplified in those humans and mice carrying AIRE mutations), there must be "backup" mechanisms to control autoreactivity of T cells that manage to escape the thymus. These mechanisms include immune privilege, anergy, and regulation.

Immune Privilege

Medawar first described the concept of "immune privilege" more than 50 years ago. Typically described areas of immune privilege include the anterior chamber of the eye, the brain, and the fetus in pregnant females.[39] The eye and the brain are critical organs for basic survival functions and yet have a limited capacity for regeneration. Thus uncontrolled immune responses in these organs could have a detrimental effect on survival. A fetus expresses MHC derived from both parents; thus the mother's immune system must develop tolerance of the paternal antigen–bearing fetus to prevent pregnancy loss.

Immune-privileged tissues evade or suppress immune effector functions through multiple mechanisms. Cells of the eye, brain, and fetal villous trophoblast display low level or absent surface expression of classic MHC class Ia protein. This feature likely protects them from cytotoxic T-lymphocyte (CTL)–mediated lysis (Chapter 17). Ocular cells express proapoptotic cell surface molecules, such as CD95 ligand (CD95L) and TRAIL (TNF-related apoptosis inducing ligand) (Chapter 13). These TNF family members may contribute to apoptosis of infiltrating CD95-bearing T cells and other inflammatory cells bearing death receptors that serve as cognate ligands for TRAIL. In mice, the presence of CD95L on ocular cells is critical for the acceptance of corneal allografts. Soluble factors elaborated by ocular DCs likely contribute to immune privilege. These include the cytokines transforming growth factor-β (TGF-β) and IL-10, which may lead to induction and/or recruitment of Tregs, and migration inhibitory factor (MIF) that suppresses natural killer (NK) cell–dependent cytolytic capacity. In addition, ocular DCs may produce high levels of indoleamine oxidase, an enzyme that supports Treg differentiation.

T-Cell Anergy

Cellular proliferation and/or potentiation of T-cell effector function are not inevitable consequences of TCR engagement. Under some conditions, TCR ligation results in *anergy,* a cellular fate characterized by reduced proliferation and cytokine production in response to subsequent TCR engagement.[40] T-cell anergy can ensue either when the TCR is engaged without concomitant costimulation or when the ligand for the TCR is not of sufficient affinity to initiate the full spectrum of biochemical second messengers. Anergy is observed in T cells stimulated with metabolically inactivated APCs incapable of providing costimulation. Conversely, CD28 costimulation prevents the induction of anergy. Treatment of cultured T cells with IL-2 can overcome the anergic state *in vitro.* In addition to TCR and costimulatory signals, recent work has shown that environmental cues, such as nutrient and energy store availability, and the products of Tregs (described below) also control the anergy/activation fate choice.

T-cell anergy can be induced by activation of the calcineurin/NFAT pathway without concomitant increases in the RAS/ERK pathway–dependent activating protein-1 (AP-1) transcription factor activity (Fig. 12.6A). Relatively unopposed NFAT activity can be induced experimentally either by treatment with calcium ionophore or by stimulation through the TCR while blocking CD28 costimulation. Concurrent treatment of TCR-stimulated cells with protein synthesis inhibitors or with NFAT pathway inhibitors, such as cyclosporine, abrogates the development of later unresponsiveness, supporting the notion that anergy induction and maintenance depend on the transcription and translation of anergy-associated factors.[41]

Inhibition of Ras pathway function in anergized T cells correlates with biochemical and gene regulatory events (see Fig. 12.6B).[42] First, preferential FYN kinase–dependent activation of c-CBL within anergized cells leads to recruitment of the RAF kinase to the nucleotide exchange factor RAP1. The RAF-RAP1 association prevents RAF recruitment to RAS and thus restricts ERK pathway activation. Second, upregulation of NFAT-dependent transcription factors EGR2 and EGR3 results in transactivation of proteins implicated in the restraint of T-cell activation, including GRAIL (gene related to anergy in lymphocytes), CBL-b, and ITCH.[41] E3 ubiquitin ligase activity associated with a number of the latter factors is responsible for ubiquitin-mediated proteolysis of TCR signal–promoting molecules, such as PKCθ and RAS-GRP. Third, posttranslational modification of the positive TCR signaling mediator LAT is also observed in anergy.[43] As described above, LAT is normally palmitoylated and its membrane localization restricted to detergent-insoluble lipid rafts. In previously anergized T cells, however, LAT palmitoylation and phosphorylation are both decreased. Fourth, increased expression of members of the diacylglycerol kinase family (DGKα and DGKζ) is observed in T-cell anergy. Augmented DGK expression reflects augmented capacity for phosphorylation-dependent conversion of DAG, the key lipid mediator upstream of RAS signaling, into an inert metabolite phosphatidic acid (PA).[44]

Cellular sensing of adequate nutrient and energy stores required for optimal differentiation and proliferation regulates the anergy/activation T-cell fate decision. The importance of amino acid– and energy-sensing pathways was suggested by observations that anergy is induced in T cells activated in the presence of antagonists to leucine or glucose despite the presence of robust combined antigen receptor and costimulatory pathway signaling.[40] Several lines of evidence suggest that establishment of "metabolic anergy" after integration of signaling inputs from antigen recognition (TCR), immune (CD28, IL-2 receptor), and metabolic (*e.g.,* GLUT1) receptors and sensors is governed by mechanistic (formerly mammalian) target of rapamycin (mTOR).[45] TCR and CD28 ligation induce T-cell anergy rather than activation when the stimuli are given in the presence of rapamycin, a selective mTOR inhibitor, suggesting that optimal T-cell activation and avoidance of anergy requires activation of mTOR. mTOR is activated by signals that communicate abundant nutrients (*e.g.,* leucine-stimulated RAG proteins). Conversely, mTOR is inhibited by activated AMPK, an enzyme that responds to low energy stores reflected by increased ratios of adenosine monophosphate (AMP) to adenosine triphosphate (ATP). Through mediators, such as AKT, mTOR activation functions to promote cell cycle entry and prevent transcriptional activation of the anergy factors GRAIL and CBL-b.

KEY CONCEPTS

Immunosuppressive Drugs That Affect T-Cell Signaling

- Cyclosporine and tacrolimus inhibit T-cell receptor (TCR)–generated signals:
  - Anti-TCR antibodies block TCR signals
  - CTLA-4Ig blocks CD28 signals
  - Rapamycin inhibits mechanistic (formerly mammalian) target of rapamycin (mTOR) activation
- Inhibitory receptor blockade enhances antitumor function of suppressed/exhausted T cells
  - Anti-CTLA4 antagonist antibodies permit CD28-CD80/86 interactions
  - Anti-PD1/anti-PDL1 antibodies prevent suppressive interactions between tumor-expressed PDL1 and PD1 on tumor-infiltrating T cells

Regulation

Subsets of T lymphocytes can enforce tolerance through active regulation of autoreactive immune responses. Tregs can suppress effector functions of other immune cells of both myeloid and lymphoid lineages (Chapter 18). The most extensively studied—and arguably the most important for tolerance induction—Treg-sensitive immune functions are proliferation and cytokine production by naïve and memory conventional T cells. Tregs inhibit these processes through both cell contact–dependent and soluble molecule secretion mechanisms.[46] By regulating the activation and proliferation of antigen-specific effectors, Tregs promote tolerance to self and suppress autoimmunity *in vivo.*

Identification of Tregs was initially described on the basis of the correlation between high CD25 expression and the potent suppressive activity of a subset of CD4 T cells. Most Tregs also express GITR, CD103, CTLA-4, lymphocyte activation gene-3 (*LAG-3*), and low levels of CD45RB. Although no single surface marker that specifies Tregs exists, CD4 T-cell expression of the transcription factor Foxp3 correlates tightly with suppressive capacity and strongly suggests a unique differentiation pathway for Tregs.[47] The absence of Foxp3, occurring either via spontaneous mutation (exemplified by the scurfy mouse, which develop fatal autoimmune disease) or through targeted disruption of the gene, leads to the complete loss of T cells with regulatory activity. Conditional deletion of Foxp3 in peripheral T cells results in loss of the suppressive phenotype. Conversely, overexpression of Foxp3 by transgenesis or retroviral methods leads to an excess of T cells with regulatory activity. Together, these findings suggest that Foxp3 is both necessary and sufficient for Treg-suppressive functions. The bulk of Foxp3-positive Tregs develop in the thymus. Dynamic Foxp3 expression and development of suppressive capacity can be observed in naïve CD4 T cells after exposure to TGFβ or retinoic acid; recent work strongly suggests that inducible Treg may have nonredundant functions in suppressing chronic inflammation.[48]

FIG 12.6 **T-Cell Anergy Induction and Maintenance Correlates With Differential Activation of T-Cell Receptor (TCR)–Dependent Second-Messenger Signaling Cascades.** (A) Stimulation of T cells by cross-linking of both TCR/CD3 and CD28 lead to upregulation of both the nuclear factor of activated T cells (NFAT) and activating protein-1 (AP-1) transcription factors, leading to increased transcription of the interleukin-2 (*IL-2*) gene and activation. An imbalance of activated NFAT and AP-1 by blockade of CD28 signals *(middle panel)* or calcium ionophore *(right panel)* leads to an anergic phenotype. (B) TCR signaling required for full T-cell activation features Calcium flux-, RAS-, and PKC-dependent biochemical events leading to cooperative transcriptional regulation by NFAT, AP-1, and NF-κB transcription factors *(left panel).* In anergized cells, TCR-dependent signaling is differentially impaired (DAG-dependent events more so than calcium-dependent events) through multiple mechanisms: (a) decreased palmitoylation of LAT results in diminished recruitment to the immunological synapse; (b) upregulated GRAIL and CBL-b degrade positive signaling regulators PLCγ1 and PKCθ; (c) diacylglycerol kinases (DGKs) convert DAG (PKC and RAS activator) to phosphatidic acid (PA); (d) active RAP1 recruits RAF, thus preventing RAS-mediated signaling to ERK. Anergy mechanisms and mediators are highlighted in red.

In humans, mutations in FOXP3 account for a majority of cases of immune dysfunction/polyendocrinopathy/enteropathy/X-linked (IPEX) syndrome. The signs and symptoms of FOXP3 deficiency are similar in mice and humans. Affected human males develop an autoimmune syndrome consisting of lymphoproliferation, thyroiditis, insulin-dependent diabetes mellitus, enteropathy, and other immune disorders.

Tregs can inhibit conventional T-cell responses through secretion of suppressive cytokines, induction of T-cell apoptosis, or repression of APC function.[49] Key Treg-secreted cytokines include IL-10, TGFβ, and IL-35; each of these molecules has the capacity to induce cell cycle arrest. Tregs, via high expression of CD25 (IL-2Rα), may compete with neighboring T effector cells for limited supplies of IL-2. The resulting growth factor deprivation can kill proliferating T cells in a B cell lymphoma 2–interacting (Bcl2-interacting) mediator (BIM)-dependent manner. Tregs preferentially express Galectin-1, a β-galactoside-binding protein that ligates CD45 and other lymphocyte surface molecules and that may suppress lymphocyte activation through induction of cell cycle arrest. Treg surface proteins that work to effectively decrease efficiency of antigen presentation by DCs include CTLA-4, which interferes with CD28-dependent T-cell costimulation; LAG3, which binds to MHC class II molecules and prevents DC maturation; and Nrp1, which mediates prolonged Treg/DC interactions that may restrict access of effector T cells to DCs.

SUMMARY AND FUTURE DIRECTIONS

ON THE HORIZON

- Better understanding of T-cell intracellular signaling pathways will lead to improved immunomodulatory therapies
- Promising targets for manipulation of T-cell signaling include:
  - SYK inhibition
  - AKT inhibition
  - Tec kinase inhibition in cancer
- Targets for relief of negative checkpoints on T-cell activation for immunoenhancement in cancer or infection include:
  - LAG3, TIGIT, TIM3, BTLA, VISTA

Antigen receptor signaling controls key T-cell developmental checkpoints as well as the fate and behavior decisions of mature T cells. Membrane-proximal TCR signaling depends on tyrosine phosphorylation events that are coupled to “second messenger” cascades through adaptor proteins. TCR affinity for ligand is the major determinant for life-or-death decisions by immature thymocytes that result in establishment of a broadly self-tolerant mature T-cell repertoire. In peripheral T cells, auxiliary signals from costimulatory molecules, coreceptors, growth factor receptors, and metabolic sensors all shape the transcriptional regulation programs that govern cell function. T cells proliferate and produce cytokines when members of the CD28 or TNFR families of receptors signal in tandem with the TCR. Immunoreceptor and costimulatory signals are also critical in maintaining immune tolerance through clonal deletion, anergy, and peripheral suppression by Tregs. Coinhibitory signals that restrain T-cell antitumor functions may be antagonized for immunotherapy of cancer. More detailed understanding of T-cell intracellular signaling pathways will lead to more specific, targeted immunomodulatory therapies.

MULTIPLE-CHOICE QUESTIONS

1. Individual mutations in T-cell signaling proteins can lead to immune deficiency, dysregulation, or lymphocyte proliferation. Among the following molecules, which one is primarily associated with lymphocyte hyperproliferation and an increased risk of autoimmunity?
   A. ZAP-70
   B. SLP-76
   C. CD45
   D. CD95

2. Which of the following are mechanisms of central tolerance
   A. Immune privilege
   B. Treg regulation
   C. Clonal deletion/AIRE
   D. Anergy

3. In the clinic, monoclonal antibodies directed against T cell signaling coinhibitory molecules are proving to be efficacious against cancers. Which of the following is a coinhibitory molecule that where blockade has proven to be helpful in tumor immunotherapy?
   A. CTLA-4
   B. CD28
   C. OX40
   D. CD3

Regulated Necrosis and Its Immunogenicity

Wulf Tonnus, Andreas Linkermann

For more than a century and a half, we have known that the process of regulated cell death (RCD) is an integral part of life. The first insights into the mechanisms underlying RCD came from the identification of apoptotic pathways in 1972.[1] For almost 40 years, the apoptotic process of RCD was viewed as the opposite of necrosis, which was considered accidental (and therefore unregulated). In 2008, however, it was realized that necrosis could be antagonized under certain conditions. This led to the appreciation that necrosis could also be a genetically determined, regulated process.

The current challenge is to elucidate the various genes and pathways that take part in regulated physiological and pathophysiological cell death and to better understand why there are multiple pathways. It has become clear from these studies that the various pathways create differences in the immunogenicity of the byproducts of necrosis. As tissue injury and inflammation are tightly linked, these discoveries fuel the need to better understand how necrosis influences pathologies, including autoimmune diseases, transplant rejection, and cancer. This chapter focuses on the most clearly identified regulated necrosis (RN) pathways. Our "selection" of the RN pathways discussed is based on the current appreciation of the importance of these pathways, either physiologically or pathophysiologically, to differences in the immunogenicity of these RN pathways and their role in diseases (Fig. 13.1).

CELL DEATH AND DAMAGE-ASSOCIATED MOLECULAR PATTERNS—THE CONCEPT OF NECROINFLAMMATION

Pattern recognition receptors (PRRs) bind a wide range of damage-associated molecular patterns (DAMPs). These include exogenous stimuli such as lipopolysaccharides (LPS) as well as an array of intracellular content.

It is now understood that necrosis triggers inflammation and that inflammation can, in turn, lead to further RN. This observation gave rise to the concept of necroinflammation. Necroinflammation can create an autoamplificatory feedback loop that results in DAMP release between organs. For example, ischemic or traumatic tissue in the lung can initiate a positive feedback loop that leads to acute respiratory distress syndrome (ARDS).[2,3] Recent observations have indicated that the DAMPs released by this type of feedback after renal transplantation can lead to RN in the lung as well.[4]

For years, immunology focused on the issue of self versus nonself recognition. However, within the past two decades, the danger/injury model has become more and more prominent. Briefly, this model proposes that cellular stress activates the innate immune system, thus leading to an inflammatory response that can, under certain circumstances, then induce a specific adaptive response.

KEY CONCEPTS

Necroinflammation—An Autoamplificatory Feed-Forward Loop

- Induced by cells dying by necrosis (*e.g.*, in hypoxia)
- Associated proinflammatory damage-associated molecular pattern (DAMP) release
- Immune cell infiltration
- Regulated necrosis (RN) in parenchymal and endothelial cells induced by immune cells
- RN in inflammatory cells (*e.g.*, macrophages undergoing pyroptosis)
- More necrotically dying cells
- DAMP transfer to remote organs
- Remote organ injury

Key to this is the concept are DAMPs (Chapter 3). DAMPs include a wide array of different stimuli, including exogenous stimuli (*e.g.*, LPS) and intracellular contents (*e.g.*, uremic acid and high-mobility group box-1 [HMGB1]).[5,6] These are sensed by either "classic" PRRs or "nonclassic" receptors found on the surface or within cells of innate immunity. When cells die by RN, these DAMPs become accessible to the immune system in the extracellular space. They are sensed especially by cells of the innate immune system. Dendritic cells (DCs) (Chapter 6) are activated by directly sensing DAMPs via surface receptors (*e.g.*, calreticulin [CALR]–CD91, adenosine triphosphate [ATP]–P2X7R, or HMGB1–Toll-like receptor 4 [TLR4]). Sensing of DAMPs by monocytes leads to activation of inflammasomes, which then promote expression of mature inflammatory cytokines (*e.g.*, interleukin-1β [IL-1β] and IL-18) (Chapter 9). Natural killer (NK) cells (Chapter 17) also directly interact with injured cells. However both monocytes and NK cells give rise to inflammation and thus support the maturation of immature DCs.

The infiltration of innate immune cells into the inflamed tissues and their subsequent inflammatory response is thought to account for a significant part of the overall damage to the organ, above and beyond initial necrosis itself. Mechanisms that mediate this deterioration may include the edema that arises following capillary leakage, induction of cell death by innate immune cells with the effect of decreased organ function, and dysregulated partial oxygen pressure within the area of inflammation/necrosis. Also, mature DCs interact with CD8 T cells (Chapter 17) via major histocompatibility complex (MHC) class I interaction and CD4 T cells via MHC class II interaction (Chapter 5), thus shifting the immune response to an antigen specific response, as cytotoxic T cells and active B cells now specifically attack stressed cells (Fig. 13.2). However, in addition to these DAMPs, other intracellular content has the potential to be sensed as a target as well, which could lead to the development of autoimmunity.

FIG 13.1 New Concept of Regulated Cell Death. When apoptosis was first identified, two models of regulated cell death were recognized: apoptosis and necrosis. More recently, however, cell death is divided into regulated cell death (including apoptosis and regulated necrosis) and accidental cell death (instant necrosis). A second parameter classifies cell death as either immunogenic or nonimmunogenic.

When challenged with injurious conditions, such as ischemia–reperfusion in solid-organ transplantations, options for cellular fate are directly succumbing via accidental cell death (ACD), restoring cellular homeostasis, or dying by RCD. ACD happens passively under certain conditions, such as extreme heat, and occurs nearly immediately in an uncontrolled fashion. Because of the direct loss of membrane integrity, huge amounts of DAMPs are released. This leads to massive recruitment of innate immunity and local inflammation. As this kind of stimulus is not given in ischemia–reperfusion, this is not further discussed here. However, if these cells do not explode directly, they balance on the edge. The issue then becomes whether balance will be restored (*e.g.*, by means of autophagy or unfolded protein response following endoplasmic reticulum [ER] stress) or, if the damage is too great, will balance be lost and RCD be induced?

Within the cells that succumb to cell death, the necroinflammatory loop starts with perturbation of intracellular homeostasis (class V DAMPs), which triggers the heat shock response, a system of critical importance for correct protein folding. Secreted or surface-exposed heat shock proteins (HSPs) can be sensed by either classic (*e.g.*, TLR2/4) or nonclassic (*e.g.*, CD91) receptors on DCs. In parallel, ER stress (which is often result of reactive oxygen species [ROS] generation) leads to secretion of calreticulin (an ER chaperone referred to as "CALR"), which then acts extracellularly as a class I DAMP by binding to CD91. This leads inactive dendritic cells (iDCs) to be activated. For full activation, however, an inflammatory milieu is required.

FIG 13.2 Central Role of Dendritic Cells (DCs). Innate immunity plays a crucial role in necroinflammation. When cells are stressed, they release damage-associated molecular patterns (DAMPs), such as calreticulin (CALR) and heat shock proteins (HSPs). These DAMPs are sensed by scavenger receptors, such as CD91. This leads to partial activation of inactive DCs. If those cells fail to restore metabolic balance, they succumb to immunogenic cell death (ICD) and release additional DAMPs, which activate inflammasomes, such as LRR and PYD domains–containing protein 3 (NLRP3) in monocytes. Activation of the inflammasomes leads to the release of interleukins, which help DCs to gain full activation. These fully activated DCs use major histocompatibility complex (MHC) class I and class II antigen presentation to stimulate cytotoxic CD8 T cells (CTCs) and CD4 T cells, which interact with B cells to trigger a humoral response. Activation of the immune response by necroinflammation can thus promote the control of cancer by immunogenic means. However, the same mechanisms can promote the development of autoimmune diseases.

An inflammatory milieu is generated mainly by monocytes. These become active as the survival response fails and the formerly stressed cell succumbs to RN. Ferroptosis is the typical mode of RN within this process. The ferroptotic cell can "leech" redox equivalents, such as nicotinamide adenine dinucleotide phosphate (NADPH), from neighbored cells (see below), which subsequently undergo secondary necrosis. This secondary necrosis seems to involve necroptosis, but the mechanism of necroptosis induction in this case remains to be elucidated. RN releases high amounts of DAMPs, so it can be named immunogenic cell death (ICD) in this context as well.

Adenosine triphosphate (ATP) as a DAMP can reach the extracellular space (eATP). When the plasma membrane is intact, the autophagy machinery seems to be necessary for ATP export. However, as soon as the membrane ruptures upon RN, export is obviously no longer required. eATP represents a class II DAMP as it activates the purinergic-receptor, ligand-gated ion channel P2X7R. This results in potassium influx, which is sensed by the NACHT, LRR and PYD domains-containing protein 3 (NLRP3) inflammasome and leads to IL-1β and IL-18 maturation. eATP is thus extremely immunogenic.

Upon membrane rupture, HMGB-1 also reaches the extracellular space and is therefore the prototype of a RN-DAMP. iHMGB-1 acts via binding to TLR4 of monocytes and activates the NLRP3 inflammasome, as well.

The DAMPs from the stressed cells and the inflammatory cytokines fully activate iDCs, which then create a *per-se* cytotoxic inflammatory environment and prime naïve CD4 and CD8 T cells, thereby inducing an antigen-specific response. This response is the basis for certain conditions, such as chemotherapy in cancer. To stably control (or wipe out) a cancer, a specific response against tumor epitopes is required, so induction of RN should be beneficial. In contrast, in some settings, such as solid-organ transplantation, an antigen-specific response induced by DAMPs can give rise to antibody-mediated rejection, which typically starts after cortisone tapering. In this setting, RN is detrimental. The activation of an antigen-specific response results in additional cells being attacked. As they succumb, these dying cells replenishing the DAMP pool, further attracting cells of innate immunity and further promoting DC maturation and T-cell priming. Thus tissue injury amplifies while the loop closes (Fig. 13.3).

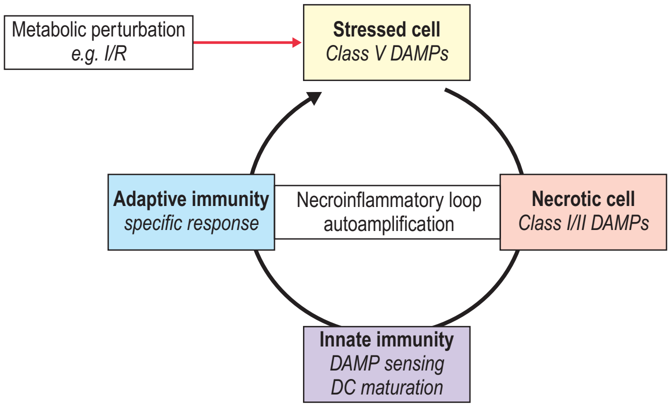

FIG 13.3 **The Autoinflammatory Loop.** The necroinflammatory loop is triggered by metabolic perturbations (*e.g.,* ischemia–reperfusion [I/R]). The so-stressed cells release class V danger-associated molecular patterns (DAMPs). In the next step, now-necrotic cells release class I/II DAMPs, which can be sensed by cells of innate immunity, such as dendritic cells (DCs), which are then stimulated to mature. Via mechanisms described in Fig. 13.2, adaptive immunity is empowered to unleash a specific response to (neo-)antigens. This leads to further stressed and dying cells, which, in turn, can themselves then release DAMPs and thus create an autoinflammatory loop.

REGULATED CELL DEATH REGULATES ITS IMMUNOGENICITY IN AN ACTIVE MANNER

Apoptosis is the prototype of nonimmunogenic cell death. Avoidance of immunogenicity is achieved by active processing and covering of DAMPs during the apoptosis program. For example, DNA is fragmented, cell organelles are consumed, and proteins degraded. Moreover, everything is packed in blebbing membranes. It is a matter of debate, however, if apoptosis should be considered somehow immunogenic as well, as some DAMPs (*e.g.,* HMGB-1) are still released and phosphatidylserines, which are usually located in the inner leaflet of the plasma membrane, are flipped outside.

Phosphatidylserine surface expression serves as an "eat me" signal for macrophages and other phagocytes, which can then act to remove these cells in an immunologically silent manner. Thus apoptotic cells recruit cells of innate immunity, but in a manner that is programmed to not induce further inflammation (as long as the uptake works properly, see "LAP" below). Thus the debate about the inflammatory potential of apoptosis might be more or less of an academic nature. The highly complex program of apoptosis appears to have evolved to prevent necroinflammation and is therefore favored in physiological settings that result in regular cell turnover (Fig. 13.4).

Under metabolic pressure, such as ischemia–reperfusion injury, however, tissue damage occurs primarily by RN, and thus the necroinflammatory loop *per se* tends to refuel itself. Therefore mechanisms are required to keep this in check. One such mechanism is the active production of IL-33 by cells undergoing necroptosis (see below), which acts to limit the immunogenicity to a certain microenvironment,[7] as IL-33 stabilizes regulatory T cells (Tregs) through ST2 receptors.[8] Cells undergoing pyroptosis (see below) actively produce and secrete IL-1β and IL-18 upon their demise. Both of these ILs are highly proinflammatory. As pyroptosis is typical for cells of innate immunity, this might be an alert function of this first-line defense. In conclusion, even in RN, cells regulate their inflammatory potential in both proinflammatory and antiinflammatory ways. When balanced, this generates a beneficial environment for both defense and regeneration.

Necroinflammation can be opposed by the uptake of extracellular debris by monocytes. This mechanism is referred to as LC3-associated phagocytosis (LAP).[9] Dysfunction of proteins of this noncanonical autophagy pathway (*e.g.,* ATG5, ATG7, ATG16L, or Rubicon) cause chronic inflammation as a result of inadequate processing of extracellular disposal. This also extends to apoptotic debris, further highlighting the importance of correct clearance.

In humans, ATG16L mutations are markedly associated with the development of autoimmunity.[10] Usually, IL-10 is secreted by monocytes engulfing dying cells to dampen the immune response. However, LAP-deficient monocytes actively produce proinflammatory IL-1β and IL-6 instead. Orchestrated with other elevated proinflammatory cytokines (IL-17, IL-18, IL-23),

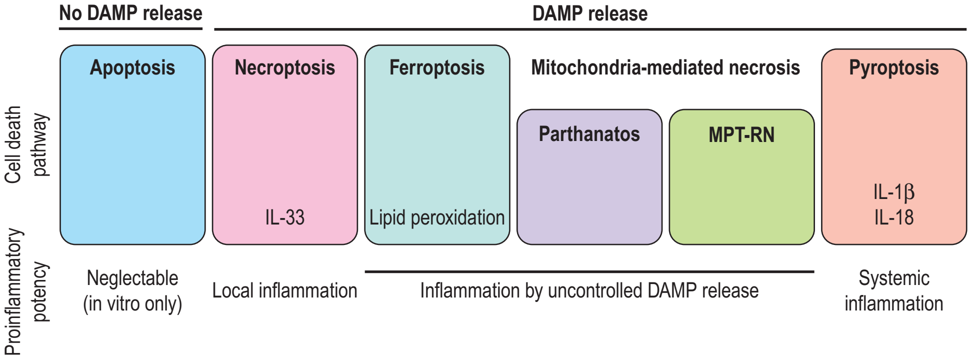

FIG 13.4 **Hypothetical Model of the Immunogenicity of Regulated Necrosis (RN) Pathways.** Apoptosis is nonimmunogenic, whereas loss of plasma membrane integrity results in the release of damage-associated molecular patterns (DAMPs)[5,6] into the extracellular space in all other pathways. During necroptosis, antiinflammatory cytokines, such as interleukin-33 (IL-33), are actively released, which triggers regulatory T cell (Treg) recruitment and thereby may limit the immunogenic response to a distinct microenvironment. In contrast, during ferroptosis or mitochondrial necrosis, no active production of cytokines or immunomodulatory factors has been described, and the uncontrolled DAMP release accounts for the immunogenic potency of these pathways. Pyroptosis, the most immunogenic cell death known so far, encompasses active production of proinflammatory cytokines, such as IL-1β and IL-18, resulting in a long-lasting, systemic inflammatory response. The difference in immunogenicity may explain the evolutionary preservation of several pathways of RN.

a low immunogenic stimulus can thus induce a strong immune response. In the presence of this stimulus, common self epitopes are classified as DAMPs by the immune system, which explains why mice deficient in LAP develop a lupus-like autoinflammatory disease. As a result, functional LAP may be required for prevention of memory B-cell priming during solid-organ transplantation as well.

SIGNALING PATHWAYS OF REGULATED CELL DEATH

RCD is an umbrella term for any genetically determined signaling pathway that results in cellular demise.[11] RCD thus includes both nonimmunogenic apoptosis and immunogenic RN. Fig. 13.5 provides an overview of the most important pathways of RCD, including caspase-dependent and caspase-independent forms of RCD.

CASPASE-DEPENDENT CELL DEATH

Apoptosis

Apoptosis is a complex program for nonimmunogenic cellular demise that is regulated by caspases. During the first hours of apoptosis, cells maintain their plasma membrane integrity and therefore, by definition, are not necrotic. The apoptotic program may be activated via the intrinsic (mitochondrial) or the extrinsic (death receptor) pathways.

The intrinsic pathway is controlled by different members of the Bcl-2 protein family, such as Bcl-2 or BAX, and therefore reacts to intracellular changes (*e.g.*, DNA damage) by forming transient pores, a process referred to as mitochondrial outer membrane permeabilization (MOMP). The intrinsic pathway reacts to internal stimuli, whereas the default activation of the extrinsic pathway occurs following an outside-in signaling, typically mediated by death receptors, such as Fas (also known as CD95 or Apo1) or the tumor necrosis factor receptor 1 (TNFR1). These death receptors, upon trimerization/hexamerization, recruit downstream molecules via death domains (DDs), such as TRADD or FADD, to form a receptor-associated platform, the death-inducing signaling complex (DISC). If nuclear factor-κB (NF-κB)–signaling (the canonical response to tumor necrosis factor receptor 1 [TNFR1] activation) is inhibited and/or receptor-interacting protein kinase 1 (RIPK1) polyubiquitination is lost, this complex is capable of activating initiator caspases (*e.g.*, caspase-8 [CASP-8] or caspase-10 [CASP-10]). Together with RIPK1, RIPK3, and FADD, a CASP-8–cFLIP heterodimer forms a cellular signaling platform named a ripoptosome that usually prevents necroptotic signaling (see below) by cleaving RIPK1, RIPK3, and Cylindromatosis (CYLD) while not proteolytically activating downstream effector caspases, such as CASP-3, CASP-6, and CASP-7. Should CASP-8 be activated, however, it will form homodimers to activate named downstream caspases, which induce apoptosis.

RIPK1 polyubiquitination represents a major checkpoint for a cellular decision of either survival or RCD. For this reason, it is tightly regulated. Inhibitors of apoptosis 1 and 2 (cIAP1/2) and the linear ubiquitination complex (LUBAC) add ubiquitin chains, whereas OTULIN, CYLD, and A20 remove them. Polyubiquitination is required for NEMO-dependent canonical NF-κB signaling and mitogen-activated protein kinase (MAPK) activation. Both provide a survival signal. In contrast, RCD is licensed on loss of polyubiquitination. Remarkably, both pro-survival NF-κB signaling and necroptosis lead to local inflammation, whereas apoptosis is noninflammatory.

The physiological role of apoptosis has been questioned following the observation that CASP-8 deficient mice (which die *in utero*) can be rescued on a RIPK3-deficient background to become viable and fertile. However, CASP-8 is of critical importance only for the extrinsic pathway of apoptosis, and BAX-/BAK-deficient mice, which cannot undergo intrinsic

FIG 13.5 **Pathways of Regulated Cell Death (RCD)—An Overview.** In contrast to nonimmunogenic, caspase-mediated classical apoptosis, which can be mediated by either the intrinsic (mitochondria-mediated) or the extrinsic (death receptor–mediated) pathway of apoptosis, all other known forms of RCD are characterized by loss of plasma membrane integrity and therefore are categorized as regulated necrosis (RN). Apoptosis and pyroptosis are triggered by proteases (caspases). Necroptosis is regulated by kinases, most importantly the RIPK3-mediated phosphorylation of MLKL. Ferroptosis is predominantly mediated by lipid peroxidation. Finally, mitochondrial permeability transition- regulated necrosis (MPT-RN) and parthanatos represent mitochondrial necrosis. apoptosis, are not viable. Therefore apoptosis appears to be important for normal development and, particularly in the case of CASP8, for the inhibition of necroptosis.

Other than hereditary autoimmune syndromes (*e.g.*, autoimmune lymphoproliferative syndrome [ALPS]), no clear role for apoptosis in diseases has been unequivocally reported, and inhibition of caspases in certain diseases has either deteriorated or not provided any benefits to disease outcomes.

Pyroptosis

Pyroptosis (from “pyro” = fever/inflammation and “ptosis” = to fall) is a form of regulated cell death induced by inflammatory stimuli, transduced via inflammatory caspases and (probably) executed by gasdermins. Inflammatory caspases include CASP-1, CASP-4/-5 (human), and CASP-11 (murine). Unlike apoptosis, caspase activation in this context leads to a necrotic phenotype.

An extraordinarily potent inflammatory stimulus for pyroptosis is LPS, a typical component of bacterial membranes. Intracellularly, LPS is directly bound by pro-CASP-11, which thereby becomes activated and cleaves gasdermin D. Proteins of the gasdermin family are composed of a self-inhibitory C-terminal and a death-inducing N-terminal fragment. Upon caspase-mediated cleavage of gasdermin D, the N-terminal fragment loses its self-inhibiting C-terminal fragment and therefore becomes active. Other gasdermins have not been shown to be cleaved by caspases but do induce pyroptosis upon (artificial) cleavage as well. Their physiological role remains unknown. The axis LPS–CASP-11–gasdermin D–pyroptosis is also referred to as “noncanonical”.

The canonical pathway is initiated by inflammasomes as NLRP3 (Chapter 3), which forms upon stimuli that include pathogen-associated molecular patterns (PAMPs), DAMPs, and absent in melanoma-2 (AIM2) as a response to cytosolic DNA. These inflammasomes recruit CASP-1 via adapter molecule ASC (apoptosis-associated speck-like protein containing a C-terminal caspase recruitment domain) and lead to gasdermin D cleavage and IL-1β/IL-18 maturation.

As both the noncanonical and canonical pathways lead to necrotic cell death, the question about its mechanism arose. It is clear that proinflammatory cytokines pro-IL-1β and pro-IL-18 are actively matured by caspases, resulting in the release of IL-1β and IL-18 from the cytosol into the extramembrane space upon necrosis execution. It is a matter of debate if, in parallel, another mechanism of release of IL-1β and IL-18 exists and functions while the plasma membrane remains intact. In this context, maturation is independent of gasdermins, but release is not. So how do N-terminal gasdermin fragments kill cells and release cytokines? There is evidence that these fragments form oligomers, which can bind to selected negatively charged lipids, such as phosphoinositide and cardiolipin. After docking to membranes, pores are formed. If these are directly formed by gasdermins or just mediated by them (or even artificial, see also "Necroptosis") remains a matter of debate. Phosphoinositides are restricted to the inner leaflet of mammalian membranes, whereas cardiolipin is restricted to mitochondrial and bacterial membranes. This might protect bystander cells and reduce numbers of intracellular bacteria before necrotic release.

In pyroptosis, proinflammatory factors are released. Indeed, active production of systemically effective inflammatory cytokines during RN has been exclusively described for pyroptosis, thus rendering this cell death modality the most inflammatory. A working model for the immunogenicity of various RCD pathways is presented in Fig. 13.4. Pyroptosis, as all other pathways or RN, therefore exhibits an example of ICD.

As expected of a cell death subroutine that causes systemic inflammation downstream of an inflammasomal trigger, pyroptosis is typically observed in macrophages during gram-negative infection and upon culture with bacterial or viral intracellular pathogens. Pyroptosis is thus thought to mediate the immunogenic destruction of colonized niches.

CASPASE-INDEPENDENT REGULATED NECROSIS

Necroptosis

Necroptosis is the best characterized mode of RN. It was discovered as a type of necrotic cell death in apoptosis-resistant cell lines. Classically, it is induced upon tumor necrosis factor-α (TNF-α) stimulation whilst apoptosis is blocked (*e.g.,* by a pan-caspase inhibitor, such as zVAD). In this context, TNFR1, Fas, and other death receptors (described at pathways of extrinsic apoptosis, see above) transduce this signal into the cell (Fig. 13.6).

RIPK1, a key checkpoint of cellular fate, contains a unique motif next to its DD referred to as RIP homotypic interacting motif (RHIM). This motif is contained in only four proteins within the whole mammalian proteome, and all these proteins are associated with the regulation of necroptosis. The necrosome, a higher order structure with a poly-RIPK3 backbone, is central to necroptosis execution and can, next to named death receptor–associated pathway, also be engaged by TRIF-binding TLR3 and TLR4, as well as by viral sensing protein DNA-dependent activator of interferon regulatory factors (DAIs).[12] Recently, DAI (also known as ZBP1) has been demonstrated to mediate *in utero* lethality of RIPK1-deficient mice by forcing RIPK3 oligomerization, which places inactive RIPK1 as an inhibitor of necroptosis. The RIPK1 kinase inhibitor necrostatin-1 (Nec-1) seems to stabilize this conformation and thereby inhibit necroptosis on death receptor activation by not releasing RIPK1s' inhibition to RIPK3 oligomerization.

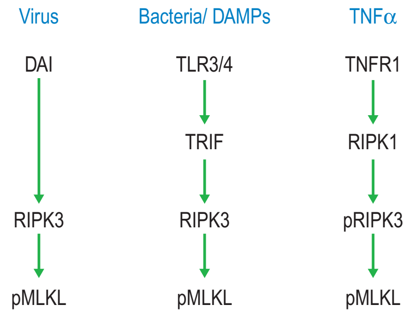

FIG 13.6 Necroptosis Induction. Different triggers are known to induce necroptosis, and they are sensed by specific adaptors. Viruses are sensed by DNA-dependent activator of interferon regulatory factors (DAIs), which subsequently triggers RIPK3 polymerization by replacing RIPK1 (receptor-interacting protein kinase 1). Bacterial pathogen-associated molecular patterns (PAMPs) and other DAMPs are sensed by Toll-like receptors (TLRs) 3 and 4, which trigger RIPK3 polymerization by RHIM-domain containing protein Toll–interleukin-1 receptor [TIR]–domain–containing adapter-inducing interferon-β (TRIF). The best-described pathway is activated upon tumor necrosis factor (TNF)-α stimulation of TNF receptor 1, which leads to RIPK1 phosphorylation. This phosphorylation licenses RIPK3 polymerization as well. As result of the active necrosome based on the poly-RIPK3-backbone, mixed linage kinase domain-like protein (MLKL) is phosphorylated and triggers membrane permeabilization and CXCL1/IL-33 transcription in the nucleus.

Downstream of the active necrosome, mixed lineage kinase-like domain protein (MLKL) becomes phosphorylated by RIPK3 (see Fig. 13.5). After phosphorylation of MLKL, this pseudokinase forms oligomers targeting the plasma membrane via its four-helical bundle (4HB) motif to mediate plasma membrane rupture and necrotic cell death by currently undefined means. Phosphorylated MLKL (pMLKL) is required, but is not sufficient to execute necroptosis. Whether pMLKL directly forms pores or mediates pore formation is unknown (as well as for gasdermins in pyroptosis). However, this is of great interest as pMLKL targets multiple intracellular membranes, translocates to the nucleus to induce CXCL1/IL-33, and is stably expressed in terminally differentiated cells, such as podocytes and endothelia, without killing these. Taken together, this might point to a still-unknown physiological role of pMLKL.

Mice deficient in RIPK3 or FADD and MLKL die following challenge with influenza A virus, which has been demonstrated to depend on DAIs' RHIM domain. Viruses also indirectly activate necroptosis by JAK-STAT–dependent protein kinase R upregulation.

Bacterial infection is sensed via TLR3 and TLR4. This also recruits RHIM domain–containing protein TRIF, which leads to necrosome formation. Current understanding favors the idea that necroptosis is an evolutionary conserved program to defend against viruses and certain bacteria. In line with this, some viruses express caspase-inhibitors, such as crmA (*e.g.*, cowpox virus), whereas viral protein M45 (*e.g.*, CMV) specifically targets necroptosis. M45 has been demonstrated to be a viral RHIM domain and thus suppresses DAI-induced RIPK3 oligomerization within the necrosome. Interestingly, cytomegalovirus (CMV) is a member of the herpesvirus family, which is famous for its persistence within the host. One might conclude that this virus adapted to the necroptotic trapdoor by this mechanism.

During necroptosis, some chemokines (Chapter 10) and cytokines (Chapter 9) are actively produced to be released apart from DAMPs. These include CXCL1 and IL-33, a stimulator of ST2 signaling on Tregs. This suggests that necroptosis, apart from being immunogenic through the release of DAMPs, also limits the inflammatory response to a certain surrounding of the damage by creating a microenvironment that may prevent necroptosis from causing a systemic inflammatory response syndrome (SIRS) and death. Necroptosis may thus be the least immunogenic RN pathway (see Fig. 13.4).

CLINICAL RELEVANCE

Selection of Clinically Relevant Conditions Associated With Necroptosis

- Acute liver failure
- Autoimmune disorders
- Acute respiratory distress syndrome (ARDS)
- Cancer (necrosis in the center of solid tumors)
- Chemotherapy
- Contrast-induced acute kidney injury (CIAKI)
- Myocardial infarction
- Sepsis
- Solid-organ transplantation
- Stroke
- Transplant rejection

Necroptosis critically contributes to diverse pathophysiological settings, such as ischemia–reperfusion injury in solid organ transplantations, myocardial infarction, stroke, and SIRS. RIPK3- and MLKL-deficient mice have been demonstrated to be protected from preclinical models of such diseases by several independent groups, so inhibitors of necroptosis (RIPK1 kinase inhibitors, RIPK3 kinase inhibitors, and MLKL inhibitors) have entered phase I and phase II clinical trials. No cell death–preventing therapy has been approved by the US Food and Drug Administration (FDA) as of the writing of this chapter. However, preclinical and first clinical data are very promising. Necroptosis inhibitors may soon become the first-in-class compounds to prevent RN.[13]

Ferroptosis

Ferroptosis is an important RN pathway in ischemic injury and cancer. Unlike extrinsic apoptosis and necroptosis, it is not initiated by specific receptors. In renal tubules, it mediates an event referred to as *synchronized regulated necrosis of an entire functional unit.* It thus provides a biochemical basis for the clinical observation of necrotic casts in the urine sediment of patients with acute kidney injury. Ferroptosis key molecules have been associated with renal clear cell carcinomas. Ferroptosis is critically mediated by the loss of NADPH (the major cellular redox equivalent) abundance as result of lipid peroxidation. This peroxidation is actively mediated by lipoxygenase ALOX5 and glutathione peroxidase 4 (GPX4) seems to be its major counterpart. Upon dysfunction of GPX4, ferroptosis occurs rapidly in all metabolically active cells by ROS generated in mitochondria and peroxisomes and at the plasma membrane.[2,14] Computed models of sepsis metabolomics also predict a benefit in improving intracellular cysteine levels, but these results still await experimental verification.

GPX4 requires glutathione (GSH) to function. Inhibition of the Glu/Cys-antiporter system X_c^- in the plasma membrane depletes intracellular cysteine required for GSH synthase. Inhibitors of antiporter system X_c^- are inducers of ferroptosis, such as the compound "erastin," which was found in a screen for lethal compounds against Ras-transformed tumor cells. Inhibitors of this process have also derived from screens, such as the first-in-class compound ferrostatin-1.[15] In fact, it is no wonder that ferroptosis inhibitors have been identified in cancer cell lines, as evidence accumulates that many cancers are highly sensitive to ferroptosis induction, especially lymphomas and clear cell renal cancer.[16] Interestingly, p53, which is among the most mutated or deleted proteins in diverse cancers, is also an inhibitor of system X_c^-. Thus p53 may mediate some of its antitumor properties by inducing ferroptosis.

As GPX4 is responsible for efficient repair of oxidized sphingolipids, GPX4 inhibition by GSH depletion, direct allosteric inhibitors (*e.g.*, RSL3), or genetic depletion leads to accumulation of peroxidized lipids. Defects in enzymes required for generation of polyunsaturated fatty acids, such as acyl-CoA synthetase long-chain family member 4 (ACSL4) or lysophosphatidylcholine acyltransferase 3 (LPCAT3), sensitize cells to undergo ferroptosis as well, further emphasizing the role of lipid peroxidation. Interestingly, although known as a redox equivalent, NADPH depletion has been identified as a downstream event of lipid peroxidation. However, this might explain the spread of RN from one cell to another in a functional unit, which is a unique feature of ferroptosis. NADPH drifts freely between neighboring cells through intercellular pores, such as gap junctions, that may give rise to a diffusion drag, leading to RCD in adjacent cells.[17,18]

Ferroptosis and synchronized RN are both active in the urogenital tract and synchronized organs, such as the brain and the heart. This has led to the hypothesis that the physiological role of ferroptosis may be preserved for obliteration processes similar to those of the paramesonephric (Müllerian) duct.

At the time of writing this chapter, no immunomodulatory role for cells that die by ferroptosis had been described, and the immunogenicity of ferroptosis is certainly high. In contrast to the more immunogenic pyroptosis and the less immunogenic necroptosis, ferroptosis may thus be a prototype cell death that leads to inflammation induced by DAMPs in the classic sense. However, it cannot be excluded that the lipid peroxidation and the high concentrations of ROS that are released into the extracellular space function as proinflammatory stimuli.

Mitochondrial Necrosis

Mitochondrial necrosis is largely a mystery. Clear data exist to demonstrate that widespread depletion of mitochondria does not affect necroptosis[19] and that RIPK3 depletion does not affect parthanatos.[20] Thus necroptosis does not require mitochondria, and mitochondrial cell death does not require RIPK3. However, almost any other RN pathway is, to some extent, affected by mitochondrial dynamics. Most models consider the release of the so-called apoptosis-inducing factor (AIF, clearly a misnomer) from mitochondria as a necrosis-inducing outcome. The detailed mechanisms about AIF-induced necrosis are unclear. Evidence from isolated mitochondria, as well as from immunofluorescence and electron microscopy, suggests a central role of swelling of this organelle and MOMP, as in apoptosis. Overlapping data point to the triggers of the loss of mitochondrial membrane integrity, most prominently the pathways of mitochondrial permeability transition (MPT)–induced regulated necrosis (MPT-RN) and parthanatos (see below).

Recently, the idea that "mitochondrial necrosis" is just an upstream event to "metabolic cell death," which certainly would involve ferroptosis and probably could be a trigger for necroptosis as well, started to emerge, but this requires further evaluation. Ferroptosis may be considered "mitochondrial" cell death, but the key regulators GPX4 and system Xc^- are clearly outside of mitochondria, so we do not classify ferroptosis in this section despite the role of mitochondria in this particular cell death subroutine. For this chapter, we separate MPT-RN from parthanatos. Although there are doubts about the correct classification of mitochondrial cell death, evidence from genetically modified animals leaves no doubt about the *in vivo* relevance.

MPT-RN

MPT-RN is the consequence of mitochondrial permeability transition, a highly effective shortcut between the mitochondrial matrix and the cytosol. MPT is mediated through a pore (the MPT pore [MPTP]), the composition of which has been a matter of debate for at least 2 decades. A current widely accepted model assumes a multiprotein complex physically or functionally involving proteins from the mitochondrial matrix, inner and outer mitochondrial membranes, the transmembrane space, and the cytosol. The pore is controlled by a cyclophilin named cyclophilin D (CYPD), a key modulator of MPTP opening and thus MPT-RN. Genetic absence of CYPD protects mice from diverse *in vivo* challenges, including stroke, myocardial infarction, and renal ischemia–reperfusion injury. As with other cyclophilins, the immunosuppressant cyclosporine (CsA) inhibits the opening of the MPTP and therefore prevents MPT-RN. This effect may well account for some of the immunosuppressive function of CsA. Other models, however, favor CYPD to interact with the c subunit of F_1F_0–ATPase complex.[21] Ca^{2+} is a well-known trigger of MPT-RN *in vitro,* but it remains largely unclear how Ca^{2+} triggers persistent MPT, which probably results in AIF release from mitochondria to the cytosol.

Parthanatos

Parthanatos is defined as cell death that occurs following so-called overactivation of the DNA repair enzyme poly [ADP-ribose] polymerase 1 (PARP1). PAR polymers are formed and translocate to the outer mitochondrial membrane by unknown targeting mechanisms. The default induction of PARP1 overactivation include a wide array of stimuli, ranging from DNA damage (*e.g.,* through irradiation) overreactive oxygen species stress to induction by toxins, such as methylnitronitrosoguanidine (MNNG). Comparable to MPT-RN, parthanatos results in AIF release. It has been suggested that AIF requires active PARP1 to transfer ATP-ribose groups from NAD^+ onto its targets. Interestingly, most of our knowledge of PARP1 originates from cancer research. Many tumors have been demonstrated to overactivate PARP1, and PARP inhibitors are in the FDA approval process for diverse cancers as a result of promising outcomes of phase III clinical trials. For *BRCA1/2* mutated ovarian and breast cancer, PARP-inhibitor olaparib has already been introduced in clinical practice.

KEY CONCEPTS

Prototype Inhibitors of Regulated Necrosis

- Inhibitors of necroptosis
  - Necrostatin-1 (Nec-1)
  - Nec-1s (Nec-1 stable)
  - Ponatinib
- Inhibitors of ferroptosis
  - Ferrostatin-1 (Fer-1)
  - 16-86
  - Liproxstatin-1
- Inhibitors of mitochondrial permeability transition (MPT)–induced regulated necrosis (MPT-RN)
  - Cyclosporine (CsA)
  - Sanglifehrin A (SfA)
- Inhibitors of parthanatos
  - Olaparib and many others
- Inhibitors of pyroptosis
  - zVAD-fmk (nonspecific caspase inhibitor)
  - Others to be developed

CONCLUDING REMARKS AND IMPLICATIONS FOR SOLID-ORGAN TRANSPLANTATIONS

Understanding the pathways of RN will allow screening for and/or design of specific inhibitors of the enzymes involved. Two major effects are expected from inhibiting RN. First, in clinically relevant conditions in which necrosis is the main determinant, such as stroke, myocardial infarction, sepsis, transplantation, acute liver failure, pancreatitis, and the center of solid tumors, it remains to be investigated how beneficial an antinecrosis therapy might be. Second, and probably of at least equal importance, necroinflammation deteriorates and amplifies the primary organ damage.

In transplantation, standard immunosuppression is tailored to preventing proliferation of immune cells, but it does not prevent the priming of memory B cells. To transplant an organ full of DAMPs after a long period of organ transfer may be the strongest possible stimulus for memory B cells, which can only expand upon tapering of the immunosuppression. That is exactly the time when antibody-mediated rejection (ABMR) becomes a major factor, lasting over years.[22] Importantly, this does not happen to a comparable extent in living donor transplantations despite full HLA mismatch and blood group incompatibilities. The upcoming years of RN and transplantation research should clarify how an anti-RN therapy may improve the outcome of transplants with a particular focus on ABMR (Table 13.1).

ON THE HORIZON

In Vivo *Interference With Regulated Necrosis*

- Receptor-interacting protein kinase 1 (RIPK1) inhibitors show promising results in animal studies/human phase I studies. Currently, they are the first-in-class compounds to prevent necrosis.
- Ferroptosis inhibitors have the potential to stop the necroinflammatory circle. First trials in humans are urgently awaited.
- As immune-checkpoint therapy becomes more and more the therapeutic standard for several cancers, questions will arise if induction of regulated necrosis (RN; to produce damage-associated molecular patterns [DAMPs]) and checkpoint blockade (to release autoimmune breaks) could work in a similar fashion.
- Most importantly, it is possible to interfere with necrosis!

TABLE 13.1 Classification of Damage-Associated Molecular Patterns (DAMPs)

Class	Definition	Example(s)
Ia	Promoting *DC maturation* as sensed by classical pattern recognition receptors (*e.g.*, TLR)	HMGB1 and nucleic acids
Ib	Promoting *DC activation* as recognized by nonclassical pattern recognition receptors (scavenger receptor CD91, purinergic receptor P2X7)	CALR and eATP
II	Second signal to NLRP3 inflammasome formation, giving rise to *monocyte activation*	Uric acid and eATP
III	Assisting *DC maturation* as exposed on stressed cells and sensed by NKG2D on natural killer cells	MICs
IV	Neoepitopes contributing to *DC activation*, as they are recognized by IgM antibodies, which activate the complement cascade	Oxidized phospholipids and actin cytoskeleton
V	Dyshomeostasis-associated molecular patterns sensed by NLRP3 receptor or UPR receptors of stressed cells, thereby contributing to an inflammatory milieu	Accumulation of unfolded proteins in the ER, ion perturbations and redox stress

An attempt to classify cell-death-associated damps.
DC, dendritic cell; HMGB1, high mobility group box-1; CALR, calreticulin; eATP, extracellular ATP; NK, natural killer; NKG2D, natural killer group 2 member D; MIC, MHC class I chain-related proteins; NLRP3, NOD-like receptor family, pyrin domain containing 3; ER, endoplasmic reticulum

ACKNOWLEDGEMENTS

MULTIPLE-CHOICE QUESTIONS

1. Which regulated cell death is the least immunogenic?
   A. Necroptosis
   B. Apoptosis
   C. Pyroptosis
   D. Ferroptosis
   E. Mitochondrial necrosis

2. Inflammasomes induce which pathway of regulated necrosis?
   A. Necroptosis
   B. Apoptosis
   C. Pyroptosis
   D. Ferroptosis
   E. Mitochondrial necrosis

3. Therapeutic interference with regulated necrosis (RN) is on the horizon, and a plethora of potential targets have arisen. Which RN pathway can be effectively inhibited *in vivo* by application of receptor interacting protein kinase 1 (RIPK1) inhibitors, the so-called “necrostatins”?
   A. Necroptosis
   B. Apoptosis
   C. Pyroptosis
   D. Ferroptosis
   E. Mitochondrial necrosis

The Microbiota in Immunity and Inflammation

Craig L. Maynard

Humans and other species of mammals are hosts to an array of microbial communities collectively referred to as the *microbiota.* The microbiota comprises prokaryotes (bacteria and archaea), viruses (bacteriophages as well as eukaryotic viruses), and eukarya or the meiofauna (mainly fungi and protozoa). As revealed by the Human Microbiome Project, specialized subcommunities colonize barrier surfaces of the digestive, respiratory, and urogenital tracts, and skin. Our immune system is believed to have evolved to ensure peaceful coexistence with these microorganisms that aid in immune homeostasis, pathogen resistance, and digestion in exchange for a nutrient-rich habitat. There is a perpetual cross-talk between the microbiota and the immune system throughout an individual's life. Specific modulation of this microbiota, particularly in infancy, has important long-term health consequences. Addition of specific symbionts to the microbiota can provide tangible health benefits. Reconstitution of a dysbiotic microbiota continues to be utilized or explored as therapy for inflammatory diseases.

OVERVIEW OF OUR NONMAMMALIAN "SELF"

Exposure to the microbiota and its products occurs via a gradual, ordered process. It begins *in utero* and accelerates during and after birth. The overall composition of an individual's microbiota is impacted by such phenomena as the method of birth delivery, diet, treatment with antibiotics, and environmental exposures. All of these modifying factors can have lasting effects on immune health.

Prokaryotes

The bacterial component of our microbiota is, by far, the most widely studied. This has been made possible, in part, by a fairly recent explosion of genomic and bioinformatics capabilities that has enabled taxonomic identification, and even enumeration, of the members of microbial communities without the need for bacterial culture. Two phyla—Bacteroidetes and Firmicutes—account for almost 90% of intestinal bacteria. The remainder comprises organisms belonging to the phyla Cyanobacteria, Proteobacteria, Actinobacteria, Fusobacteria, and Verrucomicrobia.[1] The bacteria that colonize humans belong mainly to three major phyla: Bacteroidete, Firmicutes, and Proteobacteria. It is estimated that the average human being plays host to approximately 100 trillion bacteria. Most of these cells inhabit the lumen of the gastrointestinal (GI) tract. The density of bacteria increases from ≈10^2–10^3 bacterial cells per mL in the stomach to 10^{12} cells/mL in the distal large intestine (Fig. 14.1). The sheer number of bacteria sets the stage for a very complex relationship between the mammalian immune system and the microscopic inhabitants of the various barrier surfaces.

Viruses

The viruses that inhabit mammalian hosts can be subdivided into bacteriophages, which infect prokaryotic cells; eukaryotic viruses, which infect host and other eukaryotic cells; and virus-derived genetic elements, which can incorporate into host chromosomes and result in the generation of infectious virus at a later date. It has been difficult to quantify the exact size of the *virome.* In the case of bacteriophages, it is generally accepted that they can exist in 10-fold greater numbers than prokaryotes. Bacteriophages can have profound effects on the structure and functions of intestinal prokaryotic communities via viral gene transfer of virulence factors and antibiotic-resistant genes between prokaryotic organisms or through predator–prey relationships. Indeed, the infectivity of some enteric viruses requires the microbiota.[2] Eukaryotic viruses include a vast array of viruses that permanently infect the host and can exist for decades in asymptomatic individuals. These viruses can persist locally or systemically. They can directly impact tissue-specific immunity, including in the GI tract.

Fungi

Collectively referred to as the *mycobiota,* fungal communities represent a considerably smaller proportion of the total microbes in the human body. Commensal fungi can be detected in the mouth, lungs, intestines, vagina, and skin (Fig. 14.2). Advances in our knowledge and understanding of the size and functions of the mycobiota have been hampered by relatively limited genomics and bioinformatics capabilities when compared with the study of bacteria or viruses. However, studies utilizing broad-spectrum antifungal agents have begun to highlight the possible roles played by fungi in protecting against disease processes, such as inflammatory bowel disease (IBD) (Chapter 75).

The microbes that inhabit the human body are often acceptably referred to as the *commensal microbiota,* which in the strictest sense refers to organisms that derive benefit from their host without negatively or positively affecting the host. Although this is true of some members of the microbiota, our relationship with other microbes is one of *mutualism,* whereby each organism performs unique and necessary functions that benefit the other. For example, certain bacteria find a home in the anaerobic environment of the cecum and proximal colon, where they receive a rich source of nutrients in the form of insoluble carbohydrates, which our own digestive enzymes are unable to process. By the process of anaerobic fermentation, these carbohydrates are broken

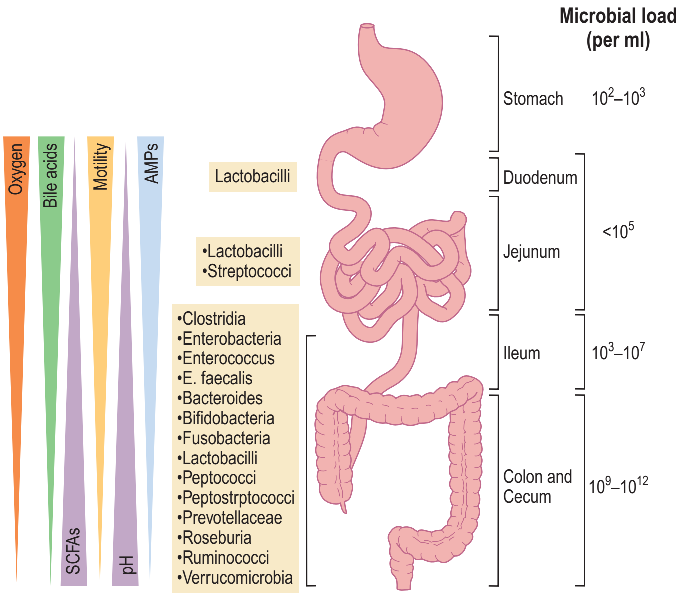

FIG 14.1 **Spatial Organization of Microbial Communities and Physiological Gradients Along the Mammalian Gastrointestinal (GI) Tract.** The numbers and types of bacterial communities, as well as physiological factors, vary along the length of the GI tract. It is well-appreciated that the oxygen levels, bile acid concentrations, intestinal motility, antimicrobial peptides (AMPs), and luminal pH in the proximal portion of the GI tract (stomach, duodenum, jejunum) play major roles in restricting the numbers and types of microorganisms. In general, aerobic and facultative anaerobic bacteria are found almost exclusively in the proximal portion of the GI tract. The hypoxic nature and more physiological pH of the distal small intestine (ileum) and colon, coupled with overall reductions of bile acids, AMPs, and gut motility, allows for unfettered growth of large numbers of obligate anaerobic bacteria. These oxygen-sensitive microbes are capable of producing large quantities of short-chain fatty acids (SCFAs; acetate, propionate, butyrate) from complex carbohydrates (fiber) to be used for important colonic and immunological processes. (From: Reinoso Webb C, Koboziev I, Furr KL, Grisham MB. Protective and pro-inflammatory roles of intestinal bacteria [Figure 2]. Pathophysiology 2016;23:67–80.)

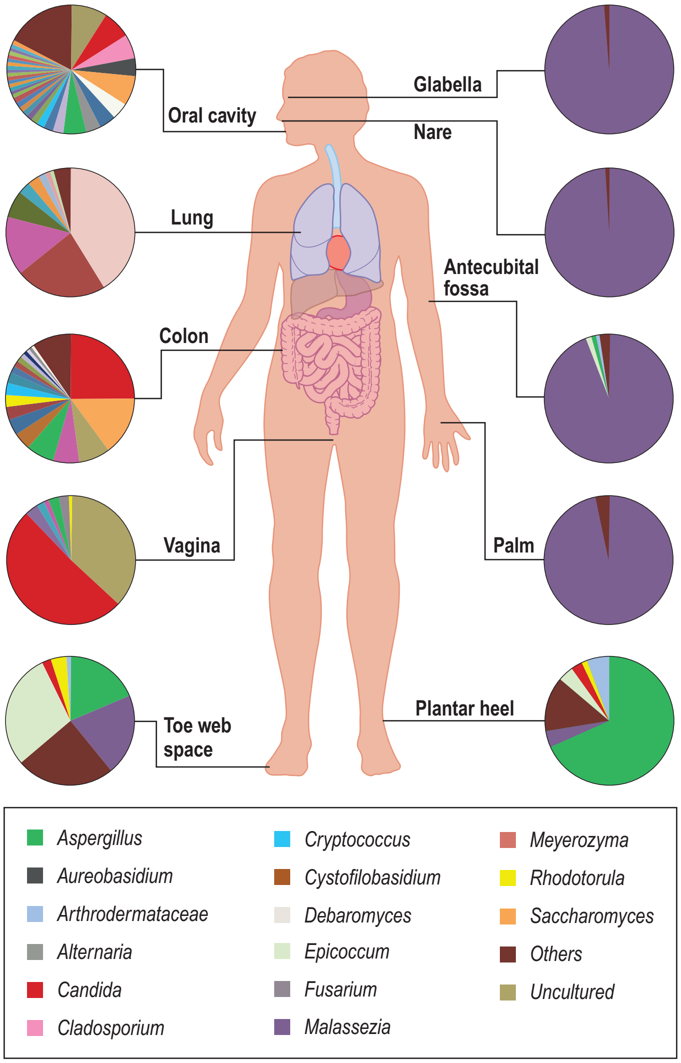

FIG 14.2 **The Human Mycobiota.** Complex populations of fungi have been found associated with the skin and all mucosal surfaces of the healthy human body. The pie charts indicate the relative proportions of fungal genera that are reported to be associated with the respective sites in representative fungal deep-sequencing studies. The fungal populations that are found on mucosal surfaces tend to be more diverse than those on the skin. The healthy lung probably reflects mostly environmental fungi, which are not included in the key. "Others" refers to sequences that represent <1% of the total recovered sequences at each site. "Uncultured" refers to sequences identified in the National Center for Biotechnology Information (NCBI) GenBank database as fungal, but of uncharacterized, origin. Data for pie charts were derived from studies of the fungal genera that are present in the oral cavity, lungs, colon, vagina, and skin. (From: Underhill DM, Iliev ID. The mycobiota: interactions between commensal fungi and the host immune system [Figure 1]. Nat Rev Immunol 2014; 14:405–416.)

down to generate short-chain fatty acids including butyrate, which not only is utilized preferentially by colonocytes but also impacts host immunity and metabolism. Obviously, parasitic or harmful microbes are not considered part of the commensal microbiota, although organisms that fit this definition can often coexist with the microbiota without driving overt disease under homeostatic conditions. More recently, the term *pathobiont* has been coined and is used to refer to any microbe that peacefully colonizes its host but can evoke severe inflammatory responses under specific genetic and/or environmental conditions.

IMMUNE PREPARATIONS FOR MICROBIAL COLONIZATION

Within the last few years, it has become obvious that the developing fetus may be exposed *in utero* to a microbiota or microbial products acquired via the placenta and/or maternal circulation.[3] The acquisition of microbial communities continues with the passage of the fetus through the birth canal and culminates in the first 2–5 years of life in humans. Despite the vast array of microbes that take up residence in the host, colonization is usually an ordered process that, in most cases, is well tolerated. This is because of a robust antimicrobial defense system that is initiated prenatally and fortified postnatally, simultaneous with rapid microbial colonization.

KEY CONCEPTS

Definitions

- **Microbiota**: A collective term for all the microscopic organisms that reside on or in the human body.
- **Microbiome**: The combined genomes of all the organisms that constitute the microbiota.
- **Mycobiota**: That subset of the microbiota that includes fungi alone.
- **Virome**: the collection of all viruses, including viruses integrated into the human genome, found in or on humans.
- **Dysbiosis**: A condition in which there is disequilibrium of the microbial communities that constitute the microbiota at a given body site.
- **Germ-free**: Experimental animals birthed and raised in a sterile environment, devoid of microbes.
- **Gnotobiotic** ("known life"): Describes animals in which the full complement of colonizing microbes is known.

Prenatal Development of the Immune System

In the fetal liver, some common lymphoid progenitor cells—ancestral to all lymphocytes—develop into a specialized subset of innate lymphoid cells (ILCs) referred to as *lymphoid tissue inducer (LTi) cells.*[4] As their name implies, LTi cells are essential for the development of all secondary lymphoid structures throughout the body. These structures will eventually become the sites for initiation of immune responses to the commensal microbiota, pathogenic invaders, and self antigens. In the developing fetus, LTi cells promote the development of mesenteric lymph node (MLN) and of the Peyer patches (PPs) (Chapters 2 and 20) in the distal ileum (Fig. 14.3). They also recruit B and T lymphocytes to these tissues and facilitate their organization into distinct B-cell follicles and T-cell zones, respectively. Throughout life, the MLN provides a so-called mucosal firewall that prevents systemic dissemination of gut bacteria.

Other local mechanisms are also initiated to limit host collateral damage to the neonatal intestine by early microbial encroachment. For example, Toll-like receptor 4 (TLR4), the receptor for lipopolysaccharide (LPS) that is derived from gram-negative bacteria, is highly expressed by intestinal epithelial cells (IECs) prior to birth, but its expression and signaling are rapidly downregulated following onset of colonization. In addition, a diverse array of lymphocytes collectively referred to as intraepithelial lymphocytes (IELs) can be found intercalated between the IECs. IELs display multiple features of activated cells and participate in the maintenance of epithelial barrier integrity by limiting bacterial translocation and promoting epithelial repair following injury.[5]

Passive Acquisition of Antimicrobial Immunity

The microbiota of the neonate is acquired from his or her mother, who has already established tolerogenic relationship with the same microbiota. The mother's "mucosal memory" also gets transmitted to her offspring. During transvaginal delivery, this mucosal memory is seeded with the mother's native microbiota. Mothers produce antibodies to bacteria-derived antigens. These bacteria-responsive antibodies enter the maternal circulation and ultimately get passed to the offspring in breast milk. Immunoglobulin A (IgA) is the major antibody isotype generated by mammary glands (Chapter 15). IgA inhibits bacterial translocation across the neonatal intestinal epithelium, thereby limiting collateral damage by an encroaching microbiota and providing passive immunity to pathogenic infection.[6] The offspring also acquires antibodies of the IgG isotype both *in utero* and via the breast milk. These antibodies serve to limit enteric infection in the newborn[7] and dampen neonatal mucosal T-cell and germinal center (GC) B-cell responses to commensal antigens.[8] Maternally acquired anticommensal antibodies can transfer bound microbial molecules to the offspring during gestation and via the breast milk. This transfer of microbial products contributes to the earliest education of the immune system and limits deleterious postnatal inflammatory responses.[3] Breast milk is also a rich source of immunosuppressive transforming growth factor-β (TGF-β) and interleukin-10 (IL-10) (Chapter 9), which also help promote tolerogenic responses to the microbiota.[9,10]

MICROBIOTA-DEPENDENT MATURATION OF THE INTESTINAL IMMUNE SYSTEM

Microbial colonization prompts a rapid organization of immune structures that are quickly seeded with immune cells. This process helps avoid overexuberant responses to the microbiota and sets the stage for continued tolerance of commensals and for defense against pathogens in the future. The intestinal epithelium limits direct encounter between luminal microbes and the immune cells in the underlying lamina propria not only by forming a physical barrier but also by the production and/or transport of immune and antimicrobial factors (Fig. 14.4). Thus the epithelium is an essential component of the elaborate network of checks and balances that synergize to help to keep pathogens at bay while limiting or preventing collateral damage induced by pathogens and commensals.

Gut-Associated Lymphoid Tissues

Although MLN and Peyer patches begin to develop before birth, complete maturation does not occur until after birth. Germ-free or "germ-reduced" mice display reduced size and cellularity and altered numbers and distribution of immune cells both in the gut and gut-associated lymphoid tissues (GALTs). Thus maturation of the mucosal immune system is contingent on the acquisition of microbiota. A third type of secondary lymphoid tissue—isolated lymphoid follicles (ILFs), which are also induced by LTi cells—is also completely dependent on colonization with the microbiota and thus only develops postnatally.

LTi cells cluster at the base of the crypts in structures referred to as *cryptopatches.* Stimulation of cryptopatches by peptidoglycan derived from gram-negative bacteria induces recruitment of B cells, thereby forming ILFs. The importance of ILFs in the direct control of bacterial growth is demonstrated by the fact that mice devoid of mature ILFs display an overrepresentation of gram-negative bacteria.[11]

Innate Lymphoid Cells

ILCs represent an early line of defense at mucosal surfaces. ILCs are classified as LTi or "LTi-like" (described above) cells or as "helper-like" cells. The progenitor of helper-like ILCs is distinct from that of LTi cells or natural killer (NK) cells. "Helper-like" ILCs are classified into three main subcategories based on their expression of particular sets of surface receptors, transcription factors, and secreted proteins. Unlike their adaptive, thymus-derived counterparts, ILCs do not express antigen receptors and are therefore activated by cytokine signals. This enables ILCs to launch an initial rapid response to microbial challenge and facilitate the development of an adaptive lymphocyte-mediated immune response. ILC1s, such as T-helper type 1 (Th1) cells, express the transcription factor Tbet and secrete interferon-γ

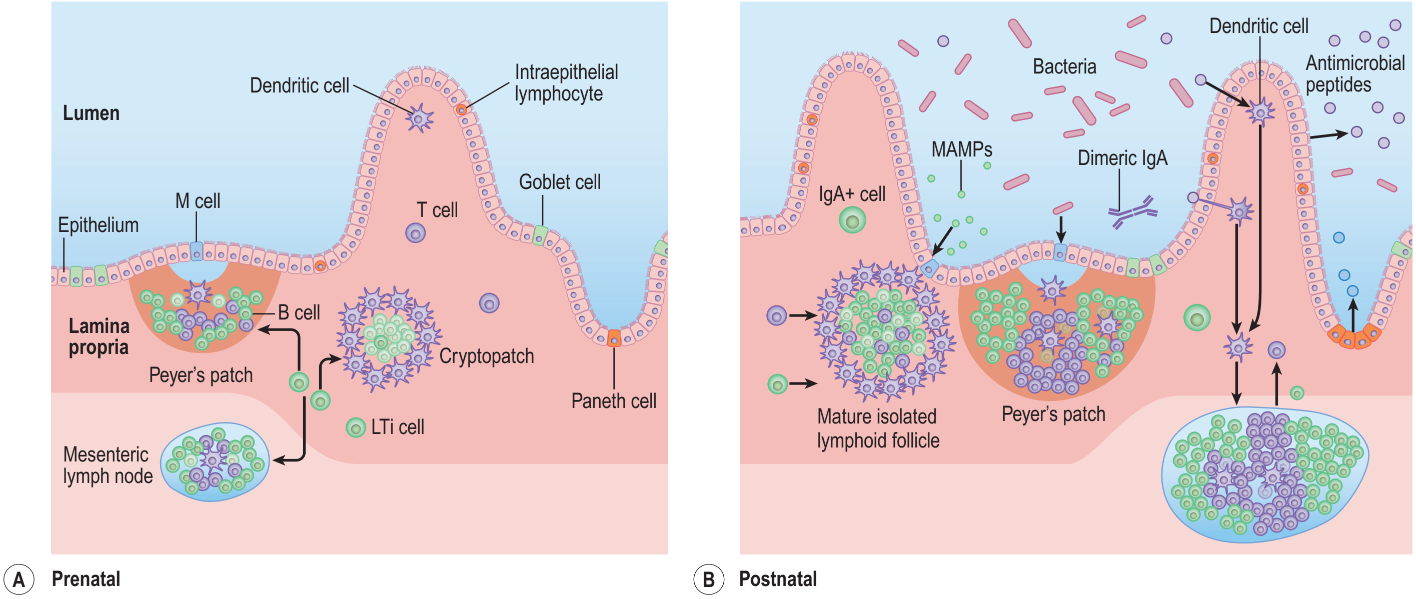

FIG 14.3 The Gut-Associated Lymphoid Tissue (GALT) Establishes Perinatal Host–Microbiota Mutualism in the Intestine. (A) Prenatally, secondary lymphoid tissues (Peyer patches and mesenteric lymph nodes) and cryptopatches develop by the spatiotemporal recruitment of lymphoid tissue inducer (LTi) cells to sites of the developing intestine and supporting neurovascular structures. This, in turn, stimulates the recruitment of dendritic cells (DCs), T cells, and B cells in preparation for the immune response to the microbiota. Intraepithelial lymphocytes (IELs) seed the epithelium before birth. (B) Postnatally, bacteria colonize the neonatal intestine immediately, initiating multiple events that affect the development or functional maturation of the mucosa and GALTs. *Shown from left to right:* Microbe-associated molecular patterns (MAMPs) sensed by pattern-recognition receptors on intestinal epithelial cells and DCs adjacent to cryptopatches stimulate the further recruitment of B cells and T cells, causing the cryptopatches to develop into mature isolated lymphoid follicles. The isolated lymphoid follicles release immunoglobulin A (IgA)–producing plasma cells, which are formed through T cell–dependent and independent interactions, into the lamina propria. Microbes also cross the epithelium and enter the Peyer patch through M cells, from which they are endocytosed by the DCs in the subepithelial dome. Antigen-loaded DCs in the Peyer patch interact with local lymphocytes to induce T-cell differentiation and T cell–dependent B-cell maturation in the germinal center (GC) to induce the development of IgA-producing plasma cells that home to the lamina propria, where they release dimeric IgA for transport into the intestinal lumen. DC-mediated luminal sampling of microbial products or transcytosis of bacteria across the epithelium results in antigen loading of the lamina propria DCs, which then migrate through the afferent lymphatics vessels (not shown) to a draining mesenteric lymph node to induce differentiation of effector T cells that traffic to the lamina propria. Shown on the far right, sensing of microbe-associated molecular patterns (MAMPs) stimulates the proliferation of intestinal epithelial cells in crypts, resulting in their increased depth and, in the small intestine, increased density of Paneth cells. This sensing also arms the intestinal epithelial cells for release of antimicrobial peptides. (From Maynard CL, Elson CO, Hatton RD, Weaver CT. Reciprocal interactions of the intestinal microbiota and immune system [Figure 1]. Nature 2012;489:231–241.)

(IFN-γ) and tumor necrosis factor-α (TNF-α) in response to intracellular bacteria. ILC2s, similar to Th2 cells, express GATA3 and secrete IL-13 and IL-5. ILC3s are arguably the most complex subset of ILCs and can be subdivided into "LTi-like" ILC3s, which populate the intestinal lymphoid follicles, and the more plastic NKp46$^+$ ILC3s, which are distributed throughout the intestinal lamina propria. Both subsets express retinoic acid–related orphan receptor (ROR)γt and produce IL-22 and IL-17, although NKp46$^+$ ILC3s can also express Tbet and secrete IFN-γ.[12]

The impact of the microbiota on ILC3 accumulation appears to commence *in utero*, as transient colonization of pregnant germ-free mice with nonpathogenic *Escherichia coli* increases accumulation of NKp46$^+$ ILC3s and F4/80$^+$CD11c$^+$ mononuclear cells in newborn pups.[3] In the normal intestine, ILC3s are the dominant source of IL-22.[12] The microbiota, acting on innate cells, including macrophages and dendritic cells (DCs), induces expression of IL-23, which, in turn, stimulates the production of IL-22 and/or IL-17 by ILC3. IL-22 can induce the secretion of antimicrobial peptides, such as RegIIIγ, by intestinal epithelial cells to limit bacterial invasion, and within GALT to prevent systemic dissemination of resident microbes. Throughout life, ILC3 expressing Major Histocompatibility Complex (MHC) class II molecules (Chapter 5) on their cell surface help regulate the pool size and function of commensal-specific CD4 T cells to prevent spontaneous inflammation.[13]

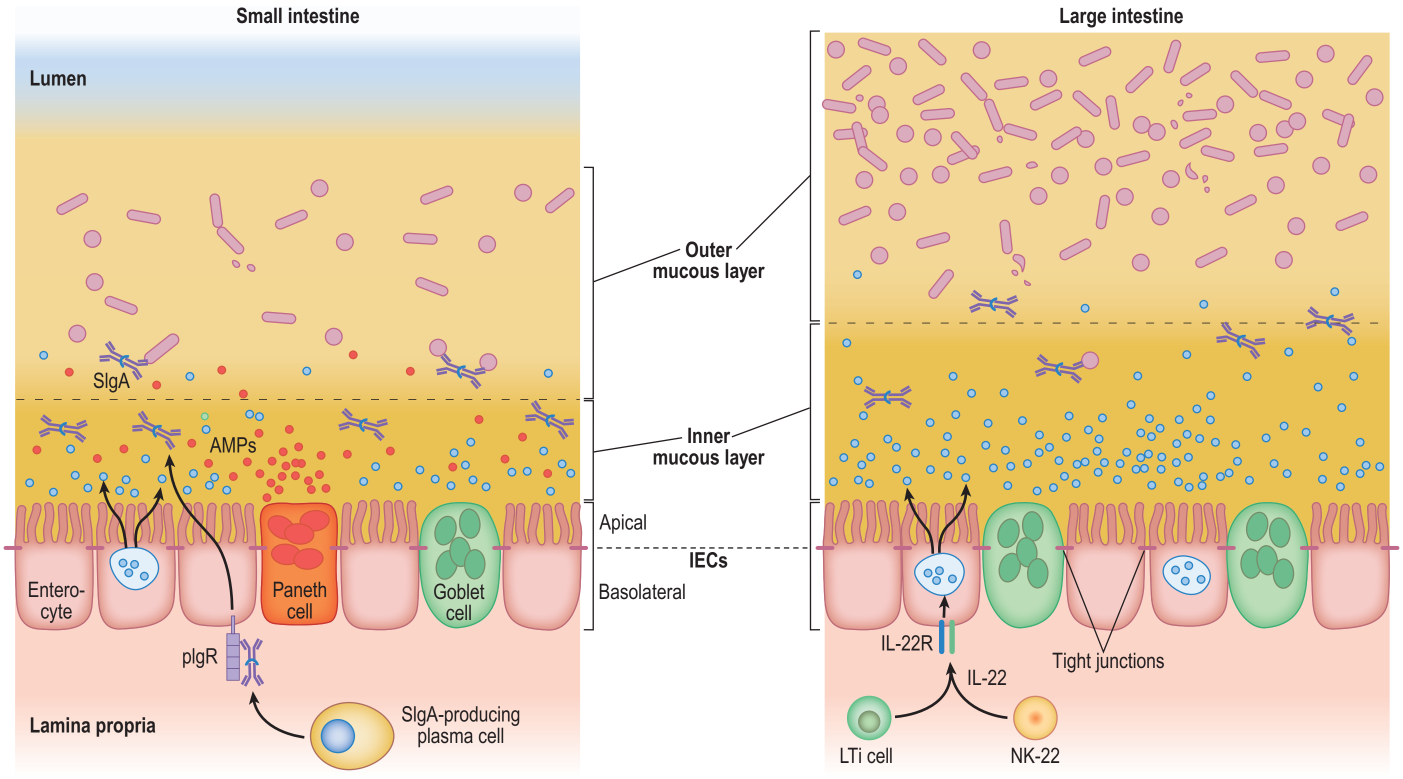

FIG 14.4 Active Barrier Functions of the Intestinal Epithelium. The intestinal epithelium comprises a single layer of polarized columnar epithelial cells (IECs), sealed by tight junctions. Specialized cells known as *goblet cells* secrete mucins that form a bilayered mucus sheath, which maintains separation between the luminal bacteria and the epithelium. The thicker inner mucus layer is sparsely populated with bacteria, whereas the outer layer is more loosely structured and contains ≈10-fold more bacteria. Paneth cells within the epithelium secrete defensins which, along with epithelial-derived antimicrobial peptides, further help with bacterial containment. Epithelial cells also transport antibodies into the lumen and transmit cytokine signals that help maintain barrier integrity.

Invariant Natural Killer T Cells

A unique subset of thymus-derived cells, invariant NK T (iNKT) cells (Chapter 17) express an invariant T-cell receptor (TCR) (Chapter 4) that recognizes lipid antigens presented by the nonclassic MHC class I molecule CD1d (Chapter 5). iNKT cells are essential for the ulcerative colitis–like phenotype that develops in experimental mice treated with the chemical compound oxazolone. Studies on the role of the microbiota in iNKT cell expansion and function provided an elaborate example of the how early postnatal colonization can profoundly impact the maturation and long-term function of the immune system. Germ-free mice harbor increased numbers of iNKT cells in both the colon and the lung, and correspondingly demonstrate increased severity of experimental colitis and asthma. The disease phenotype can be reduced to that of conventionally raised mice if germ-free mice are colonized with commensals in the neonatal period, but not during adulthood.[14]

Regulatory T Cells

Regulatory T cells (Tregs) (Chapter 18) are crucial to the establishment and maintenance of immune homeostasis. Mice or humans with absent or defective expression of the signature Treg transcription factor Foxp3 (FOXP3 in humans) succumb to spontaneous multiorgan autoimmune disease very early in life. Commencing in the first few days of life, FOXP3$^+$ Tregs are exported from the thymus to seed every lymphoid and nonlymphoid tissue. Most Tregs in the intestine express Foxp3, and most of these coexpress IL-10, TGF-β, and IL-35. However, other FOXP3$^-$ subsets also exist including IL-10-producing Tr1 cells, as well as the CD4CD8αα T cells in the human lamina propria.[15]

Commensal-specific Foxp3-expressing Tregs in the intestinal lamina propria are potentially a mixture of thymic-derived Tregs (tTregs) and peripherally induced Tregs (pTregs).[16] In support of the latter, mice deficient in their ability to generate extrathymic Foxp3$^+$ Tregs spontaneously develop intestinal pathology late in life. Colonization of germ-free mice with a benign cocktail of eight commensal microbes, collectively referred to as *altered Schaedler flora,* is sufficient to induce expansion and accumulation of Foxp3$^+$ cells in the large intestine, approaching the levels seen in conventionally raised mice. However, a case has been made for the ability of specific bacteria and/or bacterial components to uniquely promote Treg induction. For example, a cocktail of 46 mouse *Clostridium* strains potently induced expansion of colonic Foxp3$^+$ cells.[17] This cocktail, which has since been reduced to 17 strains derived from a single human donor, and recapitulates the phenotype in germ-free mice.

Several factors produced or induced by gut microbes have been shown to be essential for microbiota-dependent Treg accumulation, particularly in the colonic lamina propria. The capsular polysaccharide A (PSA) moiety of *Bacteroides fragilis,* which mediates the interaction between the bacterium and the colonic mucosa, can also act via the TLR–MyD88 pathway to promote expansion of IL-10–producing colonic Tregs.[18] Clostridial strains stimulate production of TGF-β by intestinal immune cells. This, in turn, enhances Foxp3$^+$ Treg induction. Clostridia are also very adept at anaerobic fermentation of indigestible fiber. Thus their production of butyrate might be another mechanism whereby they can enhance accumulation of Foxp3$^+$ Tregs in the colonic lamina propria.[19]

CD4 T-Helper Cells

In the intestines of both mice and humans, both IFN-γ–producing Th1 and T-helper "IL-17–producing" (Th17) cells are present (Chapter 16). Although detectable even at steady state, these populations, reactive to microbial antigens, are largely held in check by the intestinal immunoregulatory system. In some cases, expression of the Th cell signature (transcription factors and cytokines) of distinct lineages can overlap with each other or with the Treg transcription factor Foxp3, denoting either a common progenitor or the dynamic lineage transitions that can ensue in response to competing immune signals. In the absence of regulatory pathways, for example, in IL-10 deficiency, the numbers and frequencies increase gradually, coincident with the onset of chronic inflammation. The same is true during GI infection (see below), where the ability of invasive bacteria or viruses to enter a cell, or the physical interaction of the bacteria with the intestinal epithelium, culminates in induction and expansion of Th1 and Th17 cells, respectively, in the intestinal lamina propria.

Mucosal B Cells

With increasing colonization comes an increased likelihood of epithelial breach, particularly by bacteria capable of penetrating the inner mucus layer and gain access to the intestinal epithelium. By intercalating dendrites between epithelial cells and into the lumen, DCs in the intestinal lamina propria are able to sample the luminal bacteria. These antigen-loaded DCs migrate to the mesenteric lymph nodes, where they interact with B and T cells to induce B-cell production of anticommensal IgA. These IgA-producing plasma cells migrate to the intestinal lamina propria, where they secrete IgA dimers that migrate across the epithelium and into the lumen. There they bind commensals and thus limit their translocation. In germ-free mice, the absence of the microbiota and resultant absence of IgA production is seemingly replaced by IgE class switching (Chapter 4) in mucosal lymphoid tissues and a corresponding increase in susceptibility to oral antigen-induced systemic anaphylaxis.[20] Therefore the microbiota itself helps limit hyperreactivity to allergens and parasite challenge throughout an individual's life.

IMMUNE CONSEQUENCES OF EARLY MICROBIAL MANIPULATION

Because the microbiota is so essential to the early postnatal maturation of the immune system, the consequences of manipulation or insufficiency of the microbiota can impact host immunity throughout life. Microbial disruption, particularly during the neonatal–infancy period, is being associated with increased risk of autoimmunity and chronic inflammation later in life.

The increasing incidence of autoimmune disease in industrialized countries has been linked to use of antibiotics,[21] improved sanitation, and consumption of processed foods rich in fat and carbohydrates but negligibly low in fiber.[22] These practices limit microbiota diversity and deplete the bacteria that "educate" the developing immune system, leaving it prone to overreaction to subsequent challenges.

There are several observational, clinical, and epidemiological reports, supported by a growing body of experimental findings in support of this concept. For example, vancomycin treatment in young mice increases their susceptibility to asthma as well as food allergy, in large part as a result of depletion of clostridial strains known to promote colonic Treg induction and expansion. Early life treatment with low-dose antibiotics results in increased risk susceptibility to obesity and corresponding alterations in immune gene expression in the ileum. Individuals who had limited sanitary amenities during childhood or were raised around livestock are at reduced risk of developing IBD (Chapter 75) during adulthood. This latter phenomenon is commonly attributed to the acquisition of a diverse microbiota in these microbially enriched environments. However, such living conditions also pose an increased risk of parasitic helminth infection. This concept is supported by experimental data showing that treatment with *Trichuris muris* prevents development of experimental colitis in mice deficient for the IBD-related gene *Nod2*.

IMMUNE SYSTEM—MICROBIOTA CROSS-TALK IN INTESTINAL INFLAMMATION

The immune system and the microbiota are in constant dialogue at steady state. Throughout an individual's life, the microbiota undergoes transient shifts in response to external influences. These include infections; medications, such as antibiotics; and dietary changes. The timing, magnitude, and targets of these perturbations can result in immune responses aimed at resetting this balance or limiting host collateral damage. Furthermore, feces of patients with certain extraintestinal chronic inflammatory diseases also display reduced microbial abundance and diversity relative to their healthy counterparts. This may reflect the role of the intestinal microbiota in the etiology of diseases, the impact of tissue-specific inflammation on the microbiota, or both.

Gastrointestinal Infection

The microbiota helps provide resistance to pathogenic invasion at mucosal sites. This can occur either indirectly by enhancing barrier defenses through various immune and nonimmune mechanisms or directly by competing with harmful microbes. Nevertheless, several organisms still manage to breach these defenses. Such pathogen invasion induces production of proinflammatory cytokines by innate cells that can appropriately expand the magnitude of the immune response by signaling the differentiation of Th cells. The soluble products of these cells recruit other immune cells and collectively aid in pathogen eradication and sometimes in repairing any physical damage to the intestinal barrier. Unimpeded inflammatory responses can be destructive to host tissue, and thus immunosuppressive mechanisms are induced that help to restore immune homeostasis.

In a healthy host, GI infections are largely self-limiting. However the temporary disruption of microbial homeostasis (*dysbiosis*) can have lasting effects on host health. In the cases of *Salmonella enterica* serovar *typhimurium* (*S. typhimurium*) and *E. coli* infection in mice, the associated inflammation can drive production of substances that favor pathogen growth or enable the pathogen to outcompete resident microbes. The inflammatory response to the enteric pathogen *Citrobacter rodentium* promotes a restructuring of the microbiota that can predispose to chronic inflammation. Similarly, *Yersinia pseudotuberculosis* infection results in chronic inflammation and long-term defective lymphatic communication between the gut and mesenteric lymph nodes. These changes are supported by the dysbiotic microbiota.[23]

Infection of mice with the protozoan parasite *Toxoplasma gondii* (*T. gondii*) induces production of IL-12, which, in turn, promotes the differentiation of IFN-γ–secreting Th1 cells. IFN-γ is essential for pathogen control and promotes dysbiosis via targeted destruction of Paneth cells. The production of IL-10 by a subset of the Th1 cells helps overcome the inflammation, whereas IL-10–deficient mice succumb to the infection. Even when the infection is controlled, however, the brief disruption in Treg homeostasis enables systemic dissemination of commensal bacteria and a temporary disruption in tolerance to the microbiota.[24]

Certain microbes also induce specific immune responses simply by their physical interaction with host cells. The ability of certain bacteria to bind directly to the intestinal epithelium is central to their ability to provoke a Th17 cell response that culminates in the accumulation of these cells in the underlying lamina propria. In mice, this is vividly displayed following infection with bacterial species, including the *Clostridium* spp., *Candidatus arthromitus* (segmented filamentous bacteria [SFB]), *Citrobacter rodentium,* and enterohemorrhagic *E. coli* (EHEC) O157:H7, which can breach the mucous barrier and adhere directly to intestinal epithelial cells. In the case of *C. rodentium* and EHEC, this results in a temporary effacing of the epithelial cell layer, local inflammation, diarrhea, and weight loss and in robust induction of Th17 cells. The same phenomenon can be reproduced if germ-free mice are colonized with *E. coli* –adherent bacteria derived from patients with ulcerative colitis.[25] Production of IL-17 as a result of the presence of SFB in the terminal ileum provides colonization resistance to *C. rodentium.* Induction of this immune pathway is stimulated by a microbial breach and helps restore epithelial integrity and limit further invasion. This provides an explanation for the therapeutic blockade of IL-17 being ineffective in the treatment of IBD, and even exacerbating the disease, even though it was successful in reversing symptoms of psoriasis (Chapter 64).[26]

Inflammatory Bowel Disease

IBD is a collective term that refers to a group of chronic relapsing–remitting inflammatory disorders that can occur anywhere along the GI tract. The two main forms of IBD, Crohn disease and ulcerative colitis, have similar clinical presentations but can differ in terms of histopathological features, affected sites, and risk of malignancy. Although disease onset can be impacted by a vast array of genetic, environmental, and immune factors, IBD is characterized by dysregulated immune responses to microbial antigens.

Although no single causative microbe or microbial cluster has been identified, there is strong correlative evidence in support of a dominant role for the microbiota in disease development and function. First, antibiotic therapy continues to be very effective in patients with inflammation in the lower bowel.[27] Second, in treatment-naïve patients with IBD, there is increased abundance of mucosa-associated pathobionts, including Enterobacteriaceae, Pasteurellaceae, Veillonellaceae, and Fusobacteriaceae. Conversely, a decrease in "beneficial" microbes, including Erysipelotrichales, Bacteroidales, and Clostridiales, has been observed. Reduced abundance of *Faecalibacterium prausnitzii,* a member of *Clostridium* cluster IV that induces an antiinflammatory phenotype in immune cells, has also been associated with IBD and risk of relapse in distinct patient cohorts. Whether dysbiosis is a cause or consequence of disease is debatable. Dysbiosis can occur in disease-free relatives of patients with IBD,[28] which is consistent with a genetic influence on microbiota composition. However, several inflammatory mediators very effectively promote dysbiosis in experimental systems, supporting the notion that inflammation precedes microbial disruption.

Genome-wide association studies (GWAS; Chapter 33) of diverse populations of patients with IBD of different races, ethnicities, and geographical locations have all identified over 160 genetic loci that harbor polymorphisms that segregate with clinical disease. Several of the genes identified encode immune-related proteins involved in detecting and/or responding directly to microbial products, inducing or amplifying the immune response to microbial challenge, or restoring and/or maintaining immune homeostasis with intestinal microbes.[29]

The first gene to be causally linked to IBD is *NOD2,* which encodes the nucleotide-binding oligomerization domain–containing protein 2, a microbial sensor that enables the immune system to recognize and respond to intracellular fragments of bacterial peptidoglycan.[30] Loss-of-function (LOF) mutations in *NOD2* (*i.e.,* defective microbial recognition) predisposes to intestinal inflammation, but only in response to infection or injury. This is consistent with the "multiple hit" model of IBD pathogenesis. *NOD2* deficiency is associated with reduced numbers of intestinal goblet cells and therefore reduced mucous production, hyperactive IELs in the small intestine, and increased expansion of the commensal *Bacteroides vulgatus.*[31] Interestingly, all of these abnormalities can be prevented in mice infected with the helminth *Trichuris muris.* Nevertheless, to date, helminth infection as a therapy for human IBD has been largely unsuccessful.

Another immune-related IBD risk allele identified by GWAS is *IL10,* which encodes the immunosuppressive cytokine, IL-10. In addition, rare LOF mutations in *IL10RA,* or *IL10RB,* which encode the IL-10 receptor α and β chains, respectively, are found in a subset of patients with very-early-onset IBD. Mice with global or even CD4- or Foxp3-specific deletion of *IL10* develop spontaneous colitis, which is dependent on the presence of the microbiota. The importance of the microbiota is highlighted by the varying kinetics and severity (ranging from complete protection to severe inflammation) of disease in different animal colonies or even in the same colony at different points in time. Disease is more consistent and severe and can even progress to colorectal cancer in mice colonized with *Helicobacter* spp. Thus IL-10, which can be produced by multiple hematopoietic and nonhematopoietic cells, is critical for maintaining tolerance to the microbiota, particularly in the presence of species that can progressively disrupt the homeostasis of the microbiota.

Experimental studies have also suggested a role for the nonprokaryotic inhabitants of the intestines in maintaining the status quo, thus limiting susceptibility to IBD. Fungi interact with the immune system via the receptor dectin-1. A single polymorphism in *CLEC7A,* which encodes dectin-1, has been linked to a severe form of ulcerative colitis. Accordingly, dectin-1 deficiency in mice precipitates increased susceptibility to chemical-induced colitis, and long-term antifungal treatment results in increased severity of acute and chronic experimental colitis.[32]

Members of the virome can either promote or prevent development of IBD-like symptoms via their interactions with intestinal bacteria. Murine norovirus induces inflammation in mice with disruption in the IBD susceptibility gene *Atg16L1*. Antibiotic administration reverses this viral-induced disease.[33] Conversely, antiviral pretreatment of otherwise healthy mice can exacerbate acute experimental colitis by disrupting the production of antiinflammatory IFN-β.[34]

EXTRAINTESTINAL MANIFESTATIONS OF GUT MICROBIOTA–IMMUNE SYSTEM INTERACTION

Obesity develops when energy intake exceeds expenditure and culminates in deposition of excess adipose tissue. The associated chronic complications, collectively and clinically referred to as *metabolic syndrome,* include hyperglycemia, hypertriglyceridemia, dyslipidemia, and hypertension. Studies in mice and humans have revealed that there are alterations in the gut microbiota in certain conditions, such as obesity and associated metabolic diseases brought on by increased gut permeability, immune responsiveness, and aberrant bacterial translocation.

Perhaps the most striking evidence for the direct role of the microbiota in at least sustaining the obese phenotype was seen in mice transplanted with human fecal microbiota from obese or lean cotwins. Mice transplanted with the obese microbiota displayed increased weight gain and adipose tissue relative to those transplanted with the microbiota of the lean cotwins.[35]

Obesity has been associated an increased abundance of Firmicutes relative to Bacteroidetes, and differential responses of the lean and obese microbiota to the caloric content of the diet.[36] The altered composition can also lead to a reduction in microbial gene richness, which, in turn, affects the "inflammatory tone" of the microbiota and likely contributes the chronic low-grade inflammation characteristic of obesity. Lipopolysaccharides (LPSs), also known as endotoxins, derived from the outer cell membrane of gram-negative bacteria, are found at low concentrations in the circulation of healthy individuals but are dramatically increased in obese individuals and even more so in those who develop type 2 diabetes. LPS infiltrates tissues, including the liver and adipose tissues, and the activation of macrophages via TLR4 initiates an innate immune response characterized by secretion of cytokines, including IL-6 and TNF-α. Obesity-related inflammation also contributes to defective insulin signaling or insulin resistance, a major player in the transition from metabolic syndrome to diseases, including type 2 diabetes, hepatic steatosis, and cardiovascular disease.[37]

Although the microbiota (usually fecal) is distinct in certain non-GI diseases, including ankylosing spondylitis (Chapter 57), multiple sclerosis (Chapter 66), and asthma (Chapter 41), whether these changes precede or follow disease development is not clear. One measure might be the effect of microbiota-induced immune mediators on disease pathology in extraintestinal tissues. For example, although gut microbes that can adhere to the epithelial cells induce robust expression of IL-17, their functions in the gut are largely protective. In contrast, microbiota-induced IL-17 can be proinflammatory in extraintestinal tissues. In germ-free mice colonized with SFB and subjected to experimental models of arthritis or multiple sclerosis, severe IL-17–dependent disease develops.[38] Elevated induction of RORγt and IL-17 in the central nervous system is also a hallmark of virus-induced maternal immune activation (MIA), which can lead to autism spectrum disorder (ASD)–like symptoms in a murine model.

CANCER AND THE MICROBIOTA

The tissue-specific immune inflammatory response that is necessary for pathogen eradication or to restore host–microbiota homeostasis can be deleterious to the host if allowed to reach chronicity. In addition to causing permanent tissue damage (scarring), such a chronic inflammatory response predisposes to tumor development and the production of neo-self antigens that are now recognized as foreign to the host. The antitumor immunity that ensues possesses characteristics similar to those of the antipathogen response and ultimately has the same goal—eradication of a foreign body. Likewise, antiinflammatory or regulatory mechanisms are deployed to limit the magnitude and duration of the inflammatory response in an effort to restore immune homeostasis (Fig. 14.5). However, continued tumor growth means that the "foreign" antigens have not been eradicated, and/or new ones are continually being generated. In response

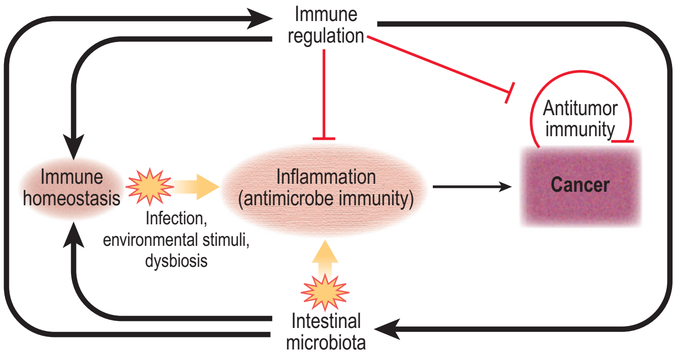

FIG 14.5 **Microbiota–Immunity–Cancer Triad.** The reciprocal interaction of intestinal microbiota and the immune system induces default regulatory pathways that help maintain intestinal immune homeostasis. Factors that promote microbial dysbiosis, such as infection and other environmental insults, can disrupt immune homeostasis. This can result in proinflammatory responses targeting the causative agent, accompanied by immune regulatory responses that aim to reset immune balance. The perpetuation of the inflammatory response enhances the likelihood of progression to cancer. In response to the novel antigens generated in the tumor, an immune response is initiated with the goal of eradicating the tumor. As this response bears similar characteristics to an antipathogen response, it is subject to the same immune suppressive mechanisms.

to cancer, the host immune response needs to persist, rather than being opposed by the host's antiinflammatory arsenal. Thus similar nondiscriminatory immune regulatory mechanisms that are beneficial in curbing inflammation can impede antitumor immunity, thereby enabling tumor growth and eventual dissemination.[39]

There are several immune-related mechanisms whereby microbes directly impact the inflammation–cancer continuum. Some pathogens can promote an inflammatory milieu that encourages tumor development, whereas others can directly transform the eventual tumor-initiating cells. Oncogenic bacteria, including certain strains of *Enterococcus faecalis,* produce carcinogenic reactive oxygen species (ROS) capable of inducing DNA-damaging compounds or can induce production of carcinogenic compounds by activated immune cells. Inflammation-induced cell turnover directly increases the likelihood of introducing mutations in replicating DNA.

Microbiota–Immune System Interactions in Cancer Susceptibility and Development

Not surprisingly, animal models in which deletions of immune genes favor the emergence of a dysbiotic microbiota tend to develop spontaneous nonremitting intestinal inflammation. These include mice deficient in IL-10, Nod1, Nod2, Tbet, or Rag1. In several cases, microbiota reduction using antibiotics, rederivation in an axenic (germ-free) environment, or colonization with the microbiota derived from a wild-type animal is sufficient to significantly inhibit the development of inflammation, as well as the severity of cancer. Thus as a community, the microbiota has the potential to drive both gut inflammation and the eventual progression to cancer.

The gut microbial community has also been implicated in modulating carcinogenesis outside the intestines in experimental systems. Infection with *Helicobacter hepaticus* enhances mammary carcinoma in mice via mechanisms dependent on innate immune activation and TNF production. In addition, TLR5 signaling promotes progression of sarcomas in mice deficient for the tumor suppressor p53, and in which the protooncogene *Kras* has been activated. This disease phenotype can be abrogated by antibiotic-mediated reduction in commensal bacterial load.

In humans, approximately one of every six cancers develop downstream of a pathogenic infection.[40] Notable pathogen–cancer axes include *Helicobacter pylori* and gastric carcinoma, human papillomavirus (HPV) and cervical cancer, and hepatitis B and C viruses and hepatocellular carcinoma.[41] As with intestinal inflammatory diseases, the composition of the fecal and mucosal microbiota in patients with colorectal cancer (CRC) is distinct from that of healthy individuals. The differences between mucosal bacterial populations present "on" and "off" the tumors in the same patient suggest a role for site-specific bacterial community structure in disease development and/or production.[42] More specifically, correlations have been made between CRC and the presence of colonic microbes, including enterotoxigenic *Bacteroides fragilis*, *Fusobacterium nucleatum, Enterococcus faecalis,* and *E. coli.* Animal studies support a role for all these strains in Wnt signaling and myeloid cell activation of nuclear factor-κB (NF-κB)–dependent inflammatory pathways.

The Microbiota in Cancer Immunotherapy

Because of its ability to educate the immune system to be constantly poised to respond to challenge, the microbiota is now also recognized as an important ally in the fight against cancer. Seminal discoveries have been made recently in delineating the pathways whereby the microbiota-primed immune system is essential for the success of common anticancer therapeutic agents.[1] Commensal bacteria support the potency of anti–IL-10R/CpG ODN treatment (a form of immunotherapy) as well as oxaliplatin (a form of platinum salt chemotherapy) in treating colon carcinoma by enhancing the production of myeloid-derived proinflammatory cytokines and ROS, respectively. The efficacy of the alkylating drug cyclophosphamide (CTX) is reduced in germ-free mice or mice treated with vancomycin, which depletes gram-positive bacteria, as a result of diminished antitumor adaptive immune responses. The microbiota is also critical for the antitumor effects of immune checkpoint inhibitors anti–programmed death ligand 1 (PD-L1) and anti–cytotoxic T lymphocyte antigen-4 (CTLA-4).[43] In human, anti–CTLA-4 treatment induces mucosal damage and microbiota modification, partly as a result of partial depletion of gut Tregs. The modified microbiota and the consequent Th1-like immune response are critical for anti-CTLA_4 antitumor functions. In this study, the microbiota of patients treated with anti–CTLA-4 was enriched with bacterial species including *Bacteroides thetaiotaomicron, Bacteroides fragilis,* and *Burkholderia cepacia*. Transplantation of germ-free mice with *B. fragilis* and *B. cepacia* partially rescued the efficacy of anti–CTLA-4 and prevented the mucosal toxicity of the antibody.

THE SKIN MICROBIOTA AND THE IMMUNE SYSTEM

Skin Microbes Maintain Barrier Integrity in the Steady State

With a surface area of approximately 1.8 m^2, skin is the largest organ in the body. Skin functions as a physical barrier against foreign agents (Chapter 19) and also participates in thermoregulation. Unlike the warm, nutrient-rich intestinal tract, skin is cool, dessicates, and is limited in available nutrients for microbial species. Thus skin is populated by microbial communities capable of tolerating its diverse physiology (Fig. 14.6).[44] The total bacterial content of healthy human skin averages about 1 million/cm^2, for upward of 10^{10} total cells covering a single individual (or ≈1% of the number of bacterial cells per milliliter in the distal colon). The skin microbiota is generally acquired in concert with the colonization of other barrier surfaces in infancy. However, coincident with the individual's sexual maturation during adolescence, his or her skin bacterial communities undergo a major shift.[45]

Unlike the gut microbiota, skin commensals are dispensable for the maturation of the immune compartment of the tissue. However, their involvement in resistance to infection is clear. In response to pathogen challenge, skin-resident microbes mount a robust innate immune response characterized by some of the more primitive and evolutionarily conserved immune system messengers—antimicrobial peptides (AMPs) including cathelicidins and β defensins, components of the complement system, and IL-1. Epithelial cells constitutively express some AMPs, which can target a vast array of skin pathogens, including bacteria, fungi, viruses, and parasites. Other AMPs are induced in a microbiota-specific manner and are expressed secondary to activation of the complement system.[45]

In addition to being part of the innate response to microbial encroachment of skin, IL-1 stimulates robust adaptive immune responses that are essential for containment of both pathogens

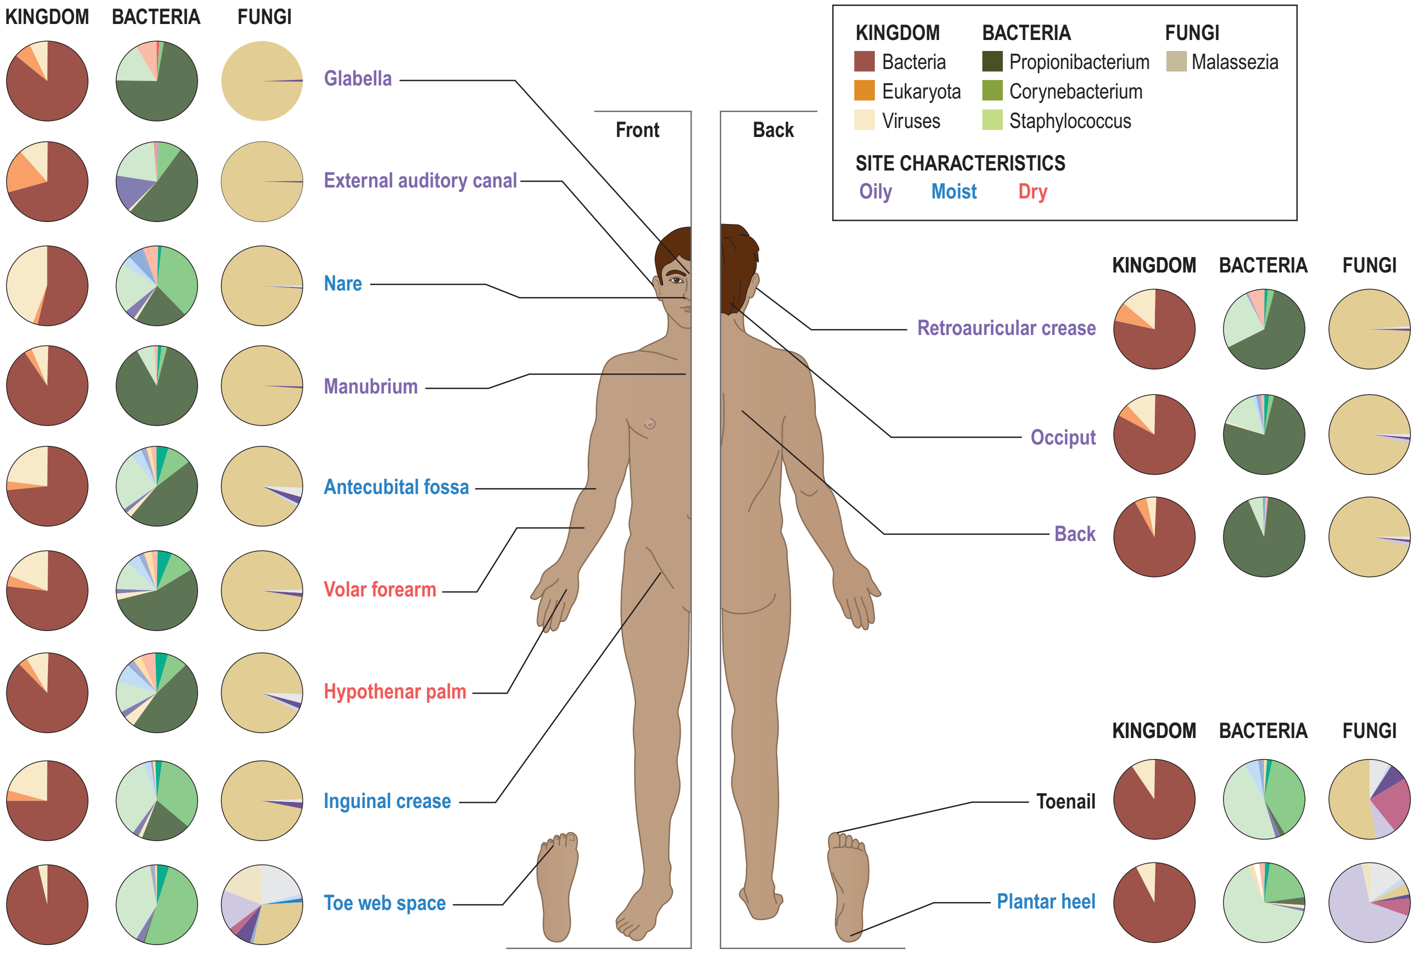

FIG 14.6 **Relative Abundance of Viral, Bacterial, and Fungal Components of the Microbial Community of Skin.** Sites represent three microenvironments: sebaceous (blue), dry (red), and moist (green). The toenail (black) is a site that does not fall under these major microenvironments and is treated separately. Pie charts represent consensus relative abundance of the different categories kingdom, bacteria, and fungi. For bacteria and fungi, major taxa colors are identified in the legend. The minor taxa are colored to represent their relative proportion. (From Belkaid Y, Segre JA. Dialogue between skin microbiota and immunity [Figure 1]. Science 2014;346(6212): 954–959.)

and commensals. In the skin of germ-free mice, there is reduced expression of IL-1, impaired induction of skin Th1, Th17, and IL-17-producing γδ T cells, and an elevated frequency of Foxp3$^+$ Tregs. Consequently these mice also mount a suboptimal response to skin infection. Additionally, in germ-free mice, the reduction in adaptive immunity results in impaired containment of skin commensals and their dissemination to the draining lymph nodes. In contrast, in immune-replete mice, introduction of commensal organisms triggers the induction of CD8 T-cell responses, including the production of IL-17, which is further reinforced by DC-derived IL-1, and helps preserve the integrity of the barrier.

Skin Microbes in Chronic Inflammatory Disease

Skin dysbiosis and resultant dysregulated immune responses have been associated with inflammatory disorders, including acne vulgaris, psoriasis, and atopic dermatitis (AD). Modulation of AMP production is critical, although the specific AMP, and whether it is upregulated or downregulated, can vary from one condition to the next.

In acne vulgaris, sebaceous hyperplasia and the release of lipids into the follicular lumen ultimately clogs the follicle and promotes a self-perpetuating outgrowth of *Propionibacterium acnes*. The follicular wall is breached, triggering an influx of inflammatory neutrophils and pustule formation. The expansion of *P. acnes*, as well as *Staphylococcus epidermidis*, leads to dysregulated immune responses, including elevated expression of AMPs and TLR expression by keratinocytes. These factors sustain the inflammatory response.[46]

Psoriasis (Chapter 64) has been associated with alterations in the relative distributions of two bacterial phyla. Psoriatic lesions in human skin have been found to contain a reduced abundance of and Actinobacteria, including the genus *Propionibacterium*, but an overrepresentation of Firmicutes. Overexpression of antimicrobial peptides, particularly IL-37 produced by stressed cells, is also detectable in diseased tissue.[47] IL-37 primes the innate immune response that subsequently induces development of Th1 and Th17 cells in the draining lymph nodes. The culpability of IL-17 expression in psoriasis has been confirmed by early clinical trials in which antibody-based targeting of IL-17 or the IL-17 receptor resulted in improvements in Psoriasis Area Severity Index (PASI) in at least 80% of patients after 12 weeks.[47]

Atopic dermatitis (AD; Chapter 44) is characterized by dry skin (xerosis), which, along with the associated change in skin pH, favors the colonization and expansion of some microbes more than others. Colonization with *Staphylococcus aureus* has been linked to development of AD, and *S. aureus* is detectable in the skin lesions of over 90% of patients with AD.[48] *S. aureus* infection induces both innate and adaptive immune activation. The expression of IL-37 transcript is markedly reduced in AD lesions, whereas other AMPs, including psoriasin, human β defensin-2, and RNase 7, are overexpressed.

THE RESPIRATORY TRACT MICROBIOTA IN HEALTH AND DISEASE

Inhaled air contains bacteria, viruses, and fungi. Thus the respiratory tract serves as the main entry portal for these airborne microbes. Yet, for over a century, the healthy lung was considered a sterile environment, free of culturable and/or resident reproducing microbes. The detection of microbes in samples collected using instruments that had to traverse the mouth or nasal cavities was often assumed to have resulted from contamination with microbes from these sites. The emergence of culture-independent techniques for detection of microbial communities has precipitated a revision of this concept and an appreciation of the presence and diversity of microbial communities along the respiratory tract even in the absence of overt disease.[49] Thus although the airway and lung microbiota does resemble the bacterial populations of the upper respiratory tract, there are differences that ultimately point to the existence of a specific lung microbiota in healthy individuals.

Although the concept of a lung microbiota during health is relatively new, the role of microbial agents in the pathogenesis of chronic lung diseases has been widely examined. In the healthy lung, the immune system eradicates potential pathogens and overcomes environmental disturbances that threaten to impair lung function. Direct impairment or intrinsic failure of the pulmonary defense mechanisms can lead to infection and/or chronic lung diseases, including asthma, chronic obstructive pulmonary disorder (COPD), cystic fibrosis, and bronchiectasis. Although microbial expansion in the lung is a characteristic of many lung diseases, it is not always clear whether the dysbiotic microbiota is the cause, the consequence, or both.

The Shaping of the Healthy Respiratory Microbiota

The bacterial density of inhaled air is approximately 10^4–10^6 cells/m^3. Thus with each breath, mammals are constantly exposing their lungs to airborne bacteria. There are system-intrinsic mechanisms that serve to regulate entry and colonization of the lungs by microbes. The lung, like skin, and in stark contrast to the GI tract, is a very low nutrient resource. The thin mucus layer, which might seem to represent reduced barrier protection relative to the intestine, also means the absence of a valuable source of nutrients for certain mucophilic microbes. Furthermore, the combination of oxygen tension, temperature, regional pH, the diverse architecture of the respiratory tract, and the proximity of inflammatory cells all help keep the bacterial biomass of the lungs extremely low relative to that of the gut. In a healthy individual, community composition at any given time is largely determined by the relative amount of microbial immigration and elimination. The major routes of immigration are microaspiration, air inhalation, and direct dispersion along the mucosal surface. Elimination is a continuous process mediated by the ciliated epithelial cells, by coughing, and by the actions of the pulmonary immune system. Colonization and growth contribute minimally to microbiota composition during homeostasis but are favored by changes in regional conditions that promote and/or sustain chronic inflammatory diseases of the lung.

Similar to the intestinal microbiota, the microbiota of the upper respiratory tract stabilizes in early childhood and can be influenced by external factors, including breastfeeding and use of antibiotics.[50] In a healthy lung, there is little spatial variation within the same individual. This lack of variation supports the theory that the composition of the lung microbiota is more heavily influenced by immigration and elimination than by local growth. The most abundant bacterial phyla in the lung are Bacteroidetes and Firmicutes. At the genus level, *Prevotella, Veillonella,* and *Streptococcus* predominate. There are also prominent fungal communities, with dramatic differences in composition observed in different healthy cohorts. The oral cavity is home to several genera of fungi, including *Candida, Cladosporium,* and *Aspergillus,* but the fungal colonization of a healthy lung is unclear. Considering the constant exposure of the lung to oral and inhaled fungi, it is likely that the immune apparatus of the lung does, indeed, encounter fungal antigens in the steady state.

The involvement of the bacterial communities of other body sites, particularly the intestines, in lung immune homeostasis is still being actively explored. This phenomenon is commonly referred to as the "gut–lung axis" and involves the action of soluble mediators produced and/or induced by the gut microbiota that can enter the systemic circulation. By this rationale, this phenomenon is more a reflection of the intestinal microbiota on the organism as a whole, and not representative of a unique relationship between these two organs. Nevertheless, there is compelling evidence that modulation of the gut microbiota, particularly during infancy, can have lifelong effects on lung immunity and susceptibility to chronic diseases.

MICROBES AS THERAPY

Certain infections or chronic inflammatory disorders are associated with a severely damaged microbiota. Transplantation of healthy donor microbiota has emerged as a successful therapeutic approach to repair and/or restore microbial communities. Fecal microbiota therapy (FMT), or fecal transplantation, has been safely and effectively utilized as a last resort to treat chronic *Clostridium difficile* infection. FMT presents the risk of adverse effects because the transplanted microbes, which are dormant in the donor, experience propathogenic conditions in the recipient. Because of the successes to date, empirical information regarding the long-term stability and resilience of one individual's microbiota transplanted into another should emerge over time. Other, more focused approaches that employ distinct microbes, groups of microbes, or microbial products known to have immune cell-specific effects to treat inflammatory diseases, such as IBD, are also being considered.

In Western, industrialized societies, there has been a consistent upward trend in the incidence of autoimmune diseases, and this has been linked to improved sanitation and diets low in fiber but rich in unhealthy fats and carbohydrates. These factors have contributed to dramatic shifts in microbial diversity away from that of our ancestral microbiota. Restoration of the richness of the microbiota using *probiotics*—live microorganisms that, when administered in adequate amounts, provide a measurable health benefit to the host—may be helpful in slowing and possibly reversing this trend. Long-term persistence of probiotic organisms within the complex microbiota of the host is essential if these organisms are to induce durable shifts in microbiota dynamics. Complementary *prebiotic* regimens that support the growth and survival of the introduced microbes without detrimental alterations in the distribution of functions of other species will likely be helpful in this regard.

SUMMARY

ON THE HORIZON

- Improved understanding of the structure and function of the microbiota in health and disease:
  - Factors that determine the assembly of the microbiota during early life colonization, and maintenance of community structure throughout life
  - Commensal microbes as a rich source of biological agents that can be used to regulate community development and resistance
  - The mycobiome and viriome—currently understudied mostly because of technical limitations
- Precision medicine and the microbiome:
  - Use of advanced genomic techniques for detailed assessment microbiota functions in health and specific diseases
  - Application of host genome and microbiome data to predict disease susceptibility and responses to therapy
  - Identification and targeted eradication and replacement of deleterious organisms
  - Assembly of limited "designer microbiotas" to initiate therapeutic reconstruction of dysbiotic patient microbiota

The peaceful interaction between humans and the microbes that colonize them is essential for a healthy life. As such, the coexistence of the two entities occurs in an organized fashion, and we now know that this commences *in utero* and is subject to perturbations that can have dire consequences. Perhaps most notable are the findings within the last decade regarding the detrimental and long-lasting effects of broad-spectrum antibiotics used during infancy. The involvement of the microbiota as an instigator and/or sustainer of chronic inflammatory diseases and cancer continues to be explored. In the future, these studies may identify novel avenues for targeting certain conditions and restoring the immune balance. Our growing understanding of the essential roles of the microbiota in diverse physiological processes presents new opportunities to harness these capabilities across the clinical spectrum.

MULTIPLE-CHOICE QUESTIONS

1. The ability of microbes to stably colonize a certain barrier tissue is directly influenced by all of the following *except:*
   A. Environmental factors, such as pH, oxygen tension, and nutrient supply
   B. The musculature of the underlying tissue
   C. The presence or absence of other microbes in that locale
   D. The immune pathways that get activated following colonization

2. Microbe X can be detected in the fecal material of 40% of healthy, immune competent laboratory mice. When pure isolates of microbe X are transplanted into mice with a deletion in gene Y, or into healthy or germ-free mice on a specific diet, the mice develop inflammatory lesions in the intestines and the liver. The most appropriate characterization of microbe X is:
   A. Parasite
   B. Commensal
   C. Pathobiont
   D. Enteric pathogen

3. Puberty has a profound impact on the microbiota of:
   A. Skin
   B. The large intestine
   C. The small intestine
   D. Lungs

4. All gnotobiotic organisms are also germ-free.
   A. True
   B. False

Immunoglobulin Function

Neil S. Greenspan, Lisa A. Cavacini

Antibody-mediated immunity generally requires noncovalent contact between an antibody and the antigen (Chapters 4 and 6). The ability of an antigen to bind noncovalently to an antibody, termed *antigenicity*, is a physical–chemical property that is evaluated with respect to a given antibody population. In contrast, *immunogenicity*, the ability to induce the biosynthesis and secretion of soluble antibody molecules, is a biological property. Thus its measurement requires *in vivo* studies. Although antigenicity is necessary for immunogenicity (as defined by the production of antibodies), it is not sufficient. Moreover, the immunogenicity of a given molecule or molecular complex is influenced by host genetic variation. When an antibody binds to a macromolecular antigen, it directly contacts only a portion of the molecular surface of that antigen. Similarly, only a portion of the antibody molecule makes direct contact with the antigen. By convention, the portion of an antibody or T-cell receptor (TCR) that makes physical contact with an antigen is referred to as the *paratope* or *combining site*. Conversely, the region of the antigen in physical contact with the paratope, the antigenic determinant, is termed the *epitope*. Most of the amino acids in an antibody variable domain that contact a given antigen are located in the hypervariable regions (also termed *complementarity determining regions* [CDRs]). However, X-ray crystallographic analyses of antibody–protein antigen complexes have shown that contact residues can reside in the framework regions[1] as well.

Although an epitope (paratope, etc.) is usually defined in terms of intermolecular contact, the region of a molecule involved in physical contact with another molecule may not correspond exactly to the structural correlates for energetics and specificity.[2]

ANTIGEN BINDING AND MOLECULAR IDENTITY

Physical Aspects of Binding

Antibody–antigen interactions are, with rare exceptions, noncovalent. This fact is significant in that these interactions are, in principle, spontaneously reversible under the conditions of temperature, pressure, pH, and ionic strength that generally prevail in living organisms.

Several types of noncovalent bonds have been shown to contribute to antibody–antigen binding. These include van der Waals forces, hydrogen bonds, ionic bonds, and hydrophobic interactions. Individually the strength of these bonds is in the range of one to a few kilocalories per mole (kcal/mole), versus 50–100 kcal/mole for covalent bonds. Since the potential to engage in these types of bonds is shared by many of the components of biological macromolecules, individual weak bonds do not usually confer a high degree of specificity. For example, any two atoms can interact through van der Waals forces. It is only through the simultaneous action of many such bonds that molecular specificity arises. Hence, the importance of a close fit, often referred to as *complementarity,* between the epitope and the paratope.

Complementarity can be maximized by matching the physical–chemical properties of the epitope and the paratope. For example, binding can be facilitated when one molecule is concave and the other is convex, when one molecule is positively charged and the other is negatively charged, or when one molecule is a hydrogen bond donor whereas the other offers a hydrogen bond acceptor. It is expected that the greater the complementarity between receptor and ligand, the stronger is the interaction (greater affinity) between the two molecules. Specificity (see below) is also expected to be influenced by complementarity.[2] In rationalizing the strength of interactions between antibodies and antigens, it is important to remember that the antibody competes with solvent for binding to antigen. The thermodynamics of the interaction between these two structures reflects the influence of the interaction on the solvent and other solutes. Moreover, bound water molecules may make important, even crucial, contributions to an interaction between two biomolecules.

Antibody recognition of antigen serves as a paradigm for understanding molecular recognition in the immune system and in biology in general. As will be discussed below, this fact, coupled with the inducibility of antibodies, permits them to be used as surrogate ligands for almost any receptor (and vice versa).

Affinity is the concept used to convey how strongly two molecules bind to each other. Antibody–antigen interactions can be categorized with respect to the numbers of different kinds of paratope–epitope bonds and the absolute number of such bonds of each kind (Table 15.1). Reflecting the different types of antibody–antigen interaction, two categories of affinity merit consideration: intrinsic affinity and functional affinity. It should be noted that some immunologists use the term “avidity” in place of “functional affinity.”

Intrinsic affinity is a measure of the strength of the monovalent interaction between a particular paratope and a particular epitope under defined conditions of temperature, pressure, ionic strength, and pH (Fig. 15.1). By convention, the intrinsic affinity is taken to be the equilibrium association constant characterizing the paratope–epitope pair. It is the reciprocal of the concentration of monovalent antigen at which half of the paratopes will be occupied. It is not an intrinsic property of either the paratope or the epitope, but rather intrinsic affinity characterizes the relationship between two molecules under defined conditions.

The intrinsic affinity of an antibody for a small molecule, such as a drug (*e.g.*, digoxin) or a hormone (*e.g.*, insulin), can be clinically important both *in vivo* and *in vitro*.[3] For example, the *in vivo* effectiveness of antibody F(ab) fragments in removing toxic levels of the drug, digoxin, from patients being treated for congestive heart failure likely depends on the intrinsic affinity of the F(ab) fragments for the drug. Alternatively, antibody intrinsic affinity can limit the analytical sensitivity of an *in vitro* immunoassay designed to determine the concentration of an analyte, such as a hormone (*e.g.*, insulin, parathyroid hormone) or a drug (*e.g.*, digoxin).

In contrast, functional affinity is defined as the equilibrium association constant characterizing the interaction between an intact antibody and an intact antigen. For a monovalent immunoglobulin G (IgG) antibody–antigen interaction, the intrinsic affinity and the functional affinity will be the same. However, if two paratopes interact simultaneously with two epitopes on the same antigen, referred to as *monogamous bivalency* (Fig. 15.2), the functional affinity of the antibody for the multivalent antigen may be substantially greater (as much as 10 000-fold for IgG) than the intrinsic affinity of that antibody for the relevant epitope on that same antigen.[2]

TABLE 15.1 Antigens and Valence

Number of Types of Epitope	Epitope Copy Number	Examples
Monodeterminant	Monovalent	Hapten: DNP, digoxin
Monodeterminant	Multivalent	Polysaccharide: dextran[a]
Multideterminant[b]	Monovalent	Monomeric protein: myoglobin
Multideterminant	Multivalent	Virion: influenza virus

[a] Even a polysaccharide composed of one type of hexasaccharide can have two or more different kinds of epitope: terminal versus internal residues, for instance. However, a given antiserum may preferentially contain antibodies specific for only one such epitope.

[b] Typically, multideterminant recognition occurs with respect to a polyclonal antibody.

Adapted from Benjamini E, Leskowitz S. Immunology: a short course, 2nd ed. New York: Wiley-Liss; 1991, with permission from Wiley-Liss, Inc., a subsidiary of John Wiley & Sons, Inc.

Functional affinity is also influenced by the degree to which the geometrical relationships among the epitopes are optimal for the paratopes, which will depend on the quaternary structure and segmental flexibility of the antibody molecule. In the presence of nonoptimal geometry, the average number of engaged sites may be less than maximal, and energy may be expended in achieving some epitope–paratope contacts. Therefore the functional affinity for a multivalent interaction does not necessarily increase in direct relationship to the maximal number of binding sites that can be engaged simultaneously by an antibody molecule. For example, the effective valency of pentameric IgM with 10 paratopes is typically half that.

Intrinsic affinity provides information, qualified as above, on the degree of complementarity between the epitope and the paratope. Functional affinity accounts for properties influenced by structural features outside of the epitope and the paratope, as normally conceived. Both concepts of affinity are valuable. Maximization of intrinsic affinity may be of prime importance for antibody-mediated inactivation of toxins or enzymes, which frequently involve monovalent interactions. However, in cases where antibodies bind to repeated epitopes on the surfaces of bacteria, viruses, fungi, parasites, or mammalian cells, the functional affinity may play a much larger role influencing the biological consequences of the interaction.

Bivalent (IgG, IgE) or multivalent (IgA, IgM) antibodies carry with them the potential to bind simultaneously to two or more epitopes on different antigenic particles, cross-linking them rather than engaging in monogamous bivalency or monogamous multivalency (see Fig. 15.2). This phenomenon has played an important historical role in immunology. It is the basis for the clinical method for typing erythrocyte antigens (*e.g.*, ABO and Rh antigens), which still rely on agglutination of red cells by antibodies (or lectins). Such antibodies may also participate in the inactivation of complex antigens such as are found on the surface of human immunodeficiency virus (HIV). Many neutralizing epitopes of HIV are normally not well exposed on native

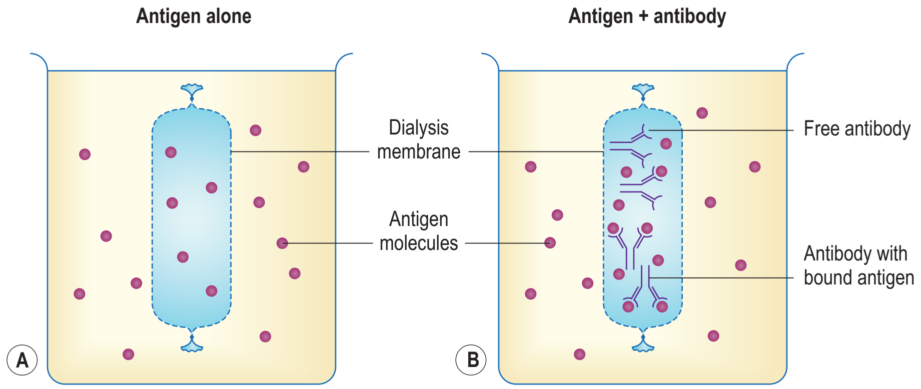

FIG 15.1 Measurement of the Intrinsic Affinity Characterizing an Interaction Between Antibody and Antigen (Hapten) by Equilibrium Dialysis. At equilibrium (A), the amount of diffusible free hapten inside the dialysis bag will be equal to the amount of free hapten outside of the dialysis bag. However, in the presence of hapten-specific antibody (B), the total hapten concentration will be greater inside of the dialysis bag (free + antibody-bound) than outside of the bag (free). The extent of this difference can be used to determine the intrinsic affinity of the antibody for the hapten. With permission from Abbas AK, Lichtman AH, Pober JS. Cellular and molecular immunology. virus; however, conformational changes following antibody binding may expose these epitopes for neutralization by other antibodies.

KEY CONCEPTS

Binding of Antibody to Antigen

- Paratopes interact with epitopes through multiple noncovalent (weak) bonds, each of which is reversible at room temperature.
- For the clinician, immunological specificity needs to be viewed in its biological rather than physical context.
- Intrinsic affinity and functional affinity both refer to the strength of antigen–antibody interactions but often play separate roles in the biology of that interaction.
- Intrinsic affinity measures the strength of the interaction between a monovalent epitope and the paratope on the antibody. This can be determined by the equilibrium association constant. Intrinsic affinity is influenced both by the degree of complementarity between the epitope and the paratope and by ambient conditions, including the temperature, pressure, ionic strength, and pH.
- Functional affinity is a measure of the average strength of the interaction between a multivalent antigen and an intact antibody. It is influenced by the spatial relationships characterizing the epitopes that are being recognized as well as the physical properties of both the underlying substrate and the antibody.

IMMUNOLOGICAL SPECIFICITY

The concept of specificity is fundamental to an understanding of the nature and consequences of interactions between immunological receptors and antigens. However, in the immunological context, the term *specificity* encompasses multiple different aspects.[2]

One aspect of specificity focuses on the goodness of fit between the paratope and the epitope. Intrinsic affinity is regarded as a reasonable measure of this goodness of fit. However, substantial conformational adjustments of either the paratope or the epitope may be necessary for formation of the complex.[4] Such conformational changes will generally incur energetic costs. Consequently, intrinsic affinity and final complementarity may not be perfectly correlated.

A second aspect of specificity focuses on the ability of a paratope to distinguish among different epitopes. Such specificity is most readily studied when the epitope is in monovalent form and evaluated relative to a specified set of ligands. Thus one should be cautious about extrapolating claims that one antibody is more or less specific than another antibody without any reference to the relevant universe of ligands. However, there are practical cases where it is justifiable to speak globally of more-or less-specific antibodies. Polyspecific antibodies have been described in the neonatal primary repertoire.[5] These antibodies appear to be globally less discriminating than antibodies typical of the immune repertoire (secondary or later response) when tested on large panels of antigens.

Nevertheless, it is important to note that even antibodies derived from secondary (or later) responses are not,[6] and cannot be, absolutely specific.[2] The impossibility of perfect recognition or discrimination can be understood in both thermodynamic and structural terms. First, perfect fit and absolute discrimination would imply infinite intrinsic affinity (negative free energy change of complex formation), which is not physically plausible.[2] Second, the convexity of atoms prevents perfect shape complementarity between antibody (receptor) and antigen (ligand).[2] Recent results also indicate that at least some antibodies can adopt two or more different unbound conformations, each of which exhibits a different ligand-binding profile. Such paratopes may undergo further structural adjustment in the process of binding to an epitope.[7] This property can be advantageous to the function of an antibody. Antibodies that react with multiple conformations of a viral surface antigen may be much more likely to interfere with viral infection because they can bind more rapidly to the virus than the virus can bind to its receptor, as demonstrated for HIV.[8]

Whereas the first two aspects of specificity focused on the epitope, a third relates to the ability of an antibody to discriminate among antigens that display multiple copies of one or more distinct epitopes. An antigen expressing many copies of one epitope is termed *multivalent,* and an antigen that expresses two or more structurally distinguishable epitopes is referred to as *multideterminant* (see Table 15.1). Because two different cells, bacteria, viruses, and so on may both express multiple copies of the same or nearly the same epitope, an antibody that is highly specific (in the first aspect above) for such a shared epitope may be a poor discriminator between such multivalent particles.[2] Yet, an antibody with a relatively poor degree of complementarity and intrinsic affinity for an epitope found on only one of two or more multivalent targets may be superior at discriminating among these antigens. Furthermore, antibodies (or other molecules)

FIG 15.3 **Types of Protein Epitopes.** Some antibodies recognize structural features of proteins that arise from the folding of the polypeptide backbone (conformational epitope). Other antibodies recognize groups of amino acid residues that are contiguous, or nearly so, in the primary (covalent) structure of the protein (linear epitope). If such a linear determinant is inaccessible in the native structure of the protein, the corresponding antibodies may only be elicited by the denatured form of the protein. Neo-epitopes are created by covalent posttranslational modifications, such as proteolytic cleavage. With permission from Abbas AK, Lichtman AH, and Pober JS. Cellular and molecular immunology, 3rd ed. W. B. Saunders Company; 1997.

expressing two or more binding sites of identical structure may not discriminate identically among antigens displaying the same epitope in different two- or three-dimensional distributions.[2]

We offer some final points regarding specificity. First, the interactions between molecules, such as CD4 and major histocompatibility complex (MHC) class II (Chapter 5), which are not clonally distributed, are often described as nonspecific, that is, not specific for an antigen under consideration. The contrast being drawn is with the antigen-specific receptors Ig or TCR. However, from the point of view of the first or second category of specificity described above (goodness of fit, discrimination between ligands), the interaction between molecules, such as CD4 and MHC class II, may be as biochemically specific as that between an antibody and a class II molecule. Ideally, this sense of "nonspecific" should be modified by the preceding term "antigen" (Chapter 6). If not, the meaning must be inferred from the context.

Second, for many purposes immunological specificity has an ultimately biological, not a physical, definition. If the endpoint of analysis is the triggering of a complex response, such as cell activation or initiation of the complement cascade (Chapters 3, 21), then the presence, absence, or the extent of that response, and not the extent of receptor–antigen interaction, will be the ultimate criterion for evaluating specificity. Such biological specificity is not always directly correlated with specificity as determined by the analysis of binding.[2]

Third, the enormous utility of antibodies is crucially dependent on the discriminatory abilities of these molecules with respect to other molecules or molecular aggregates. However, given that the discrimination mediated by antibodies is not absolute, the usefulness of a particular antibody may depend on the context. For example, which antigens or potential antigens in addition to the preferred target are available for binding to the antibody.

Fourth, apparent antibody specificity may vary with the methods used for analysis, as these methods may differ in sensitivity and the conditions (pH, ionic strength, temperature) of application such that the relevant intrinsic affinities may vary among the different assays.

PROTEIN EPITOPES

On the basis of the proximity of the relevant amino acids in the primary structure of the protein, several categories of epitopes have been defined for protein antigens (Fig. 15.3). The simplest is the *linear* epitope, where all of the relevant amino acids are derived from a contiguous stretch of the polypeptide chain. Linear epitopes are particularly characteristic of the short peptide epitopes presented to T cells by MHC molecules on specialized antigen-presenting cells (Chapters 1 and 6). However, antibodies generally recognize complex epitopes on globular proteins that involve amino acids from two or more stretches of polypeptide that are distant from one another in the primary structure. Such an epitope is referred to as a *conformational*, or *discontinuous*, epitope. In some cases, such as with the capsids of nonenveloped viruses, a conformational epitope may contain amino acids that are derived from separate polypeptide chains but that are next to each other in the final capsid structure.

Another category of protein epitope, the *neo-epitope*, is reserved for those antigenic sites that become recognizable only after a posttranslational event, such as proteolytic cleavage. For example, several neo-epitopes have been defined on cleavage products of human C1q, C3, and C9, components of the complement pathway.[9] And, in rheumatoid arthritis (RA) autoantibodies to citrullinated epitopes on such antigens as filaggrin can be of diagnostic value.

Antibodies recognizing neo-epitopes can be used to monitor the extent of activation of the complement pathway.[9] A chimeric antibody, ensituximab, targeting neo-epitopes associated with colorectal and pancreatic carcinomas, represents an evolving area of discovery of antibodies to target cancer neo-antigens.

Studies in the 1970s on the sizes of epitopes associated with synthetic peptide antigens yielded results suggesting that protein epitopes would maximally involve six or seven amino acids. However, the first structure of an antibody-variable module in complex with a globular protein antigen, determined by X-ray crystallography,[1] indicated that protein epitopes, defined on the basis of intermolecular contact, could be as large as 15–20 amino acids. A similar number of amino acids in the antibody V domains constituted the paratope. And, even peptide antigen–antibody interaction can involve at least twelve peptide amino acids in contact with the antibody. Still, it is possible that there are smaller epitopes on globular proteins, particularly for regions of proteins that protrude or have a high radius of curvature.

Antibodies specific for both linear and conformational epitopes have important practical applications. For example, a synthetic peptide corresponding in amino acid sequence to a segment of the polypeptide chain predicted from the nucleotide sequence can be used to elicit antibodies. Antibodies with the potential to recognize a linear epitope available in a denatured form of the gene product can be used to identify the protein following expression, electrophoresis, and blotting under denaturing conditions. Some antibodies raised by challenge with synthetic peptides that bind to linear epitopes can recognize a protein in denatured form but will not bind to or alter the function of the native protein.

Antibodies with the ability to neutralize protein function generally recognize conformations accessible to the native protein, usually at discontinuous epitopes. Thus antibodies specific for peptides (that correspond in amino acid sequence to a portion of a native protein) or denatured protein that can cross-react with the protein in a native (folded, functional) state can be extremely valuable. Such cross-reactivity is more likely to occur when the region being recognized is relatively disordered in the native structure.[10]

CARBOHYDRATE EPITOPES

The classic studies of Kabat on the binding of antibodies to dextran led to the concept that epitopes on carbohydrate antigens could be as large as six or seven monosaccharides. However, minimal carbohydrate epitopes can probably be as small as one or two monosaccharides. Even in the case of larger epitopes, it is typical for the terminal groups to play a dominant role in determining antibody specificity for carbohydrate antigens. Recent studies have suggested that polysaccharide epitopes can sometimes also result from conformational properties of polysaccharides.

Interactions between antibodies and polysaccharides have typically been characterized by relatively low intrinsic affinities in comparison to antibody–protein interactions.[2] Relatively weak antibody–carbohydrate binding can result from biological constraints related to protection against self-recognition and consequent tissue damage or from physical–chemical constraints related to the conformational freedom and high degree of solvation of unbound carbohydrates. However, antibodies produced in response to pathogens, such as HIV, may be much more effective at interacting with carbohydrate antigens.[11]

Another important feature of polysaccharide antigens is that they are generally multivalent. Bacterial and perhaps viral polysaccharide epitope densities can approach values in the millions per square micrometer, which is probably one to several orders of magnitude greater than the epitope densities for protein determinants on mammalian cells. Therefore multipoint attachment and functional affinity are likely to be critical factors in the mediation of immunity by antipolysaccharide antibodies or other carbohydrate-specific proteins.

IMMUNE COMPLEXES *IN VIVO*

KEY CONCEPTS

Immune Complexes

- Immune complexes are aggregates of antibody and antigen.
- Immune complexes can form in tissues, or they can form in the circulation and subsequently deposit in tissues.
- Immune complexes can activate complement or Fc receptor–bearing cells, leading to tissue damage.
- The composition, size, charge, and antibody isotypes characterizing a given population of immune complexes will influence the pathogenic potential of the complexes.

Interactions between antibodies and antigens *in vivo* can result in the formation of molecular aggregates, referred to as *immune complexes.* Deposition of immune complexes in tissues, such as blood vessels, renal glomeruli, renal tubules, the thyroid gland, and the choroid plexus, can result in pathological conditions.[12] Immune complexes can form in the circulation before deposition in a given tissue, or they can form directly in the affected tissue.

A clinical situation associated with immune complex formation is therapy with immunoglobulin (Chapter 84). During administration, infused antibodies may bind endogenous antibodies and the numbers of such complexes are greater at higher infusion rates. These "induced" immune complexes can promote adverse reactions, ranging from mild to severe, including headache, nausea, myalgia, fever, chills, chest discomfort, skin and anaphylactic reactions, and aseptic meningitis.

Some variables, such as concentration, composition, size, charge, and antibody isotype, will influence the magnitude and sites of tissue deposition of immune complexes. The magnitude of complement activation and the extent of interaction with Fc and complement receptors, in conjunction with the sites and extent of tissue deposition, determine the biological properties of the complexes. Antigen–antibody lattice size is determined by antigen valence, epitope geometry, antibody valence, the intrinsic affinity of paratope for epitope, antibody and antigen flexibility, the ratio of antibody to antigen, and the absolute concentrations of antibody and antigen. The potential diversity of immune complex morphologies is illustrated in Fig. 15.4. These complexes, between a monoclonal antibody (mAb) specific for a bacterial polysaccharide and various antiidiotypic or antiisotypic mAbs, are visualized with electron microscopy.

Immune complexes have also been found to have immunoregulatory effects,[13] particularly with respect to antibody responses. Immune complexes can bind simultaneously to B-cell surfaces through antigen (to B-cell surface Ig), antibody (to Fc receptors), and associated complement components (to complement receptors). The interaction with FcγRIIB, on the B-lymphocyte membrane, has the effect of diminishing the B-cell response

Analyzing immunoglobulin functional anatomy with monoclonal antiimmunoglobulin antibodies. BioTechniques 1989;7:1086.

(Chapter 4). The molecular events underlying these immunoregulatory effects are being intensively studied, and they have been exploited clinically for many years. For example, antibody to the erythrocyte Rh antigens is used to prevent immunization of an Rh-negative mother by an Rh-positive fetus, thereby avoiding hemolytic disease of the newborn in a subsequent Rh-positive fetus.

CORRELATIONS BETWEEN C$_H$ REGION STRUCTURE AND ANTIBODY FUNCTION

Antibodies are heterodimeric proteins that can be functionally divided into variable domains, which bind antigen, and constant domains, which define the effector function of the Ig (Chapter 4). This dual function allows an antibody to physically link a specific antigen to a separate antigen-nonspecific effector molecule, such as a component of complement or a cell-bound Fc receptor.

KEY CONCEPTS

Structure–Function Relationships of C$_H$ Domains

- Immunoglobulin (Ig) function is influenced by differences in quaternary structure and segmental flexibility.
- The hinge region helps control segmental flexibility in IgG molecules.
- The extended hinge region of IgA1 molecules allow their Fab arms to range from the "Y" configuration of an IgG or IgA2 to a more open "T" configuration.
- When interacting with multivalent antigens, IgM molecules can adopt a dislocated configuration (staple configuration) in which the Fab arms are bent out of the plane of the Fc regions.

Many features of C$_H$ domain structure exhibited by the Ig isotypes can be understood in the context of this requirement for linkage between antigens and antigen-nonspecific effector molecules.

One property of prime significance for antibody function is intramolecular mobility, often referred to as *segmental flexibility*. Hydrodynamic methods, electron microscopy, X-ray crystallography, and fluorescence polarization have all been used to evaluate the degree of flexibility exhibited by IgG, IgM, IgA, and IgE molecules. In the case of the best-studied isotype, IgG, it is clear that the structural feature most associated with relative motion of one subunit relative to another is the hinge, which connects the C$_H$1 domain to the C$_H$2 domain and is encoded by a separate exon. The human IgG3 subclass has an extended hinge region that can impart increased flexibility. In the case of IgA, the IgA1 hinge is flexible such that the F(ab) arms can range from the typical "Y" configuration to a "T" configuration whereas IgA2 molecules are relatively constrained.

Ig flexibility has important functional consequences for the antibody. First, inter-F(ab) movements can play an important role in permitting antibodies to bind in monogamous bivalent (or multivalent) fashion to antigenic surfaces that display repetitive epitopes. Second, efficiency in precipitation of multivalent antigen molecules or agglutination of multivalent antigen particles can be correlated with inter-F(ab) flexibility. And, third, optimal interactions of effector molecules with IgG antibody Fc regions has been postulated to depend on the ability of the Fc region to bend out of the plane of the F(ab) arms (*dislocation*) (but see discussion on complement activation below).

FUNCTIONS MEDIATED BY ANTIBODY ALONE

Although it is clear that in many *in vivo* situations antibodies mediate their effects with the aid of other molecules and, in selected cases, cells (see next section), there are circumstances where the antibody can influence antigenic targets directly, at least *in vitro*. The very name "antibody" implies the negation of some activity, and antibodies were first defined as factors that could inactivate or neutralize toxins. Subsequent studies have shown inactivation of viruses, parasites, and enzymes, as well.

Virus Neutralization

A phenomenon of fundamental medical and biological importance is the *neutralization* of viruses by antibodies.[14] Although neutralization is defined as the elimination or reduction of the virus's ability to replicate, it does not imply a particular mechanism of interference with the process of replication. Moreover, the measurement of neutralization can depend on the choice of host cell. Thus the neutralizing activity of a given

KEY CONCEPTS

Virus Neutralization

- Antibodies can neutralize (decrease the replication of) viruses by blocking attachment to the host cell, preventing penetration of the host cell membrane, or interfering with uncoating of the virus within the cell.
- Neutralizing antibodies typically recognize proteins or glycoproteins on the virion surface.
- Some antibodies that bind to virion surface proteins or glycoproteins are not neutralizing. In some cases, such antibodies may contribute to immunity, whereas in others, they may enhance infection.
- The magnitude of neutralization mediated by a given antibody may vary with the host cell used for the measurement.
- Neutralization *in vitro* is usually related to protection *in vivo,* but these two properties are not always perfectly correlated.

antibody for a given virus is not an intrinsic property of the antibody but is a property of the relationship between the antibody and the virus, under defined conditions. Consequently, neutralization titers in serum do not always correlate perfectly with protection from infection or disease *in vivo.*

There are several mechanisms by which antibodies can inactivate viruses (Chapter 25). The process by which a virus infects a cell involves multiple steps. These include attachment to one or more membrane components, penetration of or fusion with the membrane, uncoating, and genome expression. Although the most obvious mechanism of neutralization is prevention of viral attachment to the host cell surface, some antibodies can block other steps. For example, neutralizing antibodies for enveloped viruses, such as influenza virus, have been shown to prevent fusion between the virion and cell membranes, and neutralizing antibodies for poliovirus have been shown to interfere with viral uncoating in the host cell.

Different isotypes of antibodies may employ different neutralization mechanisms to varying degrees, although this statement should not be interpreted to mean that there is a one-to-one correspondence between isotypes and neutralization mechanisms. For example, IgG or IgM antibodies in blood can mediate protection against a virus either directly, in some cases, or with the assistance of complement components in others. However, IgA, the dominant isotype in mucosal secretions, operates under conditions where complement is less plentiful than in blood. Thus virus-specific IgA is more likely to utilize virus-inactivating mechanisms that do not require complement, such as prevention of attachment.

Traditional thinking maintains that antibody mediates any protective effects extracellularly. However, it has been reported that IgA antibodies, being transported by the polymeric Ig receptor, can mediate protection against intracellular influenza virus.[15] Similar phenomena have been reported for rotavirus and HIV.

There are several other notable features of antibody–virus interactions. Not all antibodies that bind to molecules on the virion surface will neutralize the virus in all conditions. For a given virus-encoded gene product, such as the influenza virus hemagglutinin, binding of antibodies to some sites, but not others, will effect neutralization. Some gene products on the virion surface may fail to routinely support viral neutralization (*e.g.,* influenza neuraminidase). However, antibody to influenza neuraminidase, while nonneutralizing, is thought to slow the spread of infection by interfering with the escape of progeny virions from infected cells. Nonneutralizing antibodies, or neutralizing antibodies at suboptimal concentrations, have been found in some instances to enhance the infection of host cells by virus (*e.g.,* HIV-1 or dengue virus). It should be noted, however, that the clinical relevance of this enhancement, at least in the case of HIV, remains to be determined. Finally, some nonneutralizing antibodies, or those antibodies that fail to directly neutralize virus in an *in vitro* assay, can mediate protective effects *in vivo,* presumably by engaging antigen-nonspecific effector mechanisms (*i.e.,* complement or Fc receptor-bearing cells) or perhaps through cellular signal transduction.[16]

Neutralization of Toxins and Enzymes

KEY CONCEPTS

Bacterial Immunity

- By neutralizing exotoxins, antibodies can prevent disease mediated by bacterial pathogens such as *Corynebacterium diphtheria* and *Clostridium tetani.*
- Antibodies alone or with complement-derived split products can opsonize pyogenic pathogens such as *Streptococcus pneumoniae.*
- Through activation of the classical pathway of complement leading to assembly of the membrane attack complex, antibodies can mediate destruction of some bacteria, most notably *Neisseria meningitidis* and *N. gonorrhoeae.*
- Antibodies can bind to bacterial adhesins thereby interfering with pathogen attachment to mucosal epithelial cells.
- Antibodies can bind to and inhibit bacterial proteins other than toxins performing critical metabolic or virulence-related functions.

In many bacterial infections, the clinical consequences of infection result from toxic molecules liberated by the bacterial cells rather than from the presence of the microorganisms themselves. Antibodies to such toxins can provide life-saving protection from disease while not directly eliminating the bacteria producing the toxins. A classic example is infection with *Corynebacterium diphtheriae,* which secretes a potentially lethal exotoxin. A more recent example is the emergence of *Clostridium difficile,* which secretes both an enterotoxin (toxin A) and cytotoxin (toxin B). Not only is there a correlation between antibody titers to toxin A and B and prevention of relapse, passive immunotherapy with antibody also prevented relapse.[17]

Bacteria can also produce additional virulence factors, such as enzymes that facilitate spreading of the pathogen through tissues. Host antibodies that inactivate such enzymes can have a beneficial influence on the clinical course. Inactivation of toxins or enzymes is presumed to result from direct competition between antibody and the target molecule or substrate of the toxin or enzyme or from the stabilization or induction of conformations incompatible, to some degree, with the normal function(s) of the toxin or enzyme. However, recent evidence in mice suggests that the protection afforded by exotoxin-neutralizing antibodies can depend on the presence of Fcγ receptors.[18]

FUNCTIONS MEDIATED BY ANTIBODY AND ADDITIONAL MOLECULES OR CELLS

Complement Activation

Regardless of whether binding of antibody to antigen directly mediates protective effects, antibody bound *in vivo* will activate antigen-nonspecific effector mechanisms. The exact mechanisms will depend on the isotype of the antibody as well as on other factors. One critical set of these effector mechanisms is encompassed by the classical pathway of complement activation (Chapters 3, 21). The human antibody isotypes vary considerably in their intrinsic ability to activate this pathway. The consensus view is that IgM, IgG1, and IgG3 isotypes are effective activators. Although some sources state that IgG2, IgG4, and IgA are weak or nonactivators of the classical complement pathway, evidence suggests that when epitope density is high, IgG2 can also activate the classical pathway effectively.[19] Instead of attempting to decide which subclass is absolutely superior, it is more useful to recognize that complement-fixing ability may not be determined solely by the subclass of an IgG antibody.

One obvious source for the isotype-related variation in complement activating ability is variation in affinity for C1q (IgG3 > IgG1 > IgG2 > IgG4), the portion of the first component in the classical pathway that physically contacts the C_H2 domains of antibodies. The intrinsic affinity of the C1q globular heads for Fc regions of any isotype is relatively low, which may account, in part, for the observation that two or more IgG molecules in proximity are required for activation of the classical pathway beginning with C1. Thus in the activation of the classical pathway, the functional affinity of C1q for antibody Fc regions is a crucial parameter.

IgG subclass–associated differences in some measures of complement activation have been found, under some experimental conditions, to depend on quantitative differences in steps of the cascade subsequent to the binding of C1q to antibody. Although there have been speculations regarding the role of segmental flexibility in complement activation, there is no simple correlation between this physical property and activity in fixing the classical complement pathway.[20]

It is generally agreed that IgA does not activate the classical pathway; however, its ability to activate the alternative complement pathway has been controversial. Studies with recombinant IgA molecules have suggested that neither IgA1 nor IgA2 activates either complement pathway. However, aberrantly glycosylated IgA and polymeric IgA may activate the lectin pathway and/or the alternative pathway, and this activation has been postulated to be associated with IgA nephropathy.

Antibody-mediated activation of the classical complement pathway has a variety of potential consequences, including creation of additional sites for attachment to a foreign particle, thereby facilitating ingestion (opsonization), elaboration of substances that mediate leukocyte chemotaxis, additional metabolic changes involved in the destruction of pathogens by leukocytes, and changes in vascular permeability (Chapter 21). In this process, it is the antibody that provides the specificity, whereas the other molecules function without specificity for the epitopes involved.

Receptors for Fc Regions

KEY CONCEPTS

Antibody Effector Systems

- Multivalence of Fc regions is often important in activating antibody effector functions.
- The occurrence and magnitude of effector function activation varies with antibody isotype.
- Effector mechanisms are inherently nonspecific with respect to antigen.
- Antibody Fc regions provide the mechanistic link between antigen-specific V domains and antigen nonspecific effector mechanisms.

The other major system by which antibodies mediate effector functions is cellular. The specific molecules with which cells recognize antibodies are called *Fc receptors* (FcR).[21] In humans, there are several Fc receptors for IgG (FcγRI, FcγRIIa, FcγRIIb, FcγRIIIa, FcγRIIIb), as well as other Fc receptors for IgA, IgE (FcεRI, FcεRII), and IgM (Fig. 15.5). We describe selected features of Fc receptors that illuminate the principles by which they function.

Some receptors (FcγRI, FcεRI) have relatively high intrinsic affinities for antibody molecules and can, therefore, bind significant fractions of monomeric Ig at physiological concentrations. For example, the high-affinity receptor for IgE (FcεRI) binds IgE with an intrinsic affinity of approximately 1×10^{10} M^{-1}. Therefore single IgE molecules can bind to mast cells or basophils through cell surface FcεRI before interacting with allergen (antigen). In contrast, FcγRII and FcγRIII have relatively weak intrinsic affinities for IgG Fc regions. Consequently, multivalent forms of IgG, such as are found in complexes of antibody and multivalent antigens (immune complexes), are much more readily bound to these FcR. Thus for both the complement-dependent and the FcR-dependent effector function pathways, multivalency of Fc regions (functional affinity) plays a critical role.

Several types of functional consequences can follow ligation of FcR by antibody–antigen complexes. These include activation and metabolic alteration of the FcR^+ cells, phagocytosis of antibody-coated particulate antigens, antibody-dependent cellular cytotoxicity (ADCC), and release of mediators that promote inflammation. The end result of Fc binding depends not only on the receptor but also on the cell on which it is expressed and on costimulation, if any, of additional receptors on that cell. As an example, the most studied FcR are those that bind IgG, and these receptors are expressed on many hematopoietic and even nonhematopoietic cells. Within the three classes of receptors (I, II, and III), the latter two FcR exist in two isoforms (A and B). Of interest to the regulation of the immune response, the B isoform for FcγRII transmits an inhibitory signal, and the A isoform transmits an activating signal.

CD89 has been identified in humans as a receptor for IgA, and it is expressed on myeloid cells including polymorphonuclear neutrophils (PMNs), monocytes, and a population of dendritic cells (DCs).[22] Signaling through CD89 involves an ancillary chain that transmits an activating signal. However, not all CD89 molecules associate with this chain, in which case, bound IgA is endocytosed and recycled back to the surface of the cell.[22] Interestingly, Fc binding to CD89 may be more potent at mediating antibody-dependent cellular cytotoxicity than Fc binding to one of the FcγR. Recent data have suggested another possible function that depends on the interaction between antibody (IgA) and a cell-surface receptor able to bind to polymeric Igs (pIgR). Transport of IgA–antigen complexes across epithelial surfaces by pIgR may represent a form of antibody-facilitated antigen excretion.[23]

ANTIBODIES AS SURROGATE LIGANDS

The notion that one molecule can mimic a second molecule, in one respect or another, is of extraordinarily broad applicability and profound biological significance. At least three types of mimicry can be distinguished, and each type can be regarded as a continuous (as opposed to discrete) variable.[24] First, one can conceive of limited structural mimicry of one molecule by another. By chance, two otherwise different molecules could have regions that happen to contain the same or similar (in key

FIG 15.5 **Domain Structures, Binding Properties, Cellular Expression Patterns, and Functional Effects of Human Fc Receptors.** A given FcR may exhibit differences in composition depending on the cell type expressing it. For example, FcγRIII is expressed on neutrophil plasma membranes bearing a glycosylphosphatidylinositol anchor, without FcR γ chains, whereas it is expressed on natural killer (NK)-cell plasma membranes as a conventional transmembrane protein in association with FcR γ chains. Similarly, FcγRIIB1 contains an additional stretch of polypeptide encoded by an exon whose product is not represented in the intracellular domain of FcγRIIB2. This additional portion of the polypeptide is believed to prevent the internalization of FcγRIIB1 subsequent to cross-linking. [a]A subset of FcγRIIA allotypes bind to human IgG2. [b]For these cells, FcR expression is inducible, not constitutive. [c]The molecular weight of CD89α chain is 70–100 kDa in eosinophils. respects), atoms in the same, or almost the same, three-dimensional arrangement. Second, there is mimicry at the level of noncovalent interaction. In this case, the question of interest is whether the model (object of mimicry) and the mimic bind the same receptor sites and with the same affinities. Third, there is mimicry of more complex biological functions, such as cellular or enzymatic inactivation.

It is important to make these distinctions because the extent of mimicry of one type is not a perfect predictor of the extent of mimicry of another type. We have already noted that slight changes in structure sometimes have slight effects on binding affinity or specificity, whereas in other cases, they have dramatic effects on binding affinity or specificity. Thus structural similarity (mimicry), as we perceive it, is not perfectly correlated with mimicry at the level of binding or the level of elicitation of higher biological function.

There are two aspects of receptor–ligand interaction that antibodies can potentially mimic. First, as noted earlier, the inducibility of a vast repertoire of antibody specificities suggests the potential for identifying, through screening or selection, antibodies that can bind any given target molecule at (near) a given site. Thus there should be a reasonable probability of obtaining antibodies that bind to a particular receptor at a site bound by some other, perhaps physiological, ligand or coreceptor. Evidence that antibodies can mimic the functional effects of other molecules is provided by many investigations of antiidiotypic antibodies and conventional antireceptor antibodies.[24]

Second, as noted earlier, the triggering event for many cellular and effector processes in the immune system is the aggregation of receptor molecules by clustered ligands. Therefore the ability of antibodies, which naturally have a maximal valence of ≥2, to cross-link cell-surface molecules and initiate signal transduction contributes to the abilities of antibodies to serve as surrogate coreceptors for cell-surface molecules. This property of antibodies has greatly facilitated the identification and functional characterization of many of these molecules and is also being exploited for therapeutic uses.[25]

FUNCTIONAL PROPERTIES OF ENGINEERED ANTIBODY MOLECULES

Monoclonal Antibodies

Many modern applications of antibodies in research, medicine, veterinary medicine, and other fields rely heavily, although not exclusively, on mAbs. By definition, a mAb population is derived from a clonal population of B-lineage cells (Chapter 7). Therefore all of the molecules express identical variable domains and identical antigen specificities. It is the homogeneity of V-domain structure associated with mAbs that most crucially distinguishes them from polyclonal antibodies, such as those conventionally derived from the serum. Homogeneous antibodies give more reproducible and more easily interpreted results for many kinds of assays.

KEY CONCEPTS

Monoclonal Antibodies From Hybridomas

- Hybridomas are created by fusing normal lymphocytes from immunized animals or immune humans with transformed cells of B-lymphocyte lineage (myeloma cells).
- Monoclonal antibodies (mAbs) produced by a hybridoma are generally homogeneous, expressing a single amino acid sequence.
- Hybridomas can be grown indefinitely in tissue culture.
- Hybridomas can be selected on the basis of the antigenic specificity or functional properties of the mAb secreted by the hybridoma.

mAbs of selected specificity were first produced by cells referred to as *hybridomas*.[26] In contrast, a myeloma protein would be an example of an mAb of unselected specificity. Hybridomas are hybrid transformed cells that are created by the fusion of two types of cells, with each parental cell endowing the hybridoma with desirable properties. One parent of a hybridoma (the fusion partner) is a transformed cell, usually a myeloma cell line, which contributes a metabolism that supports unlimited growth in tissue culture and high rates of Ig synthesis and secretion. Myeloma cell lines currently used as hybridoma fusion partners have been genetically manipulated in such a way that they no longer synthesize an Ig molecule, and they can be selected against in special culture media. The second parental cell is a B lymphocyte that provides the genetic information for the production of a particular antibody. Note that the choice of specificity on the part of the investigator is influenced at two stages in the process, including the choice of immunogen and the nature of the screening assay. By screening a population of hybridomas, most of which will secrete different antibodies, with an appropriately designed assay, it is possible to identify the minority of cells that secrete a mAb of desired specificity.

mAbs are useful for the identification and quantitation of diverse molecules of biological or synthetic origin, including human Igs (*e.g.,* paraproteins), antigens from infectious agents (*e.g.,* HIV p24), hormones, drugs, and toxins. They have also been exploited for therapeutic purposes, such as reversing allograft rejection, killing tumor cells, or preventing cytokine activity contributing to autoimmune disease (Chapter 89).

Recombinant Antibodies

The ability to manipulate the genes that encode antibodies, and thereby manipulate the structures of antibodies, has opened a new era in the study and application of antibodies (Fig. 15.6). Progress includes expression of recombinant intact IgG molecules,[27] expression of Ig fragments [F(ab), Fv] in eukaryotic and prokaryotic host cells, proteomic mining of combinatorial libraries of antibody fragments displayed on the surfaces of filamentous phage,[28] or yeast and bispecific or multispecific antibodies. Recombinant antibodies are also being designed to improve distribution and half-life of administered antibodies (Chapter 89). Not only does antibody engineering contribute to the design of potential therapeutics, but important basic science information has also been gained by using recombinant antibodies. For example, advances in understanding the role of specific effector functions in tumor cell destruction have been possible with the use of mutant and engineered recombinant antibodies, with rituximab being an example.

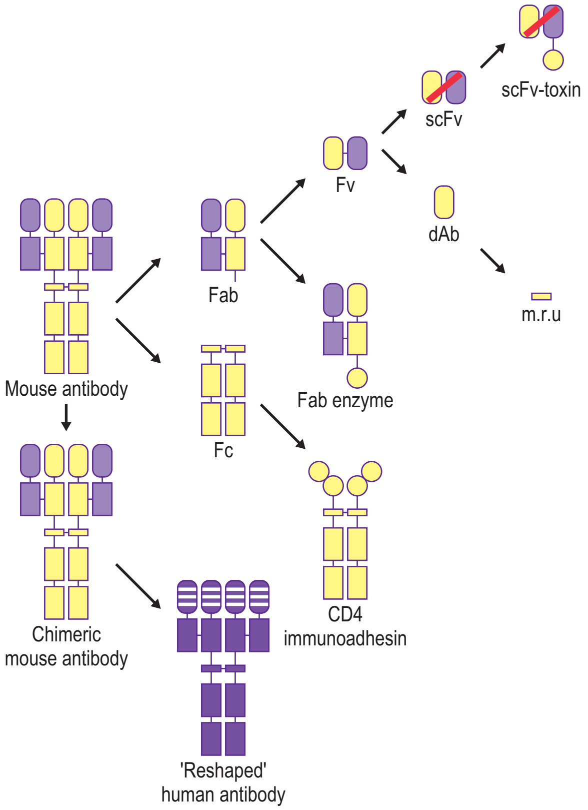

FIG 15.6 **Examples of Engineered Antibodies and Antibody-Derived Fragments That Can Be Created Through the Manipulation of Antibody Genes.** Each closed rectangular (constant) or rounded (variable) box represents a domain. The molecule at the bottom of the figure represents a humanized antibody, where the constant domains and variable domain framework regions correspond to human amino acid sequences. Only the hypervariable regions, and in some cases a small number of framework residues, correspond to mouse or rat antibody amino acid sequences. Other structures depicted include an Fab fragment; an Fv fragment; a single-chain Fv fragment (scFv) in which the C-terminus of the V_H domain is linked covalently by a linker peptide to the N-terminus of the V_L domain; an Fab-enzyme fusion protein; an scFv-toxin fusion protein; an immunoadhesin in which extracellular domains from CD4 have been covalently attached to human heavy chain constant domains; a single V_H domain (dAb); and a peptide derived from a hypervariable region (minimal recognition unit, or mru). With permission from Winter G, Milstein C. Man-made antibodies. Nature 1991;349:293.

The ability to clone Ig genes from single B cells has revolutionized the production of human mAbs. This technology has made possible the identification of broadly neutralizing antibodies for rapidly evolving pathogens, such as HIV-1 and influenza A viruses. These antibodies may prove to be clinically useful.[29] A second recent advance that could be important clinically is the ability

ON THE HORIZON

Recombinant Antibodies—Antibody Engineering

- Enhance effector function potency and half-life through Fc modification.
- Reduce or eliminate bystander effects.
- Isolate and express antibody genes using single B-cell cloning or combinatorial libraries.
- Allow expansion of the antibody repertoire and targeting possibilities.
- Facilitate agents for molecular recognition of minimal size (*i.e.,* nanobodies).
- Develop drugs or toxins that can be covalently attached to novel antibodies for therapy.
- Create multispecific or multimeric constructs.
- Guide vaccine design.
- Evaluate the roles of isotypes in protection or other functions.
- Define how differences in glycosylation can alter effector function.

ON THE HORIZON

Immunity Through Vector-Mediated Expression of Antibodies (Vectored Immunoprophylaxis)

- Host muscle cells transduced with a viral vector encoding antigen- or pathogen-specific antibodies.
- For highly variable pathogens, such as human immunodeficiency virus (HIV)-1, the antibodies are preferably broadly neutralizing.
- Based on model systems in mice, vector-mediated antibody expression can be long-term without immunization.
- Antibodies carrying different variable domains and expressing overlapping reactivities can potentially be simultaneously expressed.

to encode protective antibodies in viral expression vectors that can be introduced into experimental animals and probably humans and make possible the long-term expression of these mediators of immunity at relevant serum concentrations.[30]

MULTIPLE-CHOICE QUESTIONS

1. For which of the following phenomena is intrinsic affinity necessarily more important than functional affinity?
   - **A.** Antibody-mediated opsonization of encapsulated bacterial pathogens
   - **B.** Assay using antibodies to detect small drugs in solution
   - **C.** Binding of C1q to immunoglobulin G (IgG) or IgM
   - **D.** Binding of neutralizing IgG antibodies to nonenveloped viruses

2. Which of the following human immunoglobulin G (IgG) subclasses is the least effective in activating the classical pathway of complement?
   - **A.** IgG1
   - **B.** IgG2
   - **C.** IgG3
   - **D.** IgG4

3. Which of the following Fcγ receptors transduces signals that inhibit activation of B lymphocytes?
   - **A.** FcεRI
   - **B.** FcεRII
   - **C.** FcγR1
   - **D.** FcγRIIA
   - **E.** FcγRIIB1

4. Which of the following immunoglobulin (Ig) isotypes is dominant in colostrum and intestinal secretions?
   - **A.** IgA1
   - **B.** IgG2
   - **C.** IgG3
   - **D.** IgD
   - **E.** IgE

Helper T-Cell Subsets and Control of the Inflammatory Response

Todd N. Eagar, Stephen D. Miller

T cells are key regulators of the inflammatory processes required to limit infection. CD4 T cells were initially described as "helper" cells because of their ability to promote B-cell antibody production. It is now known that CD4 T cells have a much broader influence through regulation of the functions of phagocytes, granulocytes, and other lymphocyte subsets. This is accomplished through direct cell-to-cell interactions and via the production of cytokines. The contributions of CD4 T cells to host protection are highlighted by the recurrent bacterial, fungal, and viral infections arising in patients with impaired T-cell responses as a result of genetic diseases (Chapter 35), such as severe combined immunodeficiency (SCID), or in patients on immunosuppressive therapies.[1] Conversely, dysregulated T-cell responses are associated with rampant inflammation and autoimmunity, as seen in patients with such conditions as autoimmune lymphoproliferative syndrome (ALPS), autoimmune polyendocrinopathy syndrome type 1 (APS-1) and immune dysfunction, polyendocrinopathy, enteropathy, and X-linked (IPEX) syndrome.[2] Thus a balance must be struck between allowing T-cell inflammation to protect the hosts from pathogens and ensuring control mechanisms to prevent injury from T cell–mediated inflammation. The requisite control is established as T cells transit through stages or checkpoints of the immune response. These include activation, clonal expansion, migration, differentiation, and response termination.

- **Activation:** T-cell function requires antigen-specific T-cell receptor (TCR) signals and accessory signals. This provides fine specificity against discrete protein antigens and limits self-reactivity.
- **Clonal expansion:** Activated T cells rapidly expand in number to scale the immune response.
- **Migration:** T cells traffic through blood, lymphatics, and organs. This allows for surveillance and localized effector responses in diverse tissue types.
- **Effector responses:** T cells adapt their phenotypes to tailor the response to the organism and infected tissue. Long-term memory cells provide protection from reexposure to the same pathogens.
- **Termination:** T-cell responses are limited through inhibitory receptors, cell death pathways, and suppression.

T cells are generated in the thymus from lymphocyte progenitor cells (Chapter 8). Mature T cells enter the peripheral immune system as inexperienced or naïve cells that are incapable of carrying out effector immune responses. To participate in inflammation, T cells must go through an instructional process through defined checkpoints. This chapter will discuss the functional heterogeneity within the CD4 T-cell compartment in the context of the checkpoints involved in the generation and regulation of T-cell biology.

KEY CONCEPTS

T Cell–Mediated Inflammation Requires Activated or Memory T Cells

Naïve T Cells

- Low frequency
- Traffic through circulatory and lymphatic systems
- Require professional antigen-presenting cells (APCs) for activation
- Require strong costimulation
- Delayed expansion
- Delayed cytokine production
- Dependent on interleukin-7 (IL-7)

Activated T Cells

- Traffic through most tissues
- Respond to antigen presented by nonprofessional APCs
- Require less costimulation
- Rapidly expand following antigen encounter
- Rapidly produce effector cytokines
- Dependent on IL-2

Memory T Cells

- Traffic through most tissues
- Dependent on IL-7 and IL-15
- Respond to antigen presented by nonprofessional APCs
- Require less costimulation
- Rapidly expand following antigen encounter

Activation

Activation is required for the naïve T cell to function in effector or memory roles (Fig. 16.1). Full activation requires the cell to receive and integrate signals from a minimum of three diverse types of receptors; TCR (signal 1), costimulatory receptors (signal 2), and cytokines (signal 3).[3] TCR signals are essential for T-cell activation. Each TCR is generated through the process of somatic recombination to recognize major histocompatibility complex (MHC) and peptide complexes (Chapter 4). Engagement of cognate MHC–peptide complex by the TCR activates biochemical signals that lead to changes in transcription and ultimately to T-cell function (Chapter 12). Costimulation and cytokine signals can augment TCR signals by amplifying TCR-induced signal pathways or by eliciting additional signaling cascades. Activation

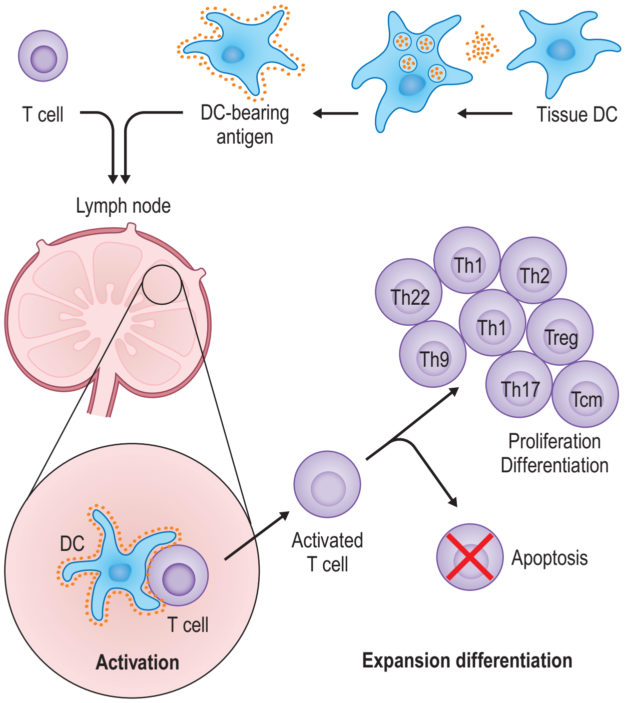

FIG 16.1 **T-Cell Expansion and Differentiation.** Following emigration from the thymus, CD4 T cells travel through the lymph nodes. Inflammation results in the recruitment of tissue dendritic cells (DCs) into the draining lymph nodes. In the lymph nodes, DCs present antigen to naïve T cells. Effective antigen presentation stimulates the activation, proliferation, and differentiation of T cells into Th1, Th2, Th9, Th17, Th22, or uncommitted T central memory (T_{cm}) cells.

requires extensive interactions between T cells and antigen-presenting cells (APCs; Chapter 6). These interactions lead to the formation of a multimolecular signaling complex known as an *immunological synapse*. This synapse brings critical receptors and intracellular signaling components that are required for activation into close proximity to elicit the activation process.[4]

TCR activation is dependent on the interactions between T cells and APCs. The primary APC type involved in activating naïve T cells is the dendritic cell (DC).[5] DCs are specialized phagocytes that are widely distributed in tissues throughout the body (Chapter 2). Mature DCs are efficient APCs and potent stimulators of naïve T cells. In response to infection or damage, DCs migrate from the tissue into the regional lymph nodes, where they enter the T cell–rich areas.[6] In the lymph node, T cells interact with numerous DCs as they scan for cognate antigen. In the absence of TCR signaling, these interactions are of short duration; however, TCR engagement elicits T cell–DC interactions that may last up to 20 hours.[7] Long-term interactions are required for full activation. In the presence of incomplete stimulation, that is, if costimulation is lacking, T cells are prevented from participating in inflammation and may become unresponsive to further stimulation (anergic) or undergo apoptosis. This is a regulatory mechanism used to prevent inappropriate T-cell activation and helps maintain self-tolerance in T cells.

T-cell activation depends on the maturation state of the DC. Immature DCs are incapable of stimulating functional T-cell responses and may instead induce unresponsiveness, whereas mature DCs readily elicit T-cell activation. DC maturation is regulated by external stimuli, such as Toll-like receptor (TLR) stimulation. T cells also stimulate DC maturation by expressing CD40 ligand (CD40L or CD154). Mature DCs instruct T cells through expression of MHC, costimulatory ligands, and cytokines. The expression of these molecules provides context to the T-cell activation process and helps tailor the immune response. For instance, TLR stimulation may elicit the expression of specific types or levels of costimulation and cytokine allowing mature DCs to promote antibacterial T-effector responses. Tissue-specific factors, such as vitamin D, transforming growth factor-β (TGF-β) and interleukin-10 (IL-10), alter costimulatory ligand and cytokine expression by the DC and reduce T-cell activation. Thus DCs transmit information from tissues to either promote specific immunity or suppress potentially damaging T-cell responses.[8]

T-cell activation defects contribute to several immunodeficiency diseases. T cells from patients with Wiskott-Aldrich syndrome, for instance, have defects in the formation of stable TCR signaling complexes. T cells in leukocyte adhesion deficiency 1 have a reduced capacity to become activated in response to stimulation due to defects in integrin β_2. Similarly, patients with mutations in the TCR signaling components lck and Zap70 show defective T-cell activation. In contrast, mutations in inhibitory receptors, including CTLA-4 and PD-1, are thought to contribute to susceptibility in autoimmune diseases.

The T-cell activation process is an important target for immunosuppression. Therapies targeting key biochemical pathways leading to activation are used to prevent rejection in solid organ transplantation, to treat graft-versus-host disease (GvHD) in bone marrow transplantation, and to reduce the severity of autoimmune diseases or other immune-mediated disorders. Cyclosporine and tacrolimus block the enzyme calcineurin and thereby inhibit TCR-induced nuclear factor of activated T cells (NFATs) signals. Rapamycin inhibits the kinase mammalian target of rapamycin (mTOR), which is induced by TCR and CD28 or by IL-2 receptor signals.[9] Monoclonal antibodies (mAbs) and fusion proteins that target T-cell activation are also applied for the treatment of autoimmune diseases and the prevention of graft rejection. A fusion of the extracellular domain of cytotoxic T lymphocyte antigen-4 (CTLA-4) with the Fc portion of immunoglobulin G (IgG; CTLA-4-Ig) is used to prevent T-cell activation by blocking the interactions between CD28 and its B7 ligands. Antibodies against the IL-2R block IL-2–driven T-cell activation. On the opposite side of the spectrum, antibodies that block the inhibitory receptors PD-1 and CTLA-4 are employed to promote or prolong T-cell activation and thereby enhance antitumor T-cell responses.[10]

Clonal Expansion

T-cell activation is detectable within hours of antigen exposure; however, days are required until T-cell responses can be detected from a naïve host. This delay partially reflects the need for T-cell expansion to produce a detectable and effective response. The initial frequency of T cells for a single epitope is estimated at approximately one per million total CD4 T cells or approximately 1×10^5 cells per human.[11] Following antigen exposure, cellular proliferation is initially slow, taking 2 days for the first divisions to occur in the lymph nodes and the spleen. Cell numbers increase rapidly between days 2 and 7 after antigen exposure, when many T cells have undergone as many as eight rounds of division. This process is known as *clonal expansion* (see Fig. 16.1). For instance, a single precursor T cell following eight rounds of division can yield 256 daughter cells, each possessing the same TCR. Through the combined proliferative responses of multiple T-cell clones to the same or different epitopes produced by the same pathogen, a rapid net increase in pathogen-reactive T cells occurs.

In the clinical setting, T-cell proliferation is a target for immunosuppression. Some drugs, such as azathioprine, methotrexate, and mycophenolate mofetil, impair T-cell proliferation by inhibiting nucleotide synthesis. Cyclophosphamide suppresses DNA replication by alkylating guanine residues. These agents are used in the treatment of various autoimmune diseases and for the prevention of graft loss in transplantation.

TRAFFICKING

Following activation, T cells change their migration patterns (Chapter 11). T-cell migration relies on the actions of selectins, chemokines (Chapter 10), integrins, and matrix proteases. Together, these permit vessel transmigration into lymphatic tissues or sites of inflammation.[12] The differential trafficking of naïve and effector T cells results from varied expressions of selectins, chemokine receptors, and integrins. The circulation of naïve T cells is restricted to blood, lymph nodes, and lymphatic ducts. This pattern of movement relies on the expression of chemokine receptor 7 (CCR7), L-selectin or (CD62L), and LFA-1($\alpha_L\beta_{2,}$ integrin, CD11a, CD18). CCR7-expressing T cells follow gradients of CCL21 into T cell–rich areas in the lymph nodes, Peyer patches, and spleen. L-selectin allows rolling on the high endothelial venule (HEV). LFA-1 and intercellular adhesion molecule-1 (ICAM-1) permit firm adhesion and extravasation. Migration to the Peyer patches also requires $\alpha_4\beta_7$ integrin in addition to leukocyte function–associated antigen-1 (LFA-1). T-cell retention in and egress from the lymph node are regulated by sphingosine 1 phosphate (S1P), a secreted phospholipid. S1P sensitivity is mediated by sphingosine 1 phosphate receptor 1 (S1P1), a G protein–coupled receptor. Recirculating T cells downregulate S1P1. As a result of low S1P levels in the lymph node, S1P1 expression allows exit from the lymph nodes in 12–18 hours after entry.[13]

During activation, T cells alter the patterns of homing receptors to reduce the cell's ability to migrate within the secondary lymphatic system while gaining receptors needed for trafficking in the peripheral tissues. Very early in the activation process, T cells downregulate S1P1 and express CD69, which suppresses chemotactic migration in response to S1P, shed L-selectin, and express the ligands for E- and P-selectin. Additionally, T cells downregulate CCR7 expression and express a new set of chemokine receptors. Following activation, LFA-1 expression is markedly increased, and the expression of additional integrin molecules is also induced. One such integrin, very late antigen-4 (VLA-4), is induced by activation and permits T-cell migration into the central nervous system (CNS), lungs, and intestines.[14]

Differential expression of homing receptors between naïve and activated T cells facilitates their diverse functions. Naïve T cells in the lymphatic tissues are in close proximity to a concentrated collection of DCs from many tissues; this facilitates antigen encounter. The function of activated T cells in immune surveillance, in contrast, is facilitated by migration through diverse tissues.

The multistep process of migration and the tissue selectivity of migration receptors have been targeted for the treatment of autoimmune diseases. Antibodies targeting CD62L and LFA-1 have been developed to prevent the entry of T cells into lymph nodes. In addition, the S1P1 inhibitor drug, fingolimod, has been recently approved for the treatment of multiple sclerosis. Fingolimod is thought to prevent the egress of recently activated T cells from the lymph nodes. Natalizumab, an mAb against the α_4 integrin, is utilized in the treatment of multiple sclerosis and Crohn disease to prevent the migration of T cells to the CNS and intestines, respectively.

DIFFERENTIATION OF CD4 TH SUBSETS

Naïve T Cells

Naïve T cells are precursors for effector and memory T cell subsets. Phenotypically, naïve T cells are small cells with little cytoplasm; they express surface markers, such as CD45RA, CCR7, CD62L, CD127, and CD132. They lack expression of markers of previous activation, such as CD25, CD44, CD69, CD45RO, or HLA-DR. Naïve T cells have low metabolism and are unable to produce proinflammatory cytokines.[15] Naïve T cells migrate within the secondary lymphoid organs, where they interact with DCs. Functionally, naïve T cells are not capable of mediating effector immune responses. Naïve T cells are predominant after birth but decline in percentage after puberty. Because of their role as precursors for all T-effector subsets, their loss is thought to be an important contributor to the immunosenescence seen in older adults.

Early studies demonstrated that CD4 T-cell clones and cell lines would express reproducible patterns of cytokine expression designated T-helper cell-1 (Th1) and T-helper cell-2 (Th2).[16] It is now appreciated that CD4 effector T cells can differentiate into many functional phenotypes (see Fig. 16.1). These can be grouped into four general categories: *(i)* those possessing proinflammatory effector characteristics, *(ii)* those possessing regulatory or antiinflammatory activities, *(iii)* those that function to promote B-cell follicle development, and *(iv)* those that provide long-term memory. Our understanding of the phenotype diversification process is rapidly expanding. From the T-effector differentiation models, we learn of three steps. First, TCR signals lead to activation and elicit the expression of cytokine receptors.[17] Second, signals through specific cytokine receptors differentially promote the expression of lineage-specific "master" transcription factors that promote expression of genes associated with a particular T-cell phenotype and suppress the expression of genes associated with other T-cell phenotypes. Third, the phenotype specific transcription factors induce epigenetic changes that control gene accessibility and maintain the T-cell phenotype in a cell-intrinsic manner.

EFFECTOR CELL PHENOTYPES

T-effector cells promote inflammation through the release of cytokines (Fig. 16.2). Cytokine release elicits the activity of accessory cells, which ultimately mediate the inflammation to clear the antigen. The pattern of cytokine production ultimately dictates the type of inflammation (Table 16.1). Effector T cells are divided into five basic groups: Th1, Th2, Th9, Th17, and Th22. Table 16.2 summarizes responses the T-effector responses associated with selected pathogens.

Th1

Th1 cells are defined by production of the cytokines interferon (IFN)-γ, granulocyte macrophage–colony-stimulating factor (GM-CSF), IL-2, and lymphotoxin (LT, tumor necrosis factor

KEY CONCEPTS

CD4 Effector Phenotypes

Th1

- Produce interferon (IFN)-γ, interleukin (IL)-2, tumor necrosis factor (TNF)-α and TNF-β (LT-α)
- Stimulate Immunoglobulin (Ig)G2 and IgG3 class switching
- Responses mediated by macrophage activity
- Promotes phagocytic activity through:
  - FcγRIII cross-linking
  - Complement deposition
  - Opsonization
  - IFN-γ-mediated macrophage activation

Th2

- Produce IL-4, IL-5, IL-6, and IL-10
- Stimulate IgG4 and IgE class switching
- Responses mediated by mast cells and eosinophils
- Increases degranulation through:
  - FcεRI cross-linking
  - IL-5–mediated eosinophil activation

Th17

- Produce IL-6, IL-17, and TNF-α
- Activate local endothelium
- Induce cytokine and chemokine production
- Increase infiltration by neutrophils
- Activates cell-mediated inflammation

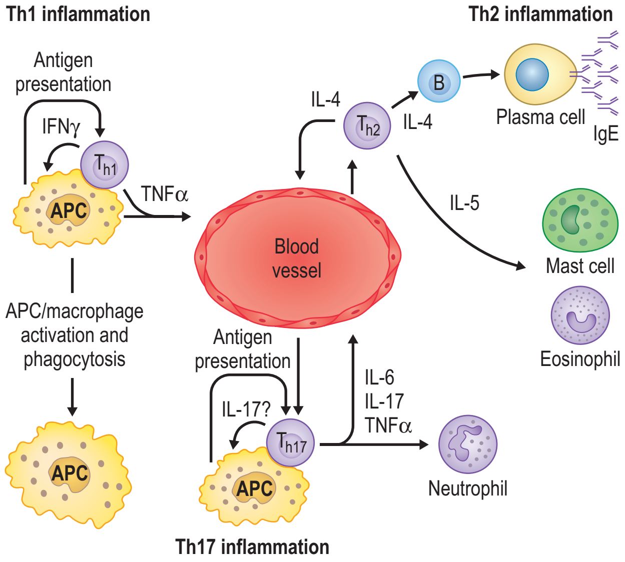

FIG 16.2 Generalized Model for T Helper (Th)–Mediated Inflammation. *Top left.* Introduction of infectious agent stimulates the release of chemokines and tumor necrosis factor (TNF)-α from tissue macrophages, stimulating the recruitment *(upward arrows)* of T cells and monocytes through the local vasculature. Antigen recognition by T cells stimulates the local production of Th1 cytokines. Interferon (IFN)-γ activates macrophages enhancing the clearance of infectious agents. *Top right.* Trafficking to sites of Th2 responses is stimulated by local chemokine expression leading to T-cell recruitment. Antigen recognition leads to interleukin (IL)-4 production by Th2 cells, which stimulates B-cell immunoglobulin (Ig)E class switching. Production of IL-5 activates eosinophils. Cross-linking of FcεR1 molecules bound to IgE leads to the degranulation of mast cells (Ma) and eosinophils (E). *Bottom.* Recruitment of Th17 cells and restimulation by antigen results in the release of IL-6, IL-17, and TNF-α, which promotes the recruitment, activation, and function of many cells, particularly neutrophils.

[TNF]-β). Th1 differentiation is elicited in response to infection by intracellular bacteria, fungi, and viruses. Infection by these pathogens leads to the production of cytokines by DCs and natural killer (NK) cells. Th1 differentiation is promoted by IL-12, IL-18, IFN-γ, and type 1 interferons and is inhibited by IL-4, IL-10, and TGF-β (Fig. 16.3). During activation, IFN-γ receptor signals activate signal transducer and activator of transcription 1 (STAT1) and promote the expression of the Th1-restricted transcription factor T-bet and IL-12R expression. IL-12R signals through STAT4 then drives the expression of high levels of T-bet. T-bet serves to reinforce the Th1 phenotype by promoting IFN-γ and IL-12Rβ_2 expression.[17] IL-18 plays a dual role in Th1 function by promoting Th1 commitment and eliciting IFN-γ production by fully differentiated Th1 cells.

Th1 cells promote cell-mediated inflammatory responses through inducing the activation of macrophages, NK cells, B cells, and CD8 T cells. Th1 cells regulate macrophage function at several levels. GM-CSF promotes the production of monocyte lineage cells from the bone marrow. IFN-γ is a potent macrophage activator, enhancing microbicidal activity by initiating nitric oxide (NO) production, upregulating production of oxygen radicals, and increasing phagocytic function. IFN-γ also promotes antigen presentation by upregulating MHC class I molecules, MHC class II molecules, and costimulatory molecule expression by macrophages (see Fig. 16.2). IFN-γ can activate NK cells and also promote humoral responses in B cells to mediate antibody class switching to an IgG1 (IgG2a in mice) isotype.[18] IgG1 activates the classical complement pathway and can bind Fcγ receptors expressed on phagocytic cells thereby promoting opsonization. Finally, IFN-γ acts in conjunction with another Th1 cytokine, IL-2, to promote the differentiation of CD8 cells into cytotoxic effector cells (Chapter 17). Macrophage-dependent Th1-mediated inflammatory responses are known as *delayed-type hypersensitivity* (DTH) responses. *In vivo*, DTH responses are critical for protection from intracellular pathogens including bacteria, fungi, and viruses. Individuals with defects in components of the IFN-γ or IL-12 signaling pathways are susceptible to atypical mycobacterial infections and have altered responses to other microorganisms. Additionally, Th1 cells are thought to contribute to the pathogenesis of autoimmune diseases, including multiple sclerosis, type 1 diabetes mellitus, rheumatoid arthritis, and Crohn disease. The Th1 pathway has been explored therapeutically. IL-12 has been studied as a way to boost vaccine immune responses against microorganisms and antitumor immunity. IL-12 neutralizing mAb-based therapies have been investigated in inflammatory and autoimmune diseases, including psoriasis, arthritis, Crohn disease, and multiple sclerosis.

Th2

Th2 cells are defined by their production of IL-4, IL-5, IL-9, IL-10, and IL-13. *In vitro*, the critical step in Th2-cell differentiation is the presence of exogenous IL-4 and the absence of IFN-γ during T-cell activation. *In vivo*, Th2 differentiation is thought to require IL-4 produced by basophils, eosinophils, mast cells, NKT cells, or even previously differentiated Th2 cells. Naïve T

TABLE 16.1 **T-Helper (Th) Cell Effector Function Through Cytokine Secretion**

Th1	
Interleukin (IL)-2	T-cell growth and potentiation of Fas-mediated apoptosis
	Natural killer (NK) cell growth and cytolytic activity
	B-cell growth and antibody production
Interferon (IFN)-γ	Increases class I and class II molecule expression on numerous cell types
	Promotes Th1 differentiation
	Activates macrophages; stimulates phagocytic killing and oxidative bursts
	Induces immunoglobulin (Ig)G2α and IgG3 class switching
	Inhibits IgG1 and IgE class switching
	Inhibits Th2 proliferation
	Activates neutrophils
	Activates endothelium to promote CD4 T-cell adhesion
	Stimulates NK cell cytolytic activity
	Required for the activation of CD8 cytotoxic T lymphocytes (CTLs)
Tumor necrosis factor-α (TNF-α)	Activates vascular endothelial cells; enhances leukocyte recruitment
	Activates neutrophils, eosinophils, and macrophages
	Stimulates IL-1, IL-6, TNF, and chemokine expression by macrophages
	Protects against viral infections, similar to interferons (IFNs)
	Increases class I molecule expression
	Induces fever
	Activates coagulation
Lymphotoxin (LT) (TNF-β)	Activates neutrophils and osteoclasts
	Activates vascular endothelial cells; enhances leukocyte recruitment
	Cytotoxic activity against tumor cells
	Stimulates adhesion molecule expression
	Increases class I molecule expression
Th2	
IL-4	Growth and differentiation of Th2 cells
	B-cell growth and class II molecule upregulation
	Induces IgG1 class switching (IgG4 in humans) and IgE
	Inhibits IgG2a and IgG3 class switching
	Mast cell growth
	Inhibits macrophage activation
	Induces vascular cell adhesion molecule (VCAM) expression on endothelium; recruits eosinophils/monocytes
IL-5	B-cell growth and activation
	Eosinophil differentiation
	Eosinophil activation and survival
IL-10	Inhibits cytokine and chemokine production in monocytes, especially TNF, IL-1, and IL-12
	Inhibits macrophage activation and function
	Inhibits T cell–mediated inflammation
	Induces IgG4 class switching (IgG1 in mice)
IL-13	Upregulates class II molecules on monocytes and B cells
	Inhibits proinflammatory cytokine production by monocytes
	B-cell costimulation
	Induces IgG4 class switching (IgG1 in mice) and IgE
	Increases class I molecule expression
Th9	
IL-9	Mast cell expansion and recruitment
	T-cell growth factor
IL-21	Promotes Th17 differentiation
	B-cell survival; antibody class switching
	Enhances NK cell proliferation; promotes killer function
Th17	
IL-17	Increases T-cell proliferation
	Promotes neutrophil recruitment and activity
	Promotes cytokine production including IL-6 and TNF-α
	Induces chemokine production
Granulocyte macrophage–colony-stimulating factor (GM-CSF)	Promotes myeloid cell development and maturation
	Promotes dendritic cell differentiation and survival
	Enhances macrophage activation
IL-6	Activates acute-phase response, inducing fever and antibacterial responses
	Promotes Th2 and Th17 differentiation
	Activates and elicits s NK responses
	Promotes plasma cell differentiation and Ig production
IL-21	See above.
TNF-α	See above.
Th22	
IL-22	Activates acute phase response, inducing fever and antibacterial responses
IL-13	See above.
TNF-α	See above.

TABLE 16.2 T-Cell Effector Responses to Selected Pathogens

Organism	Nature of the Immune Response
Bacteria	
Borrelia burgdorferi	T-helper (Th1) responses associated with protection and joint pathology
Chlamydia trachomatis	Th1 responses protective and source of pathology
Helicobacter pylori	Th1 responses involved in ulcer formation
Legionella pneumophila	Th1 responses associated with immunity
Listeria monocytogenes	Th1 responses are protective: interferon (IFN)-γ from γδ T cells and CD8 T cells is important
Mycobacterium leprae	Severity and phenotype of disease depends on Th1 and Th2 predominance
Mycobacterium tuberculosis	Th1 responses control infection
Treponema pallidum	Th1 resolves infection; Th2 chronic
Yersinia pestis	Th1 and Th17 responses associated with immunity
Fungi	
Aspergillus fumigatus	Th2 production predominates; does Th1 offer protection?
Blastomyces dermatitidis	Th1 protects; Th2 switch in progressive disease
Candida albicans	Th17 responses are protective
Cryptococcus neoformans	Susceptibility associated with Th2 response; Th17 response associated with protection
Paracoccidioides brasiliensis	Infection stimulates Th2 response, but Th1 response protects
Parasites	
Leishmania spp.	Th1 responses are protective; Th2 responses allow chronic infection
Filaria	Initiates Th2 production; Th1 response appears protective
Schistosoma mansoni	Th1 and humoral responses protect; typically Th2 responses directed against eggs
Trypanosoma cruzi	Th1 responses inhibit parasite replication, but protection is not completely CD4 dependent
Giardia lamblia	Th1 and Th2 responses protect
Viruses	
Measles	Th1 responses are protective
Hepatitis B	Th1 responses seen in spontaneous recovering patients
Human immunodeficiency virus	Shift from Th1 to a Th0 (Th2?) response late in disease correlates with susceptibility to pathogens
Respiratory syncytial virus	Th1 response protects; Th2 response kills

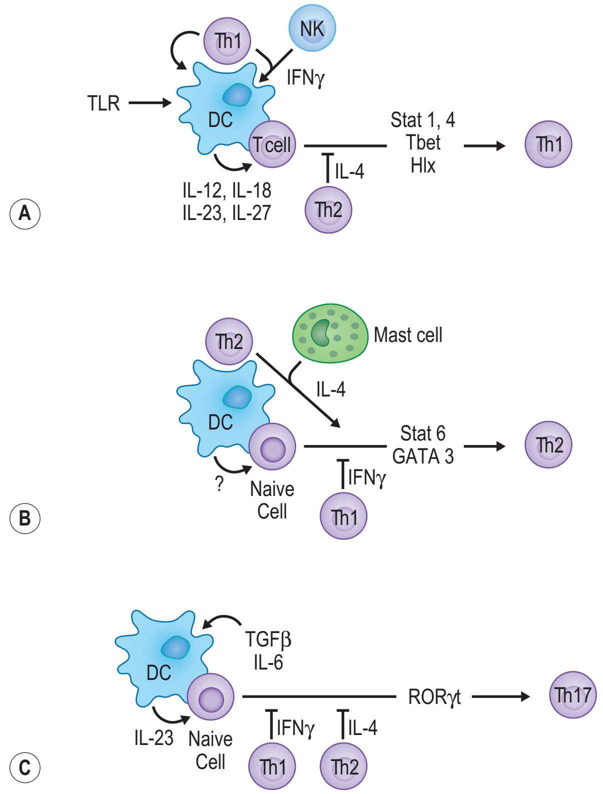

FIG 16.3 Factors Influencing T-Effector Differentiation. Cytokine exposure during the activation stage of naïve T cells strongly influences T-effector differentiation. Depicted here are the factors promoting and inhibiting Th1, Th2, Th17, and T-follicular helper (Tfh) cells following functional activation of undifferentiated T cells.

cells express the IL-4R, and the combination of TCR, costimulatory (CD28 and ICOS), and IL-4R/STAT6 signaling promotes IL-4 transcription and the production of the transcription factors c-Maf and GATA3. c-Maf helps to establish Th2 polarity by promoting IL-4 and suppressing IFN-γ production. GATA3 also appears to inhibit IFN-γ production but additionally plays a critical role in establishing Th2 cells by promoting IL-5 and IL-13 production (see Fig. 16.3).[19]

Th2 cells release IL-4 and IL-5, which attract and activate the function of eosinophils and mast cells. Th2-type cytokines enhance B-cell class switching toward IgG2, IgE, and sIgA. High levels of IgE in Th2 reactions combined with antigen exposure and FcεR1 receptor expression by eosinophils or mast cells results in triggering and release of inflammatory factors, such as histamine, platelet-activating factor, prostaglandins, and leukotrienes (see Fig. 16.2). These factors act on the local environment, producing vascular dilation and leakage, bronchial constriction, and intestinal hypermotility. On a more systemic level, anaphylaxis may be produced. Eosinophil- and mast cell–dependent reactions are known as *immediate-type hypersensitivity* (ITH) responses. ITH responses are important for ridding the body of intestinal helminths; in fact, components of helminth eggs strongly promote Th2 differentiation. Th2 responses are also associated with atopy and hyperresponsive airway conditions, such as asthma and allergies.

Th17

Th17 T cells are characterized by the production of IL-17a/f, IL-21, IL-22, IL-26, GM-CSF, and TNF-α. Th17 differentiation is promoted by IL-1β, IL-6, IL-23 and TGF-β, and the absence of type 1 interferons, IFN-γ, and IL-4 (see Fig. 16.3). Much of the potency attributed to Th17 cells derives from the production of IL-17 and GM-CSF. IL-17, together with TNF-α, strongly promotes inflammation by inducing the expression of adhesion molecules, proinflammatory cytokines (including IL-6, GM-CSF, granulocyte–colony-stimulating factor [G-CSF]), chemokines, prostaglandin E2, and matrix metalloproteinases (see Fig. 16.2). IL-21 regulates B-cell, T-cell, and NK-cell functions.[20] In B cells, IL-21 has been found to regulate plasma cell differentiation and promote IgM and IgG1 antibody production. IL-21 is a T-cell growth factor, and in the presence of TCR signals, IL-21 promotes T-cell activation, proliferation, and survival. It therefore appears that Th17 cells are important for the recruitment of effector cells, including neutrophils and monocytes.

In many ways, Th17 cells are potent cell-mediated effectors. Th17 responses are elicited in response to infection with extracellular bacteria and fungi. In addition, Th17 cells have been identified in patients with atopic dermatitis, Crohn disease, psoriasis, and multiple sclerosis. Experimental models demonstrate that Th17 cells, via the production of GM-CSF and IL-17, are important mediators of autoimmune diseases, including experimental autoimmune encephalomyelitis (EAE).[21] Patients with impaired IL-17 expression or mutations causing Th17 differentiation experience recurrent infections with *Staphylococcus aureus* and *Candida albicans.* Alleles of the IL-23R have been found to confer protection or susceptibility to Crohn disease and psoriasis. Clinical trials are underway to examine the effects of disrupting Th17 immune responses in patients with autoimmune diseases. mAbs to IL12/23 p40, IL23 p19, and IL-17a have been approved for treatment of psoriasis and are being investigated for application in other conditions.

Th9

Although Th2 cells have long been known to produce IL-9, recently, it has been proposed that an IL-9 producing T-cell subset is a separate lineage. Human Th9 cells have been shown to produce IL-9 and IL-21. IL-9 is an important growth factor for T cells, mast cells, and hematopoietic stem cells (HSCs). IL-9 functions by preventing apoptosis. The differentiation of naïve T cells into a Th9 phenotype is thought to be dependent on the presence of IL-4 and TGF-β.[22] Th9 cells express the transcription factor PU.1, which is thought to repress Th2-associated GATA3 and Th1-associated T-bet expression. Similar to Th2 cells, Th9 cells are thought to play a role in protection from helminths. In addition, Th9 cells play a role in asthma, where they promote airway restriction and mucus secretion. Experimental models also suggest that Th9 cells may contribute to the pathogenesis of autoimmune disease.

Th22

Although IL-22 was originally described as a Th17 cytokine, research has shown that a distinct CD4 T population expressed IL-22 independently of IL-17. Further work identified IL-22, IL-13, and TNF-α-secreting cells in the skin of patients with inflammatory skin disorders.[3] These IL-22–expressing cell populations also express the skin homing receptors CCR10. These cells, labeled Th22 cells, have been subsequently found to differentiate in the presence of IL-6 and TNF-α.[23] Phenotypically, Th22 cells express a different gene profile than other Th cell types, suggesting that they are a distinct effector population. They also produce fibroblast growth factors that promote epidermal repair. The hallmark cytokine IL-22 is a member of the IL-10 family with important functions in regulating skin homeostasis and protection from infection. Experimental models suggest that IL-22 and Th22 cells may play roles in regulating inflammation in other epithelial tissues.

KEY CONCEPTS

Regulation of T-Cell Responses

- Cell death pathways
  - Tumor necrosis factor (TNF) family receptors: Fas/FasL, TNF-related apoptosis inducing ligand (TRAIL), and TNFR1
- Inhibitory receptor activity
  - Cytotoxic T lymphocyte antigen-4 (CTLA-4) and programmed death-1 (PD-1)
  - Inhibition of T-cell receptor (TCR) signaling
- Cytokine-mediated regulation
  - Antiinflammatory cytokine production (interleukin [IL]-10, transforming growth factor-β [TGF-β])
  - Cytokines that promote and inhibit inflammation at different stages of a response (interferon-γ [IFN-γ], IL-2, IL-27)
  - Regulation of apoptosis (LT, TNF-α)
  - Growth factor withdrawal (IL-2, IL-7, IL-15)

REGULATORY T CELLS

Regulatory T cells (Tregs) possess the ability to suppress or otherwise downregulate the function of other proinflammatory T cells. Although multiple T-cell subsets may possess regulatory T cell activity, our understanding of regulatory function was greatly enhanced by the discovery of CD25 and FoxP3 as markers for a regulatory subpopulation of CD4 T cells (Chapter 18). This discussion focuses on the involvement of two populations of peripherally derived Treg phenotypes: adaptive Treg and Tr1 cells.

Adaptive Tregs

In mice, the majority of $CD4^+$ $CD25^+$ $FoxP3^+$ Tregs (natural Tregs) are thought to develop regulatory ability in the thymus. Peripherally derived adaptive Tregs are similar in phenotype to natural Tregs in that they express CD4, CD25, CD38, CD62L, CD103, and FoxP3. Adaptive Tregs are thought to be generated in response to prolonged exposure to antigen and are influenced by antigen presentation by immature DCs, plasmacytoid DCs, or nonprofessional APCs. Experiments suggest that the presence of inhibitory cytokines, such as IL-10 and TGF-β, also favors adaptive Treg differentiation. Similar to natural Tregs, adaptive Tregs are capable of suppressing CD4 and CD8 T-cell responses. Unlike natural Tregs, adaptive Tregs can function through both cell contact–dependent interactions and through the secretion antiinflammatory cytokines. These cytokines may directly regulate effector T cells or may inhibit DC activity. The generation of adaptive Tregs is of great interest as a cell-based therapy for inflammatory diseases, including autoimmunity.[24]

Tr1 Cells

Tr1 cells have been defined as a population of CD4 T cells that produce IL-10 in response to stimulation. Unlike adaptive Tregs, Tr1 cells do not express FoxP3 and do not necessarily express CD25. Tr1 cells are produced in the respiratory tract when antigen exposure is coupled with IL-10 and TGF-β. Experimentally, Tr1 cells can be induced by repeated intranasal antigen delivery.[25] Respiratory tract infections with *Bordetella pertussis* have also been found to elicit Tr1 cells *in vivo*.[26] Tr1 cells function by producing IL-10 to block proliferation of naïve T cells, prevent

Th1 differentiation by blocking IL-12 production, and enhance differentiation of T cells toward a Tr1 phenotype.

FOLLICULAR HELPER T CELLS (TFH)

One of the earliest described roles of CD4 T cells is their ability to promote or “help” generate effective antibody production by B cells. Th1 and Th2 cells have been described for their ability to promote B-cell class switching and effector responses. Evidence supports the role of a distinct subpopulation of T cells, known as *T-follicular helper* (Tfh) cells, as playing a key role in regulating T cell–dependent B-cell responses. Tfh cells are identified by their surface expression of CXCR5, inducible T-cell costimulator (ICOS), programmed death-1 (PD-1), CD200, B- and T-lymphocyte attenuator (BTLA), OX40, and serum amyloid P (SAP), while lacking the expression of CD127 and CCR7.[27] Tfh cells also express the transcription factor BCL6, which is essential for their differentiation and function. Interestingly, BCL6 can be coexpressed with T-bet, GATA3, or RORγt, but BCL6 modifies many of their effector lineage functions. The fact that there is an incomplete separation between Tfh and other T-effector lineages might suggest that the Tfh phenotype is generated in parallel with T-effector cell differentiation and in response to inflammatory cues present in lymph nodes.

Tfh differentiation is promoted by signals through ICOS, OX-40, and the presence of IL-6, IL-12, and IL-21. Tfh cells upregulate CXCR5, which enables homing to the interface between the T-cell and B-cell areas of lymph nodes, where they interact with recently activated B cells via antigen presentation. The B cells provide signals to the Tfh cell through ICOS and IL-6, while the Tfh cells provide CD40L and IL-21 to the B cells. Through successive interactions with B cells, Tfh cells promote the survival, proliferation, Ig class switching, affinity maturation and differentiation of B cells into memory B cells, and antibody-producing plasma cells through the germinal center reaction.[28]

Mutations affecting Tfh-associated pathways have been identified in B-cell immunodeficiency disorders. Common variable immune deficiency (CVID) is often linked to mutations in the ICOS pathway. Recurrent infections in patients with CVID are associated with hypogammaglobulinemia and reduced numbers of Tfh cells. X-linked lymphoproliferative disease type 1 (XLP1) has been associated with mutations in the *SH2D1A* gene. Interestingly, patients with XLP1 have defects in B-cell germinal center formation and decreased memory B-cell numbers but have normal Tfh numbers. XLP1 Tfh cells reduced the ability to support B-cell function.[29] Tfh cells have been implicated in autoimmune diseases, such as myasthenia gravis, Graves disease, Hashimoto thyroiditis, lupus, Sjögren syndrome, and rheumatoid arthritis, where dysregulated antibody responses are thought to contribute to disease progression. In addition, therapies to target or passively transfer Tfh cells are being studied for treatment of autoimmune disease and some forms of lymphoma.[29]

MEMORY T CELLS

Following an immune response, small numbers of T cells persist over the long term and are called *memory T cells*. Memory T cells protect the host from reinfection by the same microorganisms. Protection correlates with the number of specific memory cells present in the host. Memory cells accelerate responses against repeat antigen for several reasons. First, memory cells are maintained at higher frequencies than are naïve cells. Second, a large portion of memory T cells are maintained in peripheral tissues, allowing for rapid local responses to infection. Third, memory T cells proliferate and produce cytokines in response to stimulation with lower doses of antigen, less costimulation, and much faster kinetics compared with naïve T cells. Fourth, memory cells enhance can promote APC function and produce cytokines that promote the effector differentiation of naïve T cells.

Diverse populations of memory T cells can be defined by surface marker expression, localization, and patterns of migration. Two populations of memory T cells are identified on the basis of their reexpression of the lymph node homing receptors CCR7 and L-selectin following activation. Central memory (T_{cm}) cells are identified as CD45RA$^-$ CD45RO$^+$, CCR7$^+$, CD62L$^+$, and stem cell memory cells (T_{scm}) are identified by the markers CD45RA$^+$ CD45RO$^-$, CCR7$^+$, CD62L$^+$, CD95$^+$.[30] By expressing CCR7 and CD62L, these memory T cells permit recirculation through secondary lymphatic organs, allowing interactions with DCs from diverse tissue sites effectively expanding the area of immune surveillance. T_{cm} and T_{scm} produce IL-2 and rapidly enter the cell cycle upon activation. T_{cm} and T_{scm} are able to acquire effector phenotypes, suggesting that they function as a precursor pool for subsequent immune responses.

Two additional memory cell subsets have been described on the basis of their ability to migrate through peripheral tissues. Effector memory T cells (T_{em}) are identified by the expression pattern: CD45RO$^+$, CCR7$^-$, CD62L$^-$. These cells express chemokine receptors, selectins, and integrins to facilitate their recirculation through peripheral tissues. T_{em} cells have previously undergone effector differentiation, and upon stimulation they rapidly express restricted cytokine patterns reflecting their prior phenotype. Additional populations of nonmigratory memory T cells have been identified. These are known as tissue resident memory T cells (T_{rm}). T_{rm} cells are identified by the markers CD45RO$^+$, CCR7$^-$, CD69$^+$. They have been identified in close proximity to epithelial sites in multiple tissues. T_{rm} cells provide rapid and highly localized cytokine production in response to infection. Thus T_{em} and T_{rm} cells bolster immunity by providing immune surveillance at distinct sites.[31]

The processes underlying memory T-cell differentiation are incompletely understood. A number of signaling pathways and APC populations have been proposed to be involved in memory differentiation. It is clear that T_{cm} and T_{em} cells are generated early in the T-cell response. The pathways that lead to the differentiation of Th1, Th2, Th17, and Tfh effector cells are also important in the generation of T_{em} populations.

GENERAL CONSIDERATIONS IN EFFECTOR T-CELL DIFFERENTIATION

Several key concepts of Th maturation should be discussed with regard to the cellular differentiation of CD4 T cells. First and foremost, all T-effector, memory, and adaptive Tregs are thought to arise from naïve thymic emigrant precursors. In addition, T-cell phenotype specification is regulated independent of TCR specificity.

Second, differentiation to a specific effector phenotype is self-promoting and inhibitory to other phenotypes through production of effector cytokines (see Fig. 16.3). Early in Th1 or Th2 differentiation, for example, expression of the transcription factors T-bet or GATA3, promote proeffector differentiation while suppressing alternative cell fates. Once established, T-cell phenotypes are maintained through active signaling and chromosomal modification.

Third, polarization is incomplete at the population level. Following exposure to antigen, responding T cells may collectively possess multiple phenotypes. Heterogeneity of Th phenotypes is a common feature of some diseases, such as asthma, where Th2, Th9, and Th17 responses are thought to contribute to disease; in psoriasis, where Th1, Th17, and Th22 cell types are detectable; and in multiple sclerosis, where Th1, Th17, and Th22 cells are thought to mediate inflammation. A portion of the T cells may persist in a naïve phenotype or as uncommitted T_{cm} or T_{scm} that may give rise to T cells of a different phenotype upon antigen reexposure.

Fourth, there is limited plasticity in T-cell effector phenotypes. Effector phenotypes are reinforced by "master" transcription factors and epigenetic modifications (Fig. 16.4). For example, established Th1 cells do not express Th2 cytokines despite extended culture in Th2-skewing conditions. There is, however, growing evidence of interconversion between certain T-helper subsets.[32] Experiments tracing T-cell lineage commitment have shown that T cells that once expressed FoxP3 could become effector cells. It is not clear if plasticity is occurs between all phenotypes or if phenotype conversion can occur at any stages of phenotype commitment (see Fig. 16.4).

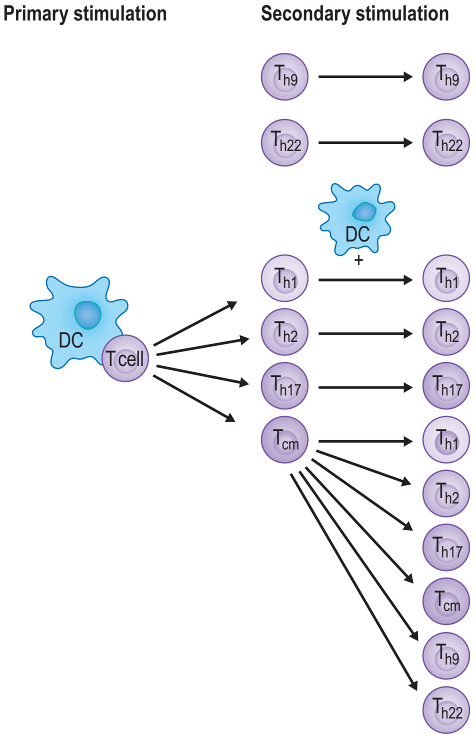

FIG 16.4 Mechanism of T-Helper (Th) Phenotype Shift. Under appropriate conditions, T-cell activation may result in daughter cells adopting one of several T-effector phenotypes. Within a polarized population of Th cells, a subset of undifferentiated T lymphocytes may exist (here referred to in the general category as T central memory [T_{cm}]). Fully committed Th1, Th2, or Th17 cells upon restimulation will produce Th1, Th2, or Th17, respectively. T_{cm} or other uncommitted cell types retain the potential to differentiate into T effectors of any phenotype, depending on the context of the secondary stimulation.

TERMINATION OF T-CELL RESPONSES

CLINICAL RELEVANCE

Diseases Associated With CD4 T-Effector Responses

Th1

- Multiple sclerosis
- Psoriasis
- Type 1 diabetes mellitus
- Tuberculoid leprosy
- Transplant rejection

Th2

- Allergy and asthma
- Helminthic infections
- Lepromatous leprosy

Th9

- Asthma
- Helminthic infections

Th17

- Asthma
- Multiple sclerosis
- Psoriasis
- Rheumatoid arthritis
- Transplant rejection

Th22

- Psoriasis
- Wound healing

As a result of the potential for unregulated inflammation, retention of activated effector T cells present three risks to the organism. First, with each succeeding infection, the body would be increasingly burdened by the energy requirements of maintaining larger T-cell numbers. Second, there would be loss of TCR diversity resulting from the overrepresentation of clonally expanded T cells. Third, there is an increased risk of damage to self by large populations of activated effector T cells. Thus a return to homeostasis is required at the end of an immune response through reductions in T-cell numbers and activity. Homeostasis is restored through the loss of the initiating stimulus and by active control processes, including cell death, inhibitory signaling pathways, and antiinflammatory cytokines.

CELL DEATH PATHWAYS IN T-CELL HOMEOSTASIS

Several cell death pathways regulate the processes of activation-induced cell death (AICD; Chapter 13). The primary pathway involved in AICD involve Fas (CD95) and Fas ligand (FasL, CD95L). Fas and FasL are expressed following T-cell activation. Fas-mediated apoptosis can be stimulated by FasL on neighboring cells ("death signal") or on the same cell ("suicide signal"). Mutations in Fas and FasL result in the accumulation of activated lymphocytes and autoimmunity. Another TNF family member, TNF-related apoptosis inducing ligand (TRAIL), has also been associated with AICD. Mice lacking TRAIL have enhanced susceptibility to autoimmune disease. Some evidence suggests that TRAIL regulates AICD primarily in Th2 cells.[33]

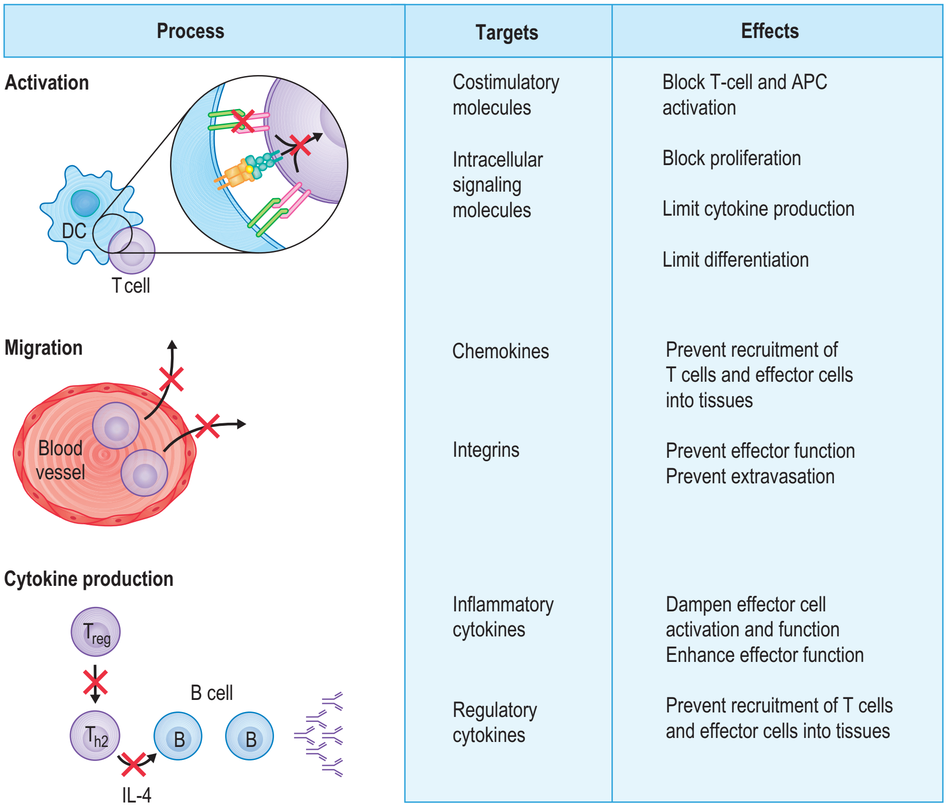
ACTION OF INHIBITORY RECEPTORS

T cells express several Ig family transmembrane proteins containing immune tyrosine inhibitory motifs (ITIMs). Two of these, CTLA4 and PD-1, play important roles in terminating T-cell responses *in vivo.* The first, CTLA4, is expressed by T cells following activation and regulates T-cell activity in two ways: first, CTLA4 binds to B7 with high affinity and competes with CD28 costimulation. Second, CTLA4 inhibits proximal TCR signaling by recruiting the phosphatases SHP-2 and PP2A. Mice deficient in CTLA4 develop a severe CD28-dependent lymphoproliferative disease, tissue infiltration, and early death.[34] PD-1 interacts with two ligands, PD-L1 and PD-L2, which are differentially expressed in immune and peripheral tissues. PD-1 engagement limits proximal TCR signals by recruiting SHP-2, thereby suppressing activation, cytokine production, and proliferation. Loss of PD-1 has been associated with autoimmune cardiomyopathy, arthritis, and a lupus-like glomerulonephritis disease.[35]

CYTOKINE-MEDIATED INHIBITION

Cytokines function to terminate immune responses in three basic methods: *(i)* by loss or withdrawal of growth factors, *(ii)* by inducing cell death, and *(iii)* by direct antiinflammatory properties (Chapter 9). IL-2 functions as a growth factor in early immune responses. Loss of IL-2 signals through decreased production or loss of receptor expression deprives the cell of survival signals, resulting in AICD. Similarly, loss of IL-7 or IL-7 receptor results in increased apoptosis among naive and memory T-cell populations.[36] As discussed in Chapter 13, cell death by growth factor withdrawal results from activation of the mitochondrial pathway of apoptosis.

Cytokines can suppress T-cell responses. This function of cytokines is exemplified by IL-10, IL-27, TGF-β, and TNF-α. IL-10 is produced by adaptive Tregs and Tr1 cells, as well as B cells, monocytes, and macrophages. IL-10 suppresses inflammation by inhibiting macrophage activation, downregulating chemokine production, and suppressing costimulatory molecule expression by APCs. IL-10–deficient mice develop inflammatory bowel disease caused by dysregulated Th1 responses. Mice genetically deficient for the IL-27 receptor develop exaggerated CD4 T-cell responses and inflammatory diseases. These effects of IL-27 can be attributed to its role in suppressing Th1 responses and CD4 T cell proliferation.[37] TGF-β_1 is another antiinflammatory cytokine that is produced by subsets of Tregs and a variety of other cell types throughout the body. Unlike IL-10, which targets APCs, TGF-β_1 directly inhibits T-cell proliferation and Th1 differentiation.[38] Mice deficient in TGF-β_1 have multitissue infiltration by activated lymphocytes and macrophages. TNF-α is well characterized as possessing proapoptotic function. TNFR1 possesses a death domain, and binding of TNF-α results in the activation of the caspase pathway and apoptosis.



Process	Targets	Effects
Activation	Costimulatory molecules	Block T-cell and APC activation
	Intracellular signaling molecules	Block proliferation Limit cytokine production Limit differentiation
Migration	Chemokines	Prevent recruitment of T cells and effector cells into tissues
	Integrins	Prevent effector function Prevent extravasation
Cytokine production	Inflammatory cytokines	Dampen effector cell activation and function Enhance effector function
	Regulatory cytokines	Prevent recruitment of T cells and effector cells into tissues

FIG 16.5 Therapeutic Regulation of Inflammation. Several techniques have been employed to reduce T-cell responses in cases of inflammation. Among these are inhibiting T-cell activation and differentiation by blocking costimulatory interactions with antigen-presenting cells (APCs) *(top)*; inhibiting T-cell and effector-cell trafficking by blocking molecules required for chemotaxis *(middle)*; and limiting the effect of T-helper responses by decreasing the availability of inflammatory cytokines *(bottom)*.

SUMMARY OF THERAPEUTIC REGULATION OF T-CELL RESPONSES FOR TREATMENT OF IMMUNE-MEDIATED DISEASES

ON THE HORIZON

- Development of effective techniques to identify antigens targeted in organ-specific autoimmune and allergic diseases and in transplant rejection
- Development and implementation of an effective tolerance-inducing strategy capable of regulating T-cell responses in an antigen-specific manner
- Identification of tolerance-specific biomarkers or assays to clearly delineate successful therapy of inflammatory diseases

T cell–mediated inflammation is central to immune-mediated diseases. Many of the most effective techniques to control inflammation are aimed at the processes of T-cell activation, differentiation, trafficking, or effector functions (Fig. 16.5). Among many potential approaches currently being employed or in development, include the following: *(i)* blockade of appropriate costimulatory signals or intracellular signaling molecules to prevent T-cell activation (*i.e.*, FK504) or to promote ongoing effector inflammatory responses (*i.e.*, anti-PD-L1); *(ii)* preventing recruitment of effector T cells into inflammatory sites by targeting pathways required for cellular recruitment (*i.e.*, VLA-4); *(iii)* neutralizing the cytokines that promote T-effector differentiation (*e.g.*, IL-6, IL-12, or IL-23); *(iv)* blocking proinflammatory cytokines (*e.g.*, IFN-γ, IL-17, GM-CSF, or TNF-α) and other effector molecules (*e.g.*, iNOS, reactive oxygen intermediates, etc.) involved in the effector limb of destructive inflammatory processes; *(v)* the use of regulatory cytokines, such as TGF-β, IL-4, or IL-10 to regulate proinflammatory responses; and *(vi) in vivo* induction of Treg activity using tolerance strategies or *ex vivo* expansion and administration of protective or regulatory T-cell subsets.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following is the earliest manifestation of a T-cell response?
   A. Cytokine release
   B. Activation and proliferation
   C. T-cell help
   D. T-cell migration
   E. Stimulation of inflammation

2. Which of the following is NOT true about regulatory T cells (Tregs)?
   A. Tregs express the transcription factor FoxP3.
   B. Tregs control immune responses by lysing effector CD4 T cells.
   C. Tregs are defective in patients with autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED).
   D. Tregs can be generated outside of the thymus.
   E. Tregs help promote homeostasis.

3. A patient arrives in the clinic with a history of recurrent infection by *Staphylococcus* bacteria. Laboratory tests indicate that the patient has low serum immunoglobulin G (IgG) levels and reduced numbers of memory B cells in blood. What T-cell population is likely impaired?
   A. CD8 T cells
   B. T-helper (Th)1 effector T cells
   C. Th2 effector T cells
   D. Regulatory T cells (Tregs)
   E. T-follicular helper (Tfh) cells

Cytotoxic T Lymphocytes and Natural Killer Cells

Stephen L. Nutt, Nicholas D. Huntington

Cytotoxic T lymphocytes (CTLs) and natural killer (NK) cells represent two distinct but functionally related lineages that contribute to pathogen and tumor immunity. Although the approaches by which CTLs and NK cells kill their target cells and produce immunomodulatory cytokines are quite similar, the mechanisms by which they recognize their targets are distinctly different. CTLs are CD8 T cells (Chapter 8) that recognize targets via the interaction of a diverse repertoire of polyclonally rearranged T-cell receptors (TCRs) (Chapter 4) with a peptide– major histocompatibility complex (MHC) class I complex (Chapter 6) and are components of the adaptive immune response. MHC class I molecules are expressed on virtually all cells in the body and allow CTLs to scan the tissues for cells expressing foreign or cancer-associated peptides. In contrast, NK cells are members of the innate immune system (Chapter 3) and use an array of invariant activating and inhibitory receptors to control their activity and specificity.[1] These fundamentally distinct approaches to the recognition of antigen allow for complementary functions, with CTLs being specialized in detecting cancerous cells or those infected with intracellular pathogens, such as viruses, whereas a prominent function of NK cells is to eliminate those cells where the pathogen or oncogene has impaired MHC class I expression and/or has induced the expression of stress ligands. As one of the principal immune-evasion mechanisms of viruses and tumors is suppression of MHC class I expression, NK cells provide a key line of defense against this strategy.

CLINICAL RELEVANCE

Functions of Cytotoxic T Lymphocytes (CTLs) and/or Natural Killer (NK) Cells

- Protective functions include:
- Host defense against:
  - Viruses, including human immunodeficiency virus (HIV), Epstein-Barr virus (EBV), pox virus, and cytomegalovirus (CMV)
  - Bacteria, including *Listeria monocytogenes*
  - Parasites, including *Plasmodium falciparum* and *Toxoplasma gondii*
  - Primary and metastatic tumors
- Positive regulation of:
  - Graft-versus-leukemia (GvL) effect
  - Placental vascularization by uterine NK cells
- Uncontrolled cytotoxicity contributes to
- Some autoimmune disease, including diabetes and rheumatoid arthritis
  - Hypersensitivity reactions
  - Graft-versus-host disease
  - Transplant rejection

The importance of the lytic function of CTLs and NK cells has been demonstrated in animal models as well as in patients with defective cytotoxicity. A number of recessive genetic syndromes that affect cytotoxic function have been reported, including familial hemophagocytic lymphohistiocytosis (FHL), which results from mutations in the perforin gene.[2] Patients with FHL present with severe immunodeficiency that is often associated with uncontrolled viral infections, including cytomegalovirus (CMV), herpes simplex virus (HSV), and Epstein–Barr virus (EBV) infections. Similarly, mice genetically deficient or depleted for CTLs and NK cells are overtly susceptible to viral pathogens and display impaired immunosurveillance.[2]

With its potent ability to control pathogen-infected and malignant cells, it is not surprising that modulation of cytolytic activity is an aim of many immunotherapies (see Part 10). These strategies involve either dampening of CTL function in such situations as transplantation or autoimmunity or enhancement of CTL and NK-cell function via vaccination, blocking antibodies to inhibitory receptors, or cytokine therapy. Tight controls need to be maintained over these effector cells, as deregulated CTL activity can promote autoimmune diseases, hypersensitivity reactions, graft-versus-host disease (GvHD) and transplant rejection. To maintain the discrimination between killing unwanted or infected cells and not killing healthy neighboring cells, numerous layers of regulation operate to control cytotoxic functions.

EFFECTOR FUNCTIONS/MECHANISMS

KEY CONCEPTS

Cytotoxic T Lymphocyte (CTLs) and/or Natural Killer (NK) Cell Effector Mechanisms

- Cytotoxicity
  - Killing by the perforin/granzyme pathway
  - Death receptor–mediated apoptosis, including Fas and tumor necrosis factor (TNF)-related apoptosis–inducing ligand (TRAIL)
- Immune modulation
  - Inflammatory cytokine production, including interferon (IFN)-γ and TNF
  - Chemokine secretion
  - Immunomodulatory cytokines, including interleukin-10 (IL-10) and granulocyte macrophage–colony-stimulating factor (GM-CSF)

Cytotoxicity

Cytotoxic cells kill their targets via two major pathways: perforin/granzyme–mediated lysis and death receptor–induced apoptosis.

https://archive.org/details/namdhari

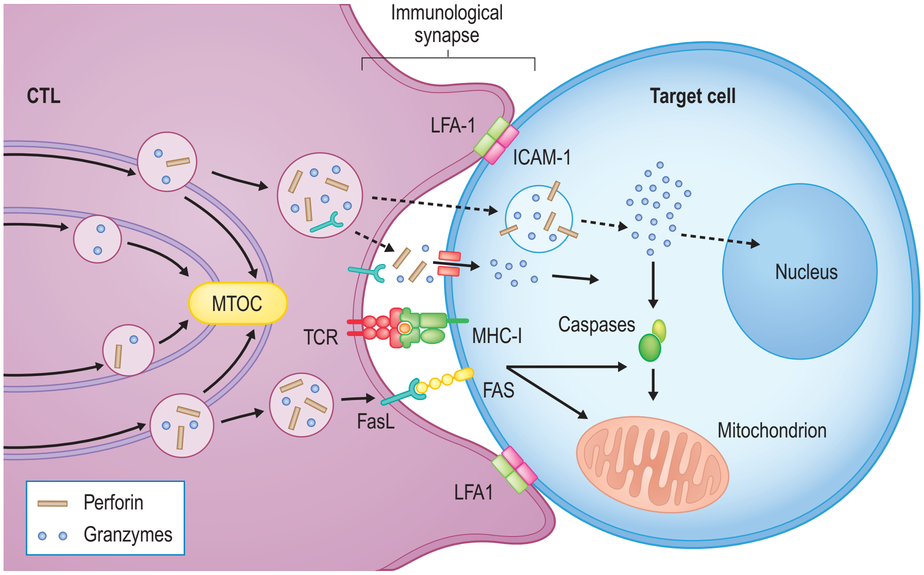

FIG 17.1 Mechanisms of Cytotoxic T Lymphocyte (CTL)–Induced Cell Death. The CTL recognizes its target via the interaction of the T-cell receptor (TCR) and the peptide–major histocompatibility complex (MHC) class I complex on the target cell. TCR signaling induces the formation of an immunological synapse that is stabilized by the binding of leukocyte function–associated antigen-1 (LFA-1) to the intercellular adhesion molecule (ICAM) on the target cell. Lytic granules containing perforin, granzymes, and FasL are polarized along microtubules and move toward the microtubule-organizing center (MTOC). Lytic granules are then secreted into the synapse, allowing perforin to form pores in the target cell membrane, which facilitates granzyme access to the target cells. Granzymes induce apoptosis by caspase-dependent and independent pathways that result in DNA cleavage and mitochondrial damage. Membrane-bound FasL can bind to its receptor on target cells and induce apoptosis through an independent pathway.

Both require intimate contact between the lytic cell and its target (Fig. 17.1).[2] Although the processes are similar for CTLs and NK cells, CTL lytic activity is acquired only after activation and differentiation, whereas NK cells can spontaneously kill target cells without prestimulation. Despite this, NK-cell killing is significantly increased by prior activation by cytokines or inflammatory signals. Both cell types also produce cytokines that further enhance the immune response, most notably interferon-γ (IFN-γ).

Perforin–Granzyme Pathway

Perforin is a membrane-disrupting protein, which, together with a family of serine proteases (granzymes), forms the bulk of lytic granules. The process of lysis has been most extensively studied in CTLs, where, upon interaction between the TCR and an appropriate MHC class I peptide, a synaptic complex forms between the CTL and its target.[2] Lytic granules can then be observed moving along a microtubule network toward the microtubule-organizing center that localizes at the synapse (see Fig. 17.1). This process allows the polarized secretion of lytic granules precisely at the CTL–target cell interface. Perforin forms a pore that disrupts the target cell membrane, including either the plasma membrane or the lysosomal membrane. Once inside the target cell, it is granzymes that are the initiators of cell death. Granzymes function directly by cleaving substrates, such as nuclear proteins and DNA, or indirectly via initiating a protease cascade. One important substrate of granzymes is the proapoptotic protein BID (BH3-interacting domain death agonist), which induces cell death via mitochondrial mediators, such as cytochrome c.

Death Receptor–Induced Apoptosis

Cytotoxic cells also have a receptor-based system to induce apoptosis of target cells (Chapter 13). This pathway uses members of the tumor necrosis factor receptor (TNFR) superfamily that are expressed on the target cells. These receptors have an intracellular signaling motif, called the *death domain,* which recruits molecules that transduce the death signal, such as FADD (Fas-associated death domain). The two most prominent apoptosis-inducing TNFR family members are Fas (CD95)[3] and TRAIL (TNF-related apoptosis–inducing ligand).[4] Fas is expressed on a wide variety of tissues, whereas Fas ligand (FasL) expression is restricted to activated CTLs and NK cells, where it is stored in lytic granules and, upon activation, released to the effector cell membrane. The Fas/FasL pathway is important in controlling T-cell numbers through activation-induced cell death (AICD), as well as in the rejection of some tumors. Cytotoxic cells also express TRAIL, which upon binding to TRAIL receptors, induces apoptosis in a wider selection of targets.[4] Of particular therapeutic interest is the fact that tumor cells are often exquisitely sensitive to TRAIL.

Cytokines

Antigen-stimulated CTLs and activated NK cells modulate the immune response by their ability to produce a variety of cytokines, most notably IFN-γ and TNF. These potent inflammatory cytokines activate macrophages and lymphocytes at the site of infection. IFN-γ helps establish a T-helper cell-1 (Th1) response (Chapter 16) and further stimulates differentiated CTLs. NK cells are also a potent source of a diverse range of cytokines, including granulocyte macrophage–colony-stimulating factor (GM-CSF), interleukin-5 (IL-5), IL-10, and IL-13 (Chapter 9). The capacity to secrete a broad spectrum of cytokines provides NK cells with a wide range of regulatory capabilities. CTLs and NK cells are capable of secreting a number of chemokines (Chapter 10), including chemokine ligand 3 (CCL3), CCL4, and CCL5. These chemokines help recruit additional lymphocytes into the immune reaction.

CYTOTOXIC T CELLS

The Development and Tissue Distribution of CTLs

CD8 T lymphocytes develop in the thymus, where they are selected for their ability to recognize nonself peptides in the context of MHC class I molecules (Chapter 8). Upon thymic export, these cells acquire a quiescent state and are referred to as "naïve" cells. Naïve CD8 T cells circulate between peripheral lymphoid organs, such as the spleen and lymph nodes, via the arterial and lymphatic systems. The tissue distribution of lymphocytes is determined by targeting proteins, which can be divided into three categories: selectins, chemokine receptors, and integrins.[5] Naïve and activated CD8 T cells display distinct sets of these targeting proteins, allowing for the differential homing abilities of these cells (Chapter 11). Naïve CD8 T cells express high levels of the lymph node homing receptor L-selectin (CD62L) and CCR7, a chemokine receptor that recognizes CCL19 and CCL21, which are produced in the T-cell areas of secondary lymphoid organs (Table 17.1; Chapter 10).[5] Here, naïve T cells interact with antigen-presenting cells (APCs), in particular dendritic cells (DCs). If a naïve CD8 T cell does not encounter its specific antigen, it leaves the lymph node.[5] If, however, a CD8 T cell encounters the correctly presented peptide–MHC I complex, a dramatic change in its localization and homing properties ensues. These cells shut down their egress program and undergo multiple rounds of proliferation to become activated CTLs. After the proliferative phase, the CTLs then reacquire egress capacity and travel via the circulation to nonlymphoid sites, where they tether to endothelial cells and extravasate into tissue. This transmigration occurs in both inflamed and noninflamed sites, such as skin, the gut, or the lung. Many of the effector memory CTLs are retained in nonlymphoid tissues, where they are poised to respond rapidly should the antigen be encountered again. The distinct types of memory T cells are discussed below.

THE CTL RESPONSE

The CTL response to an acute infection consists of three phases: first, the initial activation and proliferation of the CTL; second, the contraction of effector populations; and third, the long-term maintenance of memory cells.

Initial Activation

Naïve T cells constantly circulate through secondary lymphoid organs, where antigen encounter occurs. For a CTL response, antigen is brought to the lymph node via the lymphatic system by APC (Fig. 17.2). These APCs are typically DCs that mature after antigen acquisition in nonlymphoid tissues and migrate to the lymph node. These antigens are recognized only when complexed to MHC molecules. APCs efficiently degrade self or foreign (pathogen-derived) proteins into shorter fragments (generally 8–10 amino acids in length) by the action of proteases in the cytosol. They are then transported into the lumen of the endoplasmic reticulum, where they are loaded onto newly synthesized MHC class I molecules for presentation at the cell surface (Chapter 6). This then enables the APCs to communicate with the antigen-specific CD8 T cells via interactions between the TCR and MHC molecules.

In the lymph node, CTLs scan the APCs for the presence of antigenic peptides complexed with the MHC class I molecules, a process termed *immune surveillance.* In the absence of a specific recognition by the TCR, the encounter is only transient, and the T cell continues on to another APC to repeat the process. If the MHC class I–peptide complex is bound by the TCR and initiates signaling, a more lasting interaction occurs.

TCR activation promotes polarization of the T cell and formation of the "immunological synapse."[6] The immunological synapse is a highly structured body that functions to concentrate TCR signaling in a defined area. It is associated with the selective recruitment of signaling molecules and exclusion of negative regulators. The synapse is stabilized by a ring of adhesion molecules, including, for example, LFA-1, which binds to ICAM1 on the APC (see Fig. 17.1). For a T cell to become fully active, costimulation through a second signaling pathway is required.[6] Many costimulators that have been identified share the common characteristic of being transmembrane receptors, often of the TNFR superfamily, that bind transmembrane ligands on the APC. The most important costimulator, CD28, binds the ligands CD80 (B7.1) and CD86 (B7.2), both of which are expressed on activated APCs. Costimulation results in the clonal expansion

TABLE 17.1 **Properties of Cytotoxic T Lymphocyte (CTL) Populations**

Marker	Naïve CD8 T Cell	Effector CTL	Effector Memory (T_{EM})	Central Memory (T_{CM})	Tissue-Resident Memory (T_{RM})
CD69	–	++	–	–	++
CD62L	++	–	–	++	–
CD44	+	+++	+++	+++	+++

IL2Rβ (CD122)	+	+	++	+++	+
Main tissue distribution	Lymph nodes, spleen, blood	Lymph nodes, spleen, blood, nonlymphoid tissue (*e.g.*, lung, liver)	Nonlymphoid tissue (*e.g.*, lung, liver), spleen	Lymph nodes, spleen, blood	Nonlymphoid tissue (*e.g.*, lung, liver, skin)
Cytotoxic function	–	+++	++	–	++
IFN-γ	–	+++	+++	+	+++

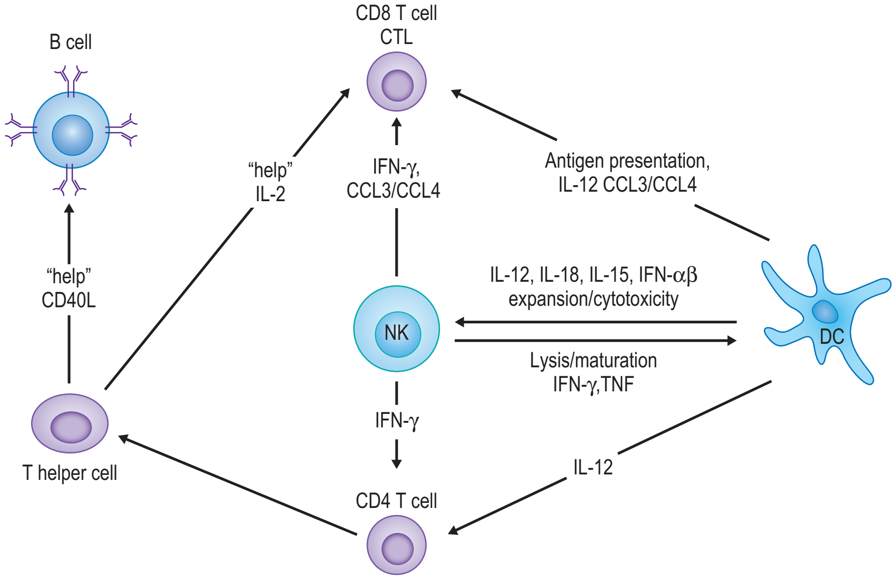

FIG 17.2 Cellular Interactions During an Immune Response in the Lymph Node. After their encounter with antigen, dendritic cells (DCs) move to the draining lymph node, where they initiate an antigen-specific immune response. In the very early stages, natural killer (NK) cells are recruited to the lymph node and modulate various aspects of this response. NK cells provide cytokines that induce the maturation of DCs, which enables these cells to efficiently present the antigen to T cells in the context of costimulatory signals. NK cells also have the ability to eliminate immature DCs and to provide "early" interferon (IFN)-γ for the initiation of a T-helper 1 (Th1)-type CD4 T-cell response. Finally, NK cells produce a range of chemokines, most notably chemokine ligand 3 (CCL3) and CCL4, which are crucial for the recruitment of CD8 T cells into the immune response.

of CTLs with the selected antigen specificity. The expression of CD80/86 is tightly regulated. High-level expression occurs only after an APC receives activation signals, such as inflammatory cytokines, or components of the pathogens such as lipopolysaccharide. Costimulation via CD28 is most critical during the initiation of the immune response, as it promotes IL-2 production, which, in turn, supports the development of effector T cells. Naïve T cells that receive TCR stimulation in the absence of costimulatory signals can become nonresponsive to antigen, a state termed *anergy.*

Cross-Presentation and Priming

After it was established that only direct interaction with an APC and appropriate costimulation led to full CTL activity, a problem arose in explaining the mechanism by which antigens in non-APCs were recognized by CTLs. This dilemma was resolved by the discovery that there are two distinct mechanisms by which CTLs encounter peptide–MHC class I complexes.[7] If the APC expresses the antigen, for example, if a virus infects it, then the APC can process the antigen via the endogenous MHC class I pathway for presentation. The more intriguing situation arises when the APC does not express the antigen. In this case, the APC acquires and processes the antigen via a process termed *cross-presentation* (Chapter 6).[7] Cross-presentation is initiated by the capture of foreign or exogenous antigens by phagosomes. The antigens are then processed by an unusual mechanism that directs the peptides to the MHC class I pathway and presentation on the cell surface. An encounter of a CTL with an antigen processed in this pathway is termed *cross-priming.*[7] This strategy assists CTLs in viral control in two ways. First, cross-priming alleviates the need for DCs to be infected for detection and therefore prevents viruses escaping immune detection by avoiding infection of DCs. Second, viruses often attempt to evade CTLs by downregulating the MHC class I pathway. "Cross-dressing" is a process related to cross-priming but involves the direct exchange of preformed peptide–MHC complexes to uninfected cells. This mechanism acts to significantly amplify the magnitude of priming of T cells, and like cross-presentation, potentially circumvents immune evasion strategies used by pathogens.[7]

The Contraction of Effector Populations

After activation of CTLs in secondary lymphoid organs, an immune response is characterized by the rapid proliferation of antigen-specific cells and their acquisition of effector functions. CTLs proliferate at one of the fastest rates known for mammalian cells, with a cell cycle time of approximately 6 hours. Infection leads to a dramatic increase in the numbers of pathogen-specific CTLs, from almost undetectable initial levels to several million cells in the course of a single week. The magnitude of this response is dependent on the kind of infection and the dose of the antigen and is controlled by the number of precursors recruited into the response.[8] The expansion phase is followed by a contraction of the CTL population that is independent of both the magnitude of the response and clearance of the antigen. This phase is essential to prevent nonspecific tissue damage through uncontrolled cytokine release and cytolytic activity. Contraction also preserves the flexibility of the T-cell response to new infections while memory of previously encountered antigens is maintained. Typically, less than 5% of the expanded antigen-specific population survives in the long-lived memory pool.

The Long-Term Maintenance of Memory Cells

The production of long-lasting antigen-independent memory cells is essential for a rapid response should reinfection occur. CTL memory provides a more vigorous response than the primary challenge for both quantitative and qualitative reasons.[8] Quantitatively, because of the substantial clonal expansion during a primary infection, the precursor frequency of antigen-specific CTLs is vastly higher in immune individuals than in naïve subjects, thus allowing for a stronger response. Qualitatively, memory CTLs exhibit striking efficiency in elaborating the effector functions associated with the rapid production of IFN-γ. This enhanced response is the result of reprogramming of gene expression profiles by epigenetic changes in DNA methylation or chromatin structure.

The CTL memory compartment is composed of three cell types: effector memory (T_{EM}) cells, central memory (T_{CM}) cells, and tissue-resident memory (T_{RM}) cells. These subsets differ in their surface molecule expression and in their ability to exhibit effector functions (see Table 17.1). Like their naïve counterparts, T_{CM} cells express high levels of CD62L and CCR7 and reside primarily in secondary lymphoid organs. T_{CM} cells are capable of prolonged homeostatic self-renewal in the absence of antigen. T_{EM} cells, in contrast, are characterized by low expression of CD62L and CCR7 and are distributed throughout the body, including peripheral tissues, such as the lung and the gut, where they can immediately confront invading pathogens. T_{RM} cells are the most recently identified memory population that resides in peripheral tissues long after an infection is cleared, providing potent early response to reinfection of the same tissue.[5] CD4 T-cell help and cytokines, including IL-15 and IL-7 and their receptors, have been identified as crucial for the survival and maintenance of the memory T-cell pool.[5,8]

CD4 T-CELL HELP

The final player in the initial activation of CTL is the "help" provided by CD4 T cells specific for an antigen linked to the CTL epitope (Chapter 16). The processes by which help is provided are poorly understood. It is likely that cytokines, such as IL-2 and IL-21, are involved and that the CD4 T cells influence both DCs and CTLs.[9,10] These cytokines, provided by the CD4 T cells, promote the survival, proliferation, and programming of memory CTLs. CD4 T-cell–deficient mice have been developed to study these CTL responses. Interestingly, "helpless" CD8 T cells resemble CTLs in chronic infections and cancer, in which the targets are not cleared despite a robust CTL response. PD-1 (*p*rogrammed *d*eath 1), an inhibitory member of the TNFR family, is expressed on both helpless CTLs and on CTL cells during chronic infections. Blocking the interaction of PD-1 with its ligands greatly enhances the numbers and functions of impaired CTLs.[11,12]

DETECTION AND ANALYSIS OF CTL FUNCTION

Much progress in our understanding of the generation of CTLs in an immune response has resulted from the development of several accurate and sensitive assays for CTL function. Traditional CTL assays were performed on bulk populations of effector cells. In these assays, target cells are labeled, often with ^{51}Cr or a nonradioactive dye, and then pulsed with peptide-antigen. Peptide-specific CTLs are incubated with the target cells. Lytic activity is then measured by the release of label into the culture supernatant or the loss of target cell viability directly. Although such an approach provides a powerful quantitative assay for CTL activity, it has the disadvantage of requiring prestimulation of the CTL population for 1–2 weeks to expand the numbers of antigen-specific CTLs to detectable levels. In mouse models, this limitation was overcome by the development of animals that were monoclonal for the TCR. These mouse strains express transgenic TCRs that recognize either MHC class I (CD8)– or MHC class II (CD4)–specific epitopes. Such T cells, which are specific for a single peptide, have proven extremely useful in the study of CTL responses, as antigen-specific cells can be easily detected.

TCR transgenic mouse models do, however, have some limitations, as they do not recapitulate the diversity of the normal immune response and represent an approach that cannot be used in human studies. The development of labeled tetramers of MHC class I–peptide complexes that bind to the endogenous TCR has made a major contribution to overcoming these previous limitations, as it allows for the detection of antigen-specific CTLs within a polyclonal population.[13] This technique is simple and broadly applicable. It can accurately detect rare antigen-specific populations from patient material or animal tissue (Fig. 17.3). The ability to prospectively identify antigen-specific CTLs has been combined with single-cell functional assays, such as ELISpot or intracellular cytokine assays. The finding that the lysosomal compartment proteins lysosomal-associated membrane protein 1 (LAMP-1/2; CD107a/b) can be detected on the cell surface of degranulating CTLs provides another powerful flow cytometry–based single-cell assay to investigate CTL lytic function.

NATURAL KILLER CELLS

Properties of NK Cells

NK cells are a lymphoid lineage, which, because of the absence of antigen–receptor rearrangements, belongs to the innate immune response. The development of B and T lymphocytes has been extensively studied, and anatomical sites and major mediators are well characterized, whereas NK cells have proven more elusive. Part of the problem lies in their relative scarcity, amounting to less than 2% of cells in bone marrow or spleen and to approximately 5% of the lymphocytes in blood. The lack of appropriate markers to distinguish NK cells, coupled with phenotypic heterogeneity between species and within mouse strains, has also complicated their analysis. In recent years, it has become apparent that NK cells develop in bone marrow from a lymphoid progenitor.[14] IL-15 is essential for most aspects of NK-cell biology, including differentiation, survival, proliferation, and activation *in vivo.* The IL-15R consists of three components: the IL-2/15β chain (CD122), a unique IL-15Rα chain, and the common γ chain, which contains the intracellular signaling component of the receptor.[15] The importance of this receptor complex is emphasized by the lack of NK cells in patients with X-linked severe combined immunodeficiency (SCID) and in dogs and mice that have mutations in the common γ-chain or the *IL2B* gene. The IL-15/IL-15R complex does not function in a manner similar to other cytokines that are produced as soluble ligands and bind to their receptor in a paracrine or autocrine manner. IL-15 is virtually undetectable in body fluids or cell culture supernatants despite the ubiquitous distribution of mRNA. The solution to this paradoxical observation is that IL-15 function requires the presence of IL-15Rα in the same cell. The IL-15/

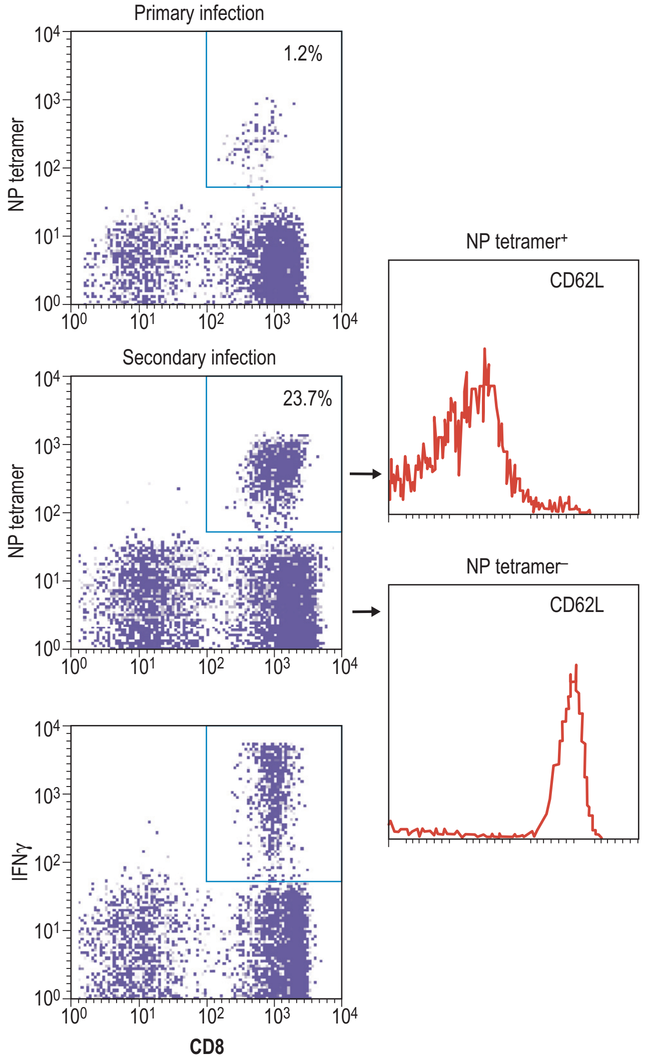

FIG 17.3 **Monitoring a Virus-Specific Cytotoxic T Lymphocyte (CTL) Response.** A fluorescent-labeled tetramer complex comprising a major histocompatibility complex (MHC) class I molecule and a virus-specific nucleoprotein (NP) antigen peptide is used to detect NP-specific CD8 T cells in the spleens of mice infected with influenza virus. During the primary response, virus-specific CTLs expand in the draining lymph node of the lung and later exit to the lung and spleen *(upper left).* After the infection is resolved, a small population of virus-specific memory CTL resides in the spleen. A second infection with influenza results in very high numbers of virus-specific CTLs in the spleen *(middle left)* and the lung. Specific CTLs can be re-stimulated with the NP peptide *in vitro,* inducing interferon (IFN)-γ secretion that is detected by intracellular staining with a labeled anti-IFN-γ antibody *(lower left).* Staining with an antibody to CD62L shows the typical profile of effector CD8 T cells in the NP-tetramer–positive CTLs *(upper right)* and of naïve CD8 T cells in the tetramer negative population *(lower right).*

TABLE 17.2 Human and Mouse Natural Killer (NK) Cell Receptors (Partial List)

Receptor	Species (H, Human; M, Mouse)	Function	Ligands (H, Human; M, Mouse)
LILRB1	H, M	Inhibitory	HLA-class I
KIR2DL1, 2, 3	H	Inhibitory	HLA-C
KIR2DL4	H	Activating	HLA-G
KIR2DL5	H	Inhibitory	?
KIR3DL1	H	Inhibitory	HLA-Bw4
KIR3DL2	H	Inhibitory	HLA-A3, A11
KIR3DL3	H	Inhibitory	?
KIR2DS1, 2, 3, 4, 5	H	Activating	HLA-class I
KIR3DS1	H	Activating	HLA-Bw4
CD94/NKG2A	H, M	Inhibitory	H; HLA-E M; Qa-1b
CD94/NKG2C, E	H, M	Activating	H; HLA-E, M; Qa-1b
NKG2D	H, M	Activating	H; MICA/B, ULBP1–4, M; H60, MULT1, RAE1
CD16 (FcγRIII)	H, M	Activating	Immune complexes
CD27	H, M	Activating	CD70
CD244 (2B4)	H, M	Activating/ Inhibitory	CD48
Ly49A-C, E-G, I-O	M	Inhibitory	MHC-class I
Ly49D	M	Activating	H-2D^d
Ly49H	M	Activating	MCMV m157
Ly49P	M	Activating	H-2D^k/MCMV m04
KLRG1	H, M	Inhibitory	E-, R-, N-cadherins
NKR-P1A	H	Inhibitory	LLT1 (CLEC2D)
NKR-P1A, B, C, E, F	M	Activating/ Inhibitory	Clr family
NKR-P1B, D	M	Inhibitory	Clr-b, Clr-g
PILRα/PILRβ	M	Activating/ Inhibitory	O-glycosylated CD99
NKp46	H, M	Activating	Viral hemagglutinin, HSPG
DNAM-1 (CD226)	H, M	Activating	CD112, CD155

IL-15Rα complex is then presented on the cell surface in *trans* to the NK cell expressing the IL-15Rβγ complex.[15] In this manner, IL-15 is thought to maintain the homeostatic frequency of NK cells in the body. Once NK cells have acquired IL-15 responsiveness in bone marrow, they proceed through an ordered differentiation process that results in an expansion phase and the acquisition of a panel of activating and inhibitory receptors (Table 17.2).[1] It was previously assumed that these bone marrow–derived NK cells were fully functional, but recent data suggest that multiple mature NK-cell subsets exist, with varying levels of effector function.[14]

Tissue Distribution and Diversity of NK Cells

In line with their surveillance function, NK cells are found at many sites in the body. In mice, where tissue distribution has been thoroughly studied, NK cells are found in bone marrow, peripheral blood, the thymus, lymph nodes, and the spleen. The broad range of tissue distribution suggests that there is diversity in the function of mature NK cells. Furthermore, NK cells are also found in organs, such as the liver and small intestine, and in the decidual lining of the uterus along with a closely related innate lymphocyte population, named *group 1 innate lymphoid cells* (ILC1; Chapter 2), which likely have a role distinct from that of NK cells in host defense. Human NK cells can be divided into subsets based on the expression of CD16 (FcγRIII) and the

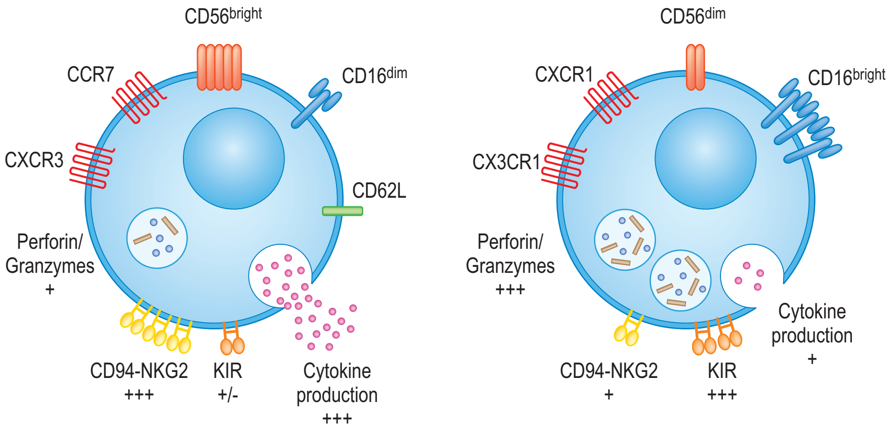

FIG 17.4 Schematic Representation of Human Natural Killer (NK) Cells. The human NK-cell subsets show distinct receptor expression and effector functions. CD56^{bright} NK cells produce high levels of cytokines and have patterns of chemokine and homing receptor expression that distinguish them from CD56^{dim} NK cells. CD56^{dim} NK cells express high levels of killer immunoglobulin-like receptor (KIR) and cytotoxic activity. The relative level of receptors and effector molecules is indicated on an arbitrary scale, with +/– being weak and +++ being strong expression.

adhesion molecule CD56 (Fig. 17.4).[16] CD56^{dim} NK cells represent less than 90% of peripheral blood NK cells, are CD16$^+$KIR$^+$, and display greater cytotoxicity. In contrast, their less mature counterparts, CD56^{bright} NK cells, show greater proliferative potential and cytokine production and are the principal NK cell population in secondary lymphoid organs. CD94$^+$CD161$^+$ NK cell progenitors can be found in cord blood and lymph nodes and develop into CD56^{dim} cells via CD56^{bright} intermediaries; this differentiation is also dependent on IL-15.[16] One important limitation in understanding the functional role played by NK-cell subsets has been the inability to identify populations corresponding to the CD56^{bright} and CD56^{dim} populations in rodents, as this molecule is not expressed in mouse NK cells. NK-cell heterogeneity, based on the differential expression of CD11b (integrin αM) and CD27, has been dissected in mice. Developing NK cells in bone marrow are CD27$^+$CD11b^{dim}, whereas these cells differentiate into CD27$^+$CD11b^{bright} and CD27$^-$CD11b^{bright} stages in the spleen. Interestingly, CD27$^+$ cells are found in lymph nodes, whereas the CD27$^-$ NK cells are localized predominantly in peripheral blood and the lung.[1,14] Comparative studies have shown that human CD56^{dim} NK cells are CD27$^-$, whereas CD56^{bright} cells are CD27^{++}, suggesting that the CD27 marker now enables direct comparisons of NK-cell subsets in mice and humans.

CYTOKINE REGULATION OF NK-CELL ACTIVATION, FUNCTION, AND HOMEOSTASIS

NK cells rely on IL-15 for their development and homeostatic maintenance in the peripheral organs. However, cultured NK cells also respond to other cytokines, including IL-2, -4, -12, -18, and -21, with their role being more important for function than homeostasis.[17] IL-2R shares its β and γ subunits with the constitutively expressed IL-15R (Chapter 9). The dimeric IL-2Rβγ is able to respond to the high levels of IL-2 supplied *in vitro* to induce proliferation of NK cells that were historically called *lymphokine-activated-killer* (LAK) cells. IL-2 activation will also induce the IL-2Rα chain to complete the high-affinity trimeric receptor. IL-4 activates human NK cells and promotes the proliferation of a fraction of NK cells characterized by their ability to produce IL-13.

The cytokines IL-12 and IL-18 have profound effects on NK-cell function.[18] IL-12 and IL-18 are produced by macrophages and DCs during inflammatory immune activation, such as viral infection. Although NK cells are present in IL-12– or IL-18–deficient mice and only marginally reduced in double mutant animals, cytotoxic activity and the ability to respond to infections, such as mouse CMV (MCMV) infection, is impaired. Cultivation of NK cells in IL-12 and/or IL-18 induces short-term activation, cytotoxicity, and IFN-γ production, whereas longer cultures produce more specialized cytokine-producing cells.[17]

Another NK cell–activating cytokine is IL-21.[19] IL-21 is a member of the common γ chain family of cytokines produced by CD4 T cells and, in contrast to IL-2 or IL-15, does not promote proliferation. Instead, it enhances maturation and effector function. Mouse NK cells treated with IL-21 display a broad-spectrum increase in cytotoxic function and produce cytokines, including IFN-γ and IL-10.[17] Of note, mice treated with IL-21 show a marked increase in NK cell–mediated tumor rejection, highlighting the potential for use of this cytokine as an anticancer therapeutic.[19]

NK-CELL RECEPTORS

NK cells differ from CTLs in that they do not require the expression of MHC class I to recognize target cells. In fact, the reintroduction of allogeneic MHC class I molecules into previously susceptible cell lines confers resistance to NK cell–mediated killing. These observations led to the missing-self hypothesis, which proposes that NK cells survey tissues for the usually ubiquitous MHC class I expression and react against cells that do not express it.[1]

The missing-self hypothesis, although altered over time to encompass other observations, has been extremely useful in providing a predictive framework by which to investigate NK-cell receptors and the recognition of target cells (Fig. 17.5).

In the past two decades, a large number of NK-cell receptors and their ligands have been identified (see Table 17.2).[20] Although a number of these NK-cell receptor ligands are MHC class I

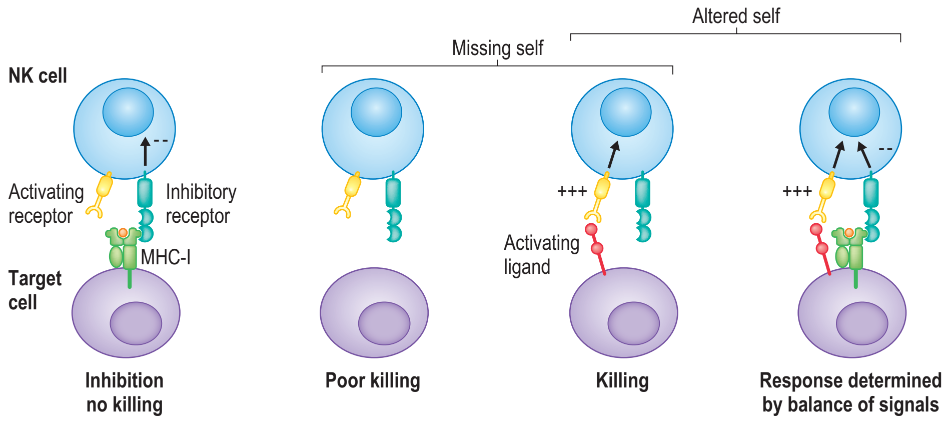

FIG 17.5 **Natural Killer (NK)–Cell Recognition of Target Cells.** NK cells express inhibitory receptors for major histocompatibility complex (MHC) class I and activating receptors for a variety of cellular, viral, and stress-induced ligands that alter the outcome of encounter with a target cell. The missing-self hypothesis initially predicted that NK cells would be activated to kill in the absence of MHC class I inhibition. However, an activating signal is also required. This activating signal can be provided by cellular ligands or by viral or stress-induced proteins, termed "altered self." In the presence of both inhibitory and activating signals, the outcome is determined by quantitative differences in signal strength between the two.

KEY CONCEPTS

Natural Killer (NK)-Cell Receptors

- Inhibitory receptors:
  - Recognize mostly major histocompatibility complex (MHC) class I ligands with high affinity
  - Signal via immunoreceptor tyrosine-based inhibitory motifs (ITIMs)
  - Recruit phosphatases (SHP and SHIP) to prevent a cytotoxic response
  - Required for NK-cell licensing
- Activating receptors:
  - Do not bind MHC class I molecules with high affinity
  - Ligands include viral molecules and stress-induced proteins
  - Signal via immunoreceptor tyrosine-based activation motifs (ITAMs)
  - Use several signaling adaptors, including DAP12

molecules themselves, as predicted by the missing-self hypothesis, there are many other classes of ligands. NK-cell receptors are classified into either activating or inhibitory types. This distinction was initially based on the *in vitro* properties of cross-linking these receptors but is increasingly regarded as the expression of the biochemical signal-transduction pathways activated by the receptor. Interestingly, although this strategy of target recognition is conserved in all mammals tested, in rodents and humans, the receptors have evolved from two independent gene families, killer immunoglobulin-like receptors (KIRs) in humans and the Ly49 family in mice (see Table 17.2).

NK-Cell Receptor Signaling

The signals derived from NK receptors are defined as inhibitory or activating in terms of their effect on NK-cell function. All extensively characterized inhibitory receptors carry an immunoreceptor tyrosine-based inhibitory motif (ITIM) in their intracellular domain. Ligation of ITIM-containing receptors causes tyrosine phosphorylation and the recruitment of a variety of phosphatases, including SHP and SHIP, that act to dampen downstream signaling pathways and NK-cell effector functions.[20] In contrast, activating receptors use immunoreceptor tyrosine-based activation motifs (ITAMs) to transduce stimulatory signals. Engagement of an ITAM-containing receptor results in tyrosine phosphorylation and recruitment of adaptor molecules, including FcεR1γ, CD3ζ, or DAP12/DAP10. The best-characterized activating receptor is CD16, an Fc receptor that binds IgG and is responsible for the antibody-dependent cellular cytotoxicity (ADCC) of human NK cells. CD16 recruits FcεR1γ and CD3ζ, which, in turn, attract the tyrosine kinases syk and ZAP70. These molecules then promote effector functions via multiple signal-transduction pathways.

NK RECEPTORS THAT RECOGNIZE MHC-I MOLECULES

NK cells recognize a wide variety of MHC class I molecules of both classic and nonconventional types. The receptors providing this recognition fit broadly into the immunoglobulin-like and lectin-like superfamilies. They show significant differences between mice and humans.

Killer Cell Immunoglobulin-Like Receptors in Humans

The *KIR* genes are a family of 15 genes that are physically linked on chromosome 19.[21] The locus shows a high degree of variation in humans, with both the number of *KIR* genes varying between individuals and extensive allelic polymorphisms. The KIR family was originally called *killer inhibitory receptors,* but subsequent studies have demonstrated that activating receptors are also encoded by the KIR locus. As expected, the inhibitory KIRs contain the ITIM, whereas all activating KIR utilize DAP12 to transduce signals from an ITAM.[20] Surface expression of KIR is acquired with maturation, driven by IL-15, and as such, NK cells lacking KIR or NK cells with combinations of multiple activating and inhibitory KIRs can be found in human blood. Similar to most other NK-cell receptors, some T cells can also express KIRs after activation, in particular in response to IL-15.

KIRs recognize the human MHC class I molecules human leukocyte antigen-A (HLA-A), -B, and -C (see Table 17.2).[20,21] The specificity of the inhibitory KIRs has been extensively characterized, with, for example, the different isoforms of KIR2D recognizing all known alleles of HLA-C. The ligands of the activating KIRs are less clear; however, they do not bind with high affinity to HLA molecules. KIR2DL4 is the most evolutionarily distinct member of the family and appears to be expressed in all activated NK cells in culture and on the CD56$^{\text{bright}}$ subset in peripheral blood. KIR2DL4 also has some distinct structural features and may act as an unconventional activating receptor binding HLA-G.

There are epidemiological data implicating particular KIR in a variety of autoimmune pathologies and viral responses.[22] For example, individuals with KIR2DS2 and some HLA-C alleles are predisposed to rheumatoid arthritis with vascular complications. Conversely, individuals with human immunodeficiency virus (HIV) infection who are homozygous for HLA-Bw4 progress to acquired immunodeficiency syndrome (AIDS) more slowly than those with other haplotypes, especially when they have the *KIR3DS1* gene. The mechanism by which this occurs is unknown, but the activity suggests that KIRs recognize an HIV-associated peptide in the context of HLA-Bw4.[23]

The Ly49 Family in Rodents

In a remarkable example of the power of selection to shape the evolution of the immune system, a multigenic locus with functional properties almost identical to those of the *KIR* genes evolved independently in rodents.[21] Mice, which have only two *KIR* genes of unknown function, have an analogous cluster of type II transmembrane spanning lectin-like genes called the Ly49 family on chromosome 6.[20] This family consists of more than 20 members and is highly polymorphic between mouse strains. Like KIR molecules, Ly49 receptors are also highly variegated in their expression in NK cells. *Ly49* genes encode activating and inhibitory receptors that bind to MHC class I molecules and signal via ITAMs and ITIMs, respectively (see Table 17.2).[20] Ligand-binding studies have revealed that inhibitory Ly49 receptors, such as A, C, and I, function to prevent self-reactivity by NK cells by binding to MHC class I molecules. The function of the activating receptors has proven more difficult to elucidate. Ly49D is known to have high affinity for the MHC class I H-2D^d allele and is involved in rejecting bone marrow allografts expressing H-2D^d, but the function of Ly49D in the normal immune response is unclear. For one activating receptor, Ly49H, the physiological function is known, as it recognizes the m157 molecule of MCMV and is important in early viral control.[24]

CD94 and NKG2 Family

Unlike the KIR or Ly49 families, the CD94/NKG2 complex is present both in rodents and humans. CD94/NKG2 receptors recognize nonclassic MHC class I ligands, such as HLA-E in humans and Qa1^b in mice.[22] A single CD94 gene is physically linked to four *NKG2* (A, C, E, and a truncated F) genes in humans. CD94 is found on the cell surface, either alone or with activating (C, E) or inhibitory (A) forms of NKG2. Interestingly, both the activating and the inhibitory complexes recognize HLA-E, which present predominantly the leader peptides of other HLA molecules, but not HLA-E itself. This system may provide a mechanism for NK cells to monitor the expression of multiple MHC class I proteins using HLA-E as a surrogate, with a prominent example being the requirement of CD94 for the control of mouse ectromelia virus.[25]

NKG2D

NKG2D, which is only distantly related to the NKG2 family, is a single, nonpolymorphic gene that is expressed on all NK cells from an early stage.[26] In the mouse, NKG2D signals through both DAP12 and another adaptor, DAP10, whereas human NK cells use only DAP10. Activation of NKG2D using a specific antibody results in enhanced cytotoxicity and cytokine secretion. The ligands of NKG2D are a family of molecules with structural similarity to MHC class I proteins, including MICA/B in humans and RAE-1 in mice. These ligands represent a diverse array of sequences, yet all bind with high affinity to NKG2D.[26] Interestingly, the MIC family in humans is highly polymorphic, suggesting that in this receptor–ligand interaction, the diversity comes from ligands rather than receptors. Transfection of otherwise resistant tumor cells with NKG2D ligands restores the susceptibility of these cells to NK-cell cytotoxic function. The key to understanding NKG2D function lies in the fact that the ligands are inducible and provide a mechanism for NK cells to detect stressed tissue, such as virally infected or malignant cells, a phenomenon that has been termed *altered self* (see Fig. 17.5).[26] Conversely, certain cancers have been found to mutate or lose NKG2D ligand expression to evade NK cell immunity.

NK CELL RECEPTORS THAT RECOGNIZE NON-MHC I MOLECULES

Beyond the multiple systems of activating and inhibitory receptors that NK cells have evolved to recognize MHC class I molecules and their structural variants, they also have several other receptor families that bind non–MHC class I ligands.[20,22] These include the NKR-P1 family, which is a polymorphic multigene family in rodents consisting of activating (A, C, F) and inhibitory (D) forms, but consists of only a single member in humans, whose activity is inhibitory. The ligands for some family members have been recently reported and are themselves lectin family receptors, including Clr-b and Clr-g in mice and LLT1 in humans.[20] Another NK receptor that is conserved between species is CD244 (2B4), a pan-NK-cell–expressed molecule whose ligand is CD48. Based on antibody cross-linking studies, human CD244 is designated an activating receptor. However, analysis of CD244-deficient mice suggests that the mouse homolog is inhibitory. A number of additional activating receptors exist, including the natural cytotoxicity receptors NKp30, NKp44, and NKp46. NKp30 and NKp46 are broadly expressed on human NK cells, and NKp46 is expressed on all mouse NK cells.[27] NKp44 is specifically expressed on activated human NK cells. These receptors can be activated by antibody cross-linking, and although their ligands are unknown, there is evidence that NKp46 binds hemagglutinin on influenza virus–infected cells, to *Fusobacterium nucleatum* and yet to be determined ligands on tumors, indicating that NKp46 may have a direct role in NK-cell activation to various pathogens.[27]

NK-CELL LICENSING AND SELF-TOLERANCE

The plethora of MHC class I–binding inhibitory receptors, as proposed by the missing-self hypothesis, explains the influence of

MHC class I on NK-cell lytic function against tumors. However, how self-tolerance is achieved has been less clear. The initial theory to explain self-tolerance was the "at least one receptor" model, which proposed that NK cells must express at least one self–MHC class I inhibitory receptor. A second model suggested that the receptor repertoire is shaped by selection by the specific MHC haplotype and the presence of self-ligands. The observation that NK cells are not autoreactive in the absence of any inhibitory ligands (MHC class I–deficient mice) and are actually poor killers suggests that the situation is more complex than these models allow for. A concept termed *licensing* was proposed to account for these observations.[28] Under this model, NK cells are initially unresponsive or "unlicensed" and acquire functional competency through binding of at least one inhibitory receptor before they can be activated and display cytotoxic function. An alternative "disarming" model proposes that all NK cells are initially responsive but that chronic stimulation by normal cells renders these cells unresponsive, or "anergic," unless the stimulation is opposed by MHC class I–specific inhibitory receptors. More recently a third "rheostat" model has also been proposed, whereby the number and affinity of inhibitory receptors it expresses tune NK-cell reactivity in a quantitative manner.[28] Regardless of the exact tolerance mechanism, it is interesting that unlike with T cells, there is no evidence for clonal deletion of autoreactive NK cells.

SPECIFIC NK-CELL FUNCTIONS

The ability to separate NK cells from T cells both phenotypically and genetically has greatly enhanced the understanding of NK-cell functions. Although some cytotoxic and immunomodulatory capacities overlap with those of T cells, it is also apparent that some functions of NK cells are unique. Specific examples of NK-cell functions are discussed below.

Control of Viral Infections

NK-cell activity rises early in the course of viral infection, partly driven by the release of IL-12, IL-18, and IFN-α/β, which stimulates activation (Chapter 25). The evidence that NK cells are essential for host defense against viruses comes directly from patients and mice lacking NK-cell function and indirectly from viral strategies to avoid NK-cell recognition. Human patients with selective deficiencies in NK cells show a pronounced susceptibility to recurrent severe infections, especially with HSV and CMV.

A powerful example of the role of NK cell–activating receptors in viral control is NK cell–mediated resistance to MCMV. Mouse strains that lack Ly49H are highly susceptible to MCMV, leading to uncontrolled viral replication and death.[24] Importantly, this protection is mediated by the recognition of the m157 protein of MCMV by Ly49H. The rapid accumulation of Ly49H$^+$ NK cells during MCMV infection is the first example of clonal expansion of NK cells in a manner similar to that of B and T cells.[24] Surprisingly, these studies also found compelling evidence for the maintenance of a long-lived NK-cell "memory"-like population (described below), blurring the line between innate (NK cells) and adaptive (B and T cells) immune cells.

As mentioned earlier, there is also evidence that NK cells have direct effects on the progression of HIV infection.[23] NK cells are able to lyse HIV-infected target cells either directly or by ADCC. Despite this ability, NK-cell responses are impaired in patients with HIV infection, as infected T-cell blasts selectively downregulate some *HLA* genes to avoid CTL activity but remain resistant to NK-cell cytotoxicity. These findings are supported by studies that show that high-risk, but uninfected, individuals appear to have increased NK-cell activity and that the combination of the expression of HLA-Bw4 and the *KIR3DS1* gene is associated with delayed progression to AIDS. Finally, HIV viremia induces several functional abnormalities on NK cells, suggesting that this complex virus and NK cells interact at multiple levels.[23]

Control of Malignant Cells

NK cells were named as such during the early 1970s for their potent ability to kill leukemia cell lines *in vitro* and since then have been the focus therapies to boost cancer lysis in humans. Evading the immune system is a hallmark of cancer, but the contribution of NK cells in tumor immune surveillance has been difficult to assay as specific NK cell–deficient mouse models have only recently been generated. There is abundant evidence that NK cells can reduce tumor burden in animal models, and that the administration of cytokines that enhance NK-cell function or number, including IL-2, -12, -15, and -21, or those that induce IFN-α production, are protective against metastasis.[18] In light of this, many clinical trials have been conducted to assess either cytokine treatment or the injection of *ex vivo* treated NK cells.[18] Unfortunately, the high doses of IL-2 and IL-15 required for efficacy are relatively toxic, and transferred NK cells have proved difficult to target to tumors. Despite this, some successes have been demonstrated for melanoma, leukemia, and lung and hepatic cancers. Today, numerous immunotherapy trials are ongoing and aim to exploit and boost NK cell–mediated tumor killing, including antibodies against inhibitory receptors on NK cells, modified IL-2/IL-15 reagents, bispecific or trispecific and killer engaging (BiKE or TRiKE) antibodies that bind NK cells and tumor antigens, tumor-specific antibodies, *in vitro* expanded patient-derived NK cells, and irradiated NK cell lines, to name a few.[18]

Role of NK Cells in Hematopoietic Stem Cell Transplantation

CLINICAL PEARLS

Exploiting Natural Killer (NK) Cells in Leukemia Therapy

- Hematopoietic stem cell transplantation requires donor and recipient human leukocyte antigen (HLA) matching to reduce graft-versus-host disease (GvHD) mediated by transplanted cytotoxic T lymphocytes (CTLs).
- Haploidentical donors and recipients (those that share only one HLA haplotype) represent 50% of unrelated transplants and undergo a stronger conditioning regimen to avoid GvHD.
- Alloreactive NK cells are present after haploidentical transplant and provide a potent graft-versus-leukemia (GvL) effect in animal models.
- Transplantation from NK cell–alloreactive donors controls leukemia relapse and improves engraftment without causing GvHD.

In humans, allogeneic bone marrow transplantation can cure leukemia through the reaction of donor CTLs in the graft against the residual leukemic cells. These transferred T cells also mediate GvHD. The need to prevent GvHD as a result of strong immunosuppression is the major cause of transplantation failure because of infection and cancer relapse. It has been proposed that obtaining the transplant from a haploidentical donor (identical at one HLA haplotype and fully mismatched on the other, for example, a parent) provides allogeneic NK cells with an HLA haplotype that supplies more KIR ligand than a matched recipient would provide. Hence it would yield a stronger graft-versus-leukemia (GvL) effect.[29] Indeed, mice treated with alloreactive NK cells tolerate 30 times the lethal dose of mismatched bone marrow cells without developing GvHD, and alloreactive NK cells eradicated human acute myeloid leukemia (AML) transplanted into immune-deficient mice. Retrospective studies on patients with AML and acute lymphoblastic leukemia (ALL) who received haploidentical grafts revealed that transplants with alloreactive NK cells showed better engraftment and GvHD protection and less relapse.[29]

These studies suggest that therapeutic treatment with alloreactive NK cells will be effective in eliminating residual cancer cells following frontline treatments or in preventing cancer relapse. Feasibility studies have shown that the production of clinical-grade cultured human NK cells is possible and that the transferred cells persist for some time in the patient. An alternative strategy is the use of monoclonal antibodies (mAbs) directed against a particular inhibitory KIR. Preclinical studies suggest that blockade of the inhibitory KIR enhances antitumor activities of the endogenous NK cells, providing a rationale for ongoing clinical trials to test this approach.[18,29]

NK-Cell Memory

ON THE HORIZON

Clinical Trials of Transferred Alloreactive Natural Killer (NK) Cells

- Adoptive transfer of cultured clinical grade NK cells has proven feasible and well tolerated by patients and is a promising therapy to limit relapse in patients with cancer.
- A treatment regimen comprising preconditioning with chemotherapeutic reagents followed by alloreactive NK cells and interleukin-2 (IL-2) administration has been examined.
- Therapeutic blockade of inhibitory NK-cell receptors using anti–killer immunoglobulin-like receptor (KIR) monoclonal antibodies is undergoing clinical trials for their efficacy in boosting NK cell–mediated killing of cancer cells.

During the last decade several studies have described the ability of NK cells to generate a "memory" response to pathogens and antigens. The original documentation of NK-cell memory was in a cutaneous contact hypersensitivity (CHS) model. CHS involves the sensitization by skin exposure to the haptens 2,4-dinitrofluorobenzene (DNFB) and oxazolone (OXA), followed by rechallenge at a previously unexposed site, such as the ear, several days later. NK cells accumulated in the ears of T/B cell– deficient mice upon DNFB rechallenge, and this was dependent on the adhesion molecules of the selectin family.[24] The concept of NK-cell memory has since been extended to viral responses, including MCMV, influenza, vaccinia virus, HSV, HIV, and vesicular stomatitis virus where NK cells from mice preexposed to the virus were more efficiently activated and prolonged survival from lethal infection compared with naïve NK cells. Although the interaction between Ly49H and the viral protein m157 is required for the memory response elicited by MCMV infection, the NK cell receptor–ligands combinations involved in the other viral models are not established. In most settings, the NK-cell memory response is specific to the antigen (hapten or virus), and the memory NK cells or their precursors are found within the CXCR6$^+$CD49a$^+$ liver ILC1 pool.[14] These liver-resident ILC1 are transcriptionally and phenotypically distinct from conventional NK cells, and their role in mammalian immunity is still to be elucidated. Interestingly, ILC1 do not migrate in steady state. Thus how they are activated in a hapten-specific manner during CHS remains to be determined.[14] Furthermore, inflammation, in general, and especially the cytokines IL-12, IL-18, type I IFN, and the NLRP3 inflammasome, are critical for the generation of hapten-dependent memory NK-cell development.[24]

INTERACTIONS OF CTL AND NK CELLS IN THE IMMUNE RESPONSE

Although studies of CTLs and NK cells in isolation have greatly advanced our understanding of their functions, it is obvious that these immune cells function in a system that depends on numerous interactions between the various cell types at multiple levels. In the case of cytotoxic cells, these immunomodulatory interactions are becoming increasingly appreciated (see Fig. 17.2). In particular, it has become apparent that NK cells and DCs interact specifically to promote some outcomes, such as maturation and priming of NK cells. CTL activation by mature DCs is influenced directly by NK cell–derived IFN-γ and indirectly through the role of NK cells in promoting a Th1 response in CD4 T cells (Chapter 16).[30]

Increasing evidence has emerged to implicate DC–NK cell cross-talk in various aspects of the immune response. DCs produce a variety of cytokines that modulate NK-cell behavior, including IL-12, IL-15, IL-18, and IFN-α.[30] The outcome of these interactions for the DC depends on its maturity; immature DCs are killed by NK cells, whereas mature DCs are resistant to lysis. The interactions of mature DCs and NK cells would be expected to occur at the site of infection, where DCs provide inflammatory stimuli for NK cells. Type I IFN production by DCs promotes MHC-I upregulation by CTLs and their protection from NK-cell killing during viral infections. The other site of encounter is the lymph node, where, during an immune reaction, NK cells are recruited by chemokines and interact with mature DCs and CD4 T cells to induce a Th1 response. This process requires IFN-γ production from NK cells (see Fig. 17.2).[30]

NK cell–CTL interactions are also important in generating an immune response to tumors that are, in general, poorly immunogenic.[31] DCs that are matured *in vitro* by NK cells show strongly enhanced ability to induce Th1 and CTL responses, including cytokine secretion. IFN-γ, in particular, is very important in the rejection of primary tumors and the formation of CTL memory to tumors. It is also likely that killing by NK cells and CTLs provides DCs with increased access to tumor antigens and promotes further adaptive immunity. Using DCs to harness the helper function of NK cells as well as the cytotoxic functions of both CTLs and NK cells offers therapeutic promise and is currently being tested in a variety of cancers.

EVASION OF THE CYTOTOXIC RESPONSE

Viruses

As one principal function of CTL and NK cells is the control of viral infections, it is not surprising that viruses have strategies to interfere with the host response (Chapter 25). The multiplicity of these evasion strategies indicates that this is an essential step for long-term viral persistence.

These strategies include:

Latency. This involves minimizing viral gene expression and thereby avoiding detection. Examples include HSV in neurons, HIV in T cells, and EBV in B cells.

Antigenic variation. Viruses possess the ability to rapidly mutate its genome and produce escape variants that are no longer visible to CTLs. Such mutations were shown for MCMV infection in mouse and HIV infection in humans.

Infection of immune nonaccessible sites. Such inaccessible sites include infection of the central nervous system by HSV or rubella virus.

Production of viral defense molecules (immunoevasins). Many viruses, including adenovirus and EBV, interfere with cytotoxic activity by producing proteins that either hinder Fas or TNF-mediated killing or inhibit the function of antiviral cytokines, such as IFN-α. A number of viruses, including EBV, produce homologs of antiapoptotic molecules, such as Bcl2, to inhibit killing by CTLs. Various members of the poxvirus family have evolved homologs of the naturally occurring IL-18–binding protein that inhibits IL-18 activity and NK-cell function.[32]

Modulation of molecules involved in recognition. A widely utilized viral strategy to evade the cytotoxic response is to interfere with antigen processing, presentation, or the expression of other molecules required for CTL recognition (Chapter 6).[33] Several viruses, including adenovirus, downregulate MHC class I expression on the cell surface. This can be achieved by a number of mechanisms. For example, adenovirus type 2 E3 protein forms a complex with MHC class I to prevent antigens from being processed; MCMV gpm152 protein causes retention of the MHC class I molecules in the Golgi compartment; and CMV proteins US2 and US11 promote the rapid degradation of newly synthesized MHC class I complexes. An alternative approach is to interfere with antigen processing, either inhibiting the expression of the TAP protein, as is the case for HSV, or producing proteins that are resistant to antigen digestion by the proteasome, such as the EBNA-1 protein of EBV. This inhibition strategy is not restricted to MHC class I, as both human CMV and MCMV express proteins that inhibit the cell surface expression of NKG2D ligands.

Tumor Cells

Part of the evidence that CTLs and NK cells function to control malignant cells comes from the effort tumor cells will go to avoid cytotoxic activity (Chapter 77). Conversely, promoting the cytotoxic response either through specific tumor antigens, blocking immune checkpoint inhibitors, or through polyclonal stimulation remains one of the most actively pursued strategies in cancer therapy.

Tumors evade cytotoxic function in a number of ways:

Downregulation or loss of MHC class I expression. This strategy is common in solid tumors, including metastatic melanoma and breast cancer, where MHC class I downregulation accounts for up to 50% of samples. MHC class I loss is also induced by mutations in the gene encoding β_2-microglobulin or transcription factors that regulate its expression. MHC class I downregulation is associated with changes in the regulatory mechanisms controlling antigen presentation and can often be corrected by treatment with cytokines, such as IFN-γ.

Induction of immune checkpoint ligands. One mechanism to suppress the infiltrating antitumor CLT/NK cell response is upregulation of ligands to inhibitory receptors expressed on CTLs/NK cells. Two inhibitory receptors, CTLA-4 and PD-1, are expressed on CTLs and to a less extent on NK cells, and blocking of antibodies against these has revolutionized cancer immunotherapy.[12] In particular, IFN-γ upregulates PD-1 ligands (PD-1L and PD-2L) on tumor cells, and their binding to PD-1 potently inhibits tumor-specific CTL activity. Anti-PD-1 monotherapy offers a high rate of sustained tumor regression in metastatic melanoma and is in clinical trials in lung and breast cancers.

Antigenic mutation. Tumors can also avoid CTL activity by antigenic loss. This strategy takes the form of silencing or mutating epitopes that are particularly immunogenic to CTL.[31]

Broad-spectrum tumor-derived immune suppression. Tumors express a variety of membrane-bound and soluble factors that can suppress the immune response, including FasL, which protects the tumor by inducing apoptosis in activated Fas-expressing CTLs. This model is not universally accepted, and a role for FasL in inducing the expression of inflammatory cytokines is also possible. Tumors can also express TGF-β, which acts on CTLs and NK cells to inhibit their metabolism, proliferation, and expression of effector molecules, such as perforin and granzymes. TGF–β also acts on NK cells to downregulate the expression of NKG2D. Pharmaceutical inhibitors of TGF-β signaling have been developed, and one of them, galunisertib, is being tested in patients with cancer.[18] In addition, tumors can produce soluble decoy ligands, such as MIC, which suppresses NKG2D function. CD73-mediated adenosine production also plays important immunosuppressive roles in the tumor microenvironment. CD73 is a surface receptor expressed on many tumors and catalyzes extracellular adenosine monophosphate (AMP) into adenosine that can bind its receptor (A2AR) on NK cells/CTLs to suppress their activity. As such, A2AR and CD73 antagonists are being developed, and their trials in cancer are ongoing.[18]

MULTIPLE-CHOICE QUESTIONS

1. How do cytotoxic T cells recognize target cells?
   A. They cannot, only natural killer cells can recognize tumor cells
   B. Through detection via stress-induced ligands
   C. Recognition of major histocompatibility complex (MHC) class I–peptide complexes specific for the T-cell receptor
   D. Through sensing the inflammatory environment

2. How is the immunity provided by memory cells superior to that elicited by primary challenge?
   A. The memory compartment has a higher frequency of cells specific for the given antigen.
   B. Memory cells are intrinsically able to respond faster to rechallenge with the same infection.
   C. Memory cells can remain at the site of previous infection.
   D. All of the above.

3. How do tumor cells evade cytotoxic T cells?
   A. Avoid them by residing away from the bloodstream
   B. Express ligands that interact with inhibitory receptors on cytotoxic T cells
   C. Cytotoxic T cells cannot kill tumor cells
   D. Proliferate more rapidly than the tumor cells

4. Natural killer cells selectively target:
   A. The tumor microenvironment
   B. Immune cells activated by infection
   C. Cells that have lost MHC class I expression on the cell surface
   D. Memory cytotoxic T cells

5. Which is NOT a pathway that cytotoxic T cells and natural killer cells use on their targets?
   A. Cellular senescence
   B. Fas pathway
   C. Perforin pores
   D. Granzyme activity

Regulatory Immune Cells

James B. Wing, Shimon Sakaguchi

The normal mammalian immune system protects the individual from a myriad of potentially pathogenic microorganisms. However, the immune system must also be tightly regulated to prevent it from attacking self-constituents and thus causing autoimmunity. This is partly achieved through central tolerance and the deletion of T cells that recognize self antigens in the thymus. However, this process is incomplete; that is, some self-reactive T cells are present in the periphery of healthy individuals and are capable of causing autoimmunity. This creates a need for peripheral tolerance mechanisms that control the action of such self-reactive cells.

The mechanisms that suppress harmful immune responses are of interest to both basic and clinical immunologists, as the failure of protective immunity can lead to increased susceptibility to infectious diseases, and loss of self-tolerance may trigger an autoimmune disorder. Furthermore, it is often clinically desirable to enhance an immune response to certain self (or quasi-self) antigens, such as tumor antigens, or to induce immune suppression for the purpose of facilitating organ transplant acceptance. Elucidation of the mechanisms responsible for immune regulation and maintenance of self-tolerance is, therefore, one of the primary goals of current medical immunology.

KEY CONCEPTS

Immunological Self-Tolerance

Immunological self-tolerance is actively acquired and maintained throughout life by a series of mechanisms that cooperatively and complementary operate to prevent the maturation and activation of potentially self-reactive lymphocytes.

The mechanisms include:

- Clonal deletion
- Clonal anergy
- Clonal ignorance
- Dominant suppression

One key feature of the adaptive immune response is that once triggered, it shows essentially the same effector activity, whether the target antigen is a microbe or a self antigen, leading to elimination of the microbe or destruction of self-tissue. To prevent self-destructive immune responses while allowing protective immune responses to nonself antigens, the mammalian immune system has evolved various regulatory contrivances that inhibit the initial generation of potentially harmful self-reactive T and B lymphocytes, termed *central tolerance,* or, after lymphocyte generation, downregulate cellular activation and expansion upon encounter with self antigens, termed *peripheral tolerance.* For T cells, central tolerance is established in the thymus, where many potentially dangerous lymphocytes carrying high-affinity T-cell receptors (TCRs) for self antigens are deleted via negative selection during development. This results in the generation of a peripheral T-cell repertoire that is largely self-tolerant. However, there is abundant evidence that some autoreactive T cells escape thymic deletion, and potentially pathogenic self-reactive T cells are, indeed, present in most individuals. Nevertheless, autoimmune diseases only occur infrequently, indicating that autoreactive T cells are somehow controlled in the periphery. Such peripheral mechanisms of self-tolerance include further deletion of self-reactive T cells, seclusion of self antigen from T lymphocytes, low TCR affinity or lack of costimulation in antigen recognition (clonal ignorance), inactivation of autoreactive T lymphocytes upon encounter with antigen without costimulation (clonal anergy), and active suppression of self-reactive lymphocytes by other lymphocytes (peripheral suppression).[1]

There are various mechanisms of peripheral self-tolerance, and this chapter deals with peripheral suppression mediated by regulatory T cells (Tregs) and other suppressive non–T cells. Several types of T cells with regulatory activity have been described, including subpopulations of $\gamma\delta$ T cells, natural killer T cells (NKT cells), and CD8 and CD4 T cells (Table 18.1; Fig. 18.1). Some of these Tregs are constitutively produced as a separate lineage in the immune system, whereas others are induced from naïve T cells as a product of a particular mode of antigen stimulation in a particular cytokine milieu. Although it remains to be determined how each cell population is functionally stable and physiologically important, this abundance and apparent redundancy of Treg populations may not be surprising when one considers how essential it is to maintain immune homeostasis and self-tolerance.

This chapter focuses on CD4 Tregs; in particular thymically produced Tregs (tTregs) that specifically express the transcription factor Foxp3 and maintain high expression of the interleukin-2 (IL-2) receptor α chain, CD25. Foxp3$^+$CD25$^+$CD4$^+$ Tregs have been the subject of the majority of recent Treg studies and may have the broadest implication to our understanding of the mechanism of various immunological disorders. Loss of function or numerical deficiency of tTreg function or number can be a primary cause of autoimmune disease, allergy, and inflammatory disorders, such as inflammatory bowel disease (IBD) in humans. Conversely, since these cells can prevent targeting of tumor tissues by conventional CD4 and CD8 T cells, inactivating them is a key goal in cancer immunotherapy. Because of their natural presence in the immune system, they are also a good target for

TABLE 18.1 Subsets of Thymic and Peripheral Foxp3$^+$ Tregs and Foxp3$^-$ Tregs

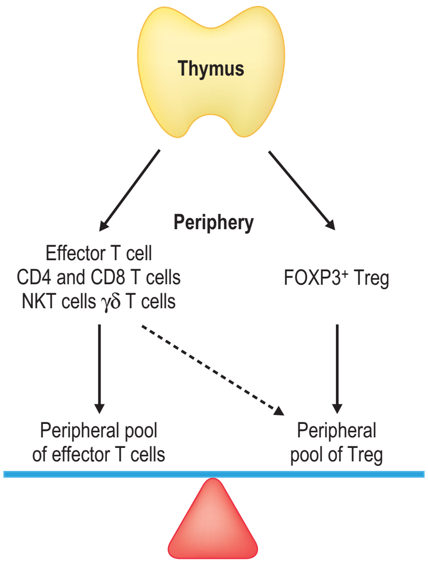

FIG 18.1 Developmental Pathways of Regulatory T Cells (Tregs). Treg cells can develop either in the thymus or the periphery and are vital for maintaining tolerance as a counterbalance to effector T cells. Thymically generated Tregs express Foxp3 and develop within the thymus following to a specialized combination of T-cell receptor (TCR) and costimulatory signals. Extrathymic development of CD4$^+$ Tregs and CD8$^+$ Tregs can ensue from a host of different conditions, such as high concentrations of transforming growth factor-β (TGF-β), interleukin-10 (IL-10), or other particular circumstances surrounding antigen priming. The signals that control differentiation of γδ T cells and natural killer T cells (NKT cells) to cells with regulatory properties are less well defined.

the treatment and prevention of a variety of immunological diseases.[2]

CD4 REGULATORY T CELLS

The nomenclature used to define Tregs has been inconsistent over the years, but recent efforts have been made to standardize the naming of these cells.[3] It is recommended that Foxp3$^+$ Tregs be clearly separated into thymus-derived tTregs, peripherally *in vivo*–induced pTregs and *in vitro*–induced iTregs. Readers should be aware that in the past tTregs have often been referred to as *natural Tregs* (nTregs), whereas both pTregs and iTregs were grouped together as *induced* or *adaptive Tregs.* Where there is no specific identification allowing confirmation of the cells being tTregs or pTregs, the simple term *Tregs* can be used to refer to Foxp3$^+$Tregs. In this chapter, Foxp3$^-$ Treg populations, such as Tr1 and Th3, are referred to collectively as *Foxp3$^-$ Tregs* but have also previously been described as induced or adaptive Tregs.[4]

Foxp3$^-$ CD4 Tregs, such as IL-10–secreting type 1 regulatory T cells (Tr1) and transforming growth factor-β (TGF-β)–secreting T-helper-3 (Th3) cells also differentiate from naïve T cells following antigen stimulation in conjunction with specific conditions in the periphery. Although both Foxp3$^+$ Tregs and Foxp3$^-$ Tregs are suppressive, they differ in their development, phenotype, and function, and they are thus considered to be of separate lineages (see Table 18.1 and Fig. 18.1).[4]

Thymus-Derived Regulatory T Cells

The first report of autoimmune-preventive, thymus-derived T cells in the normal immune system occurred about 40 years ago when thymectomy on day 3 of life (d3Tx) was shown to cause organ-specific autoimmune diseases, such as oophoritis, in otherwise healthy mice, a finding later attributed to the slightly delayed thymic emigration of tTregs in comparison with effector T cells.[5] Subsequent studies showed that the development of autoimmune diseases could be inhibited if the thymectomized animals were reconstituted with CD4$^+$CD8$^-$ thymocytes or CD4$^+$ splenocytes from histocompatible immune-uncompromised animals. Athymic mice transferred with non-Tregs or thymocytes spontaneously develop organ-specific autoimmune diseases, which can be reversed by cotransfer of tTregs from normal adult mice.[6,7] Tregs can suppress the proliferation and cytokine production of conventional CD4 or CD8 T cells *in vitro.* tTregs are thought to arise from T-cell clones with relatively high reactivity to self antigens presented in the thymus.

To pinpoint a specific phenotype for CD4 T cells with regulatory function, surface markers with more restricted expression patterns have been explored. High and stable expression of the IL-2 receptor α chain, CD25 has been found to be a useful and specific surface marker of Foxp3$^+$ Tregs. Between 5% and 10% of CD4$^+$ T cells express CD25 constitutively in the thymus and periphery of mice. Importantly, transfer of CD4 lymphocytes depleted of CD25$^+$ cells induces autoimmunity in athymic nude mice, whereas cotransfer of CD4$^+$CD25$^+$ cells protects the mice from disease induction (Fig. 18.2). Other markers shown to be associated with Foxp3$^+$ Tregs are cytotoxic T lymphocyte antigen-4 (CTLA-4; CD152) and glucocorticoid-induced tumor necrosis factor receptor protein (GITR). However, these and CD25 are not truly specific markers of tTregs, since conventional T cells upregulate GITR, as well as CTLA-4 and CD25, after activation.[6] This dilemma is especially apparent when investigating Foxp3$^+$ Tregs in humans, where a significant proportion of CD4$^+$ T cells in peripheral blood express CD25, yet only 2%–4% of CD4$^+$ T cells, enriched among cells with the highest expression level of CD25 (CD25^{high}), have suppressive properties (Fig. 18.3).[8] The fact that CD25$^+$ Tregs are not a discrete population in humans poses a problem both when obtaining cells for experimental purposes and when evaluating their role in a clinical setting. Therefore finding more specific cell surface markers of CD4$^+$ natural Tregs remains an important goal.

Thymus-Derived Tregs Express the Transcription Factor Foxp3

Specific expression of the transcription factor Foxp3 is closely linked with the development and function of Tregs.[9] The first hint as to the significance of Foxp3 was given by studies of the Scurfy mutant mouse. This mouse strain suffers from a spontaneous X-linked mutation of the *Foxp3* gene, which leads to fatal lymphoproliferative disease associated with multiorgan infiltrates and early death by 3–4 weeks of age in hemizygous males. Similarly, mutations in the human orthologue *FOXP3* are linked to immune dysregulation, polyendocrinopathy, enteropathy, IBD, allergic dermatitis, food allergy, hyperimmunoglobulinemia E, hematological disorders, severe infections and X-linked (IPEX) syndrome, which is an X-linked immunodeficiency syndrome associated with organ-specific autoimmune diseases, such as type 1 diabetes (see Fig. 18.2).[6] Common features of IPEX syndrome and scurfy mice are deficient levels of both tTregs and pTregs.

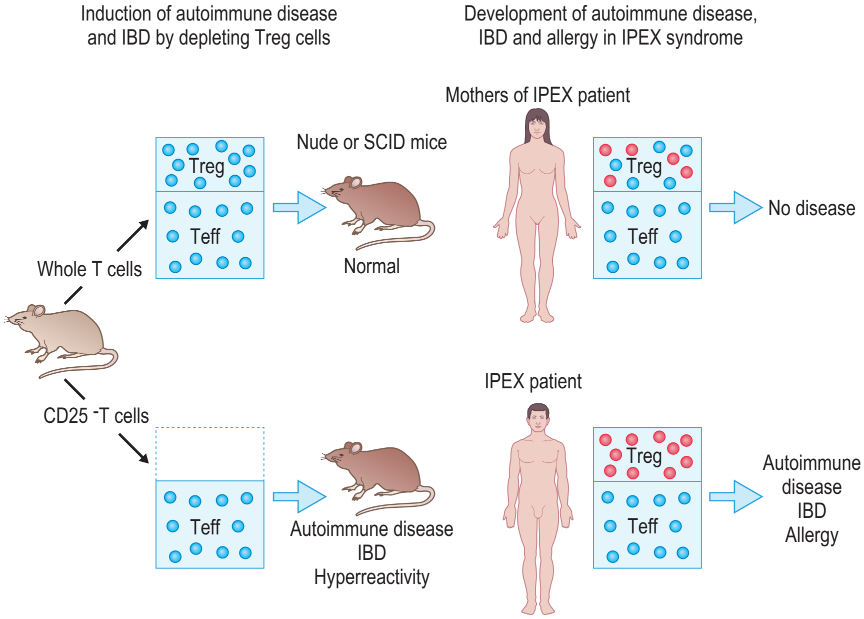

FIG 18.2 Dominant Self-Tolerance in Rodents and Humans. Transfer of T-cell suspensions depleted of Foxp3$^+$CD4$^+$ Tregs induces autoimmune disease and inflammatory bowel disease (IBD) and heightens immune responses to nonself antigens in athymic nude or severe combined immunodeficiency (SCID) mice *(left).* Male children are afflicted by infections and immune dysfunction/polyendocrinopathy/enteropathy/X-linked (IPEX) syndrome. Their mothers with hemizygous defects of the *FOXP3* gene bear defective and normal Tregs as a mosaic because of random inactivation of the X chromosome in each Treg cell. They are completely normal because normal Tregs dominantly control the activation and expansion of effector T (T_{eff}) cells that mediate autoimmune disease, IBD, and allergy *(right).* Blue circles represent intact Treg or T_{eff} cells; red circles represent defective Tregs.

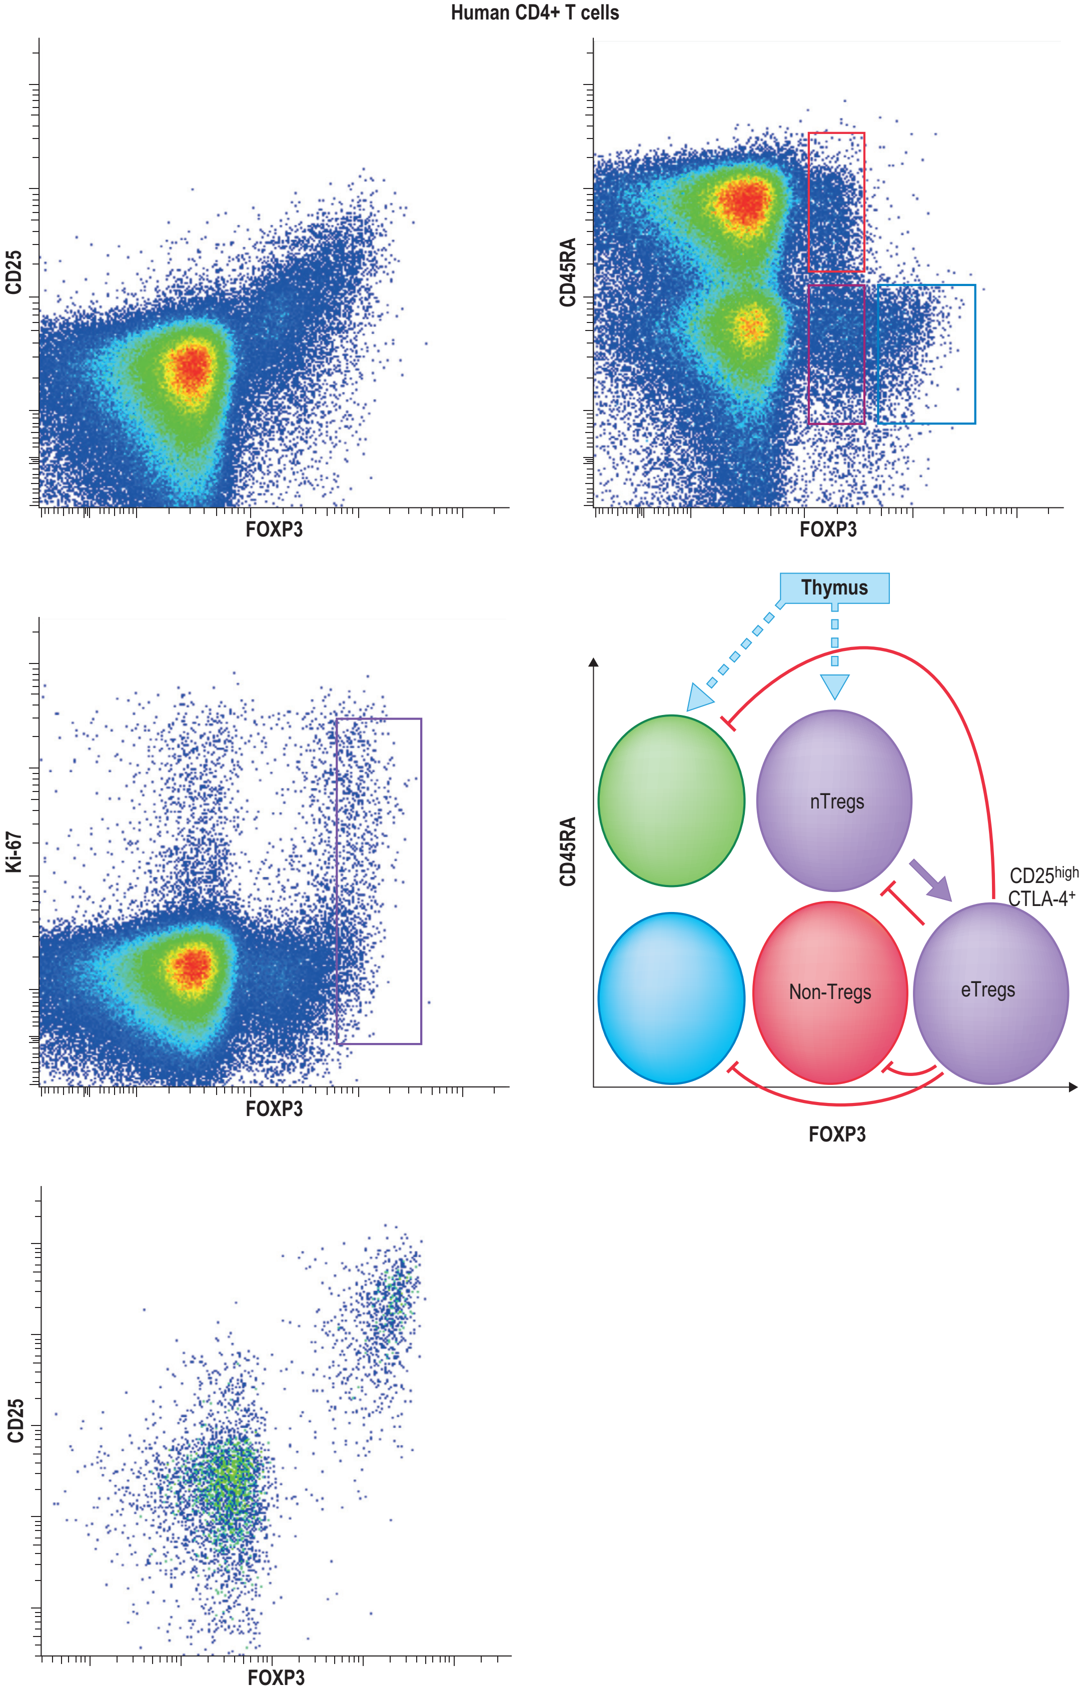

FIG 18.3 **Expression of CD25 and Foxp3 Denotes Tregs in Mice and in Humans.** In mice, between 5% and 10% of CD4$^+$ T cells express CD25, and among these, almost all are Foxp3$^+$. In addition, a few Foxp3-expressing cells reside among CD4$^+$CD25$^-$ T cells. In the peripheral blood of humans, expression of surface marker CD25 is well correlated with intracellular FOXP3, especially when the levels of CD25 and FOXP3 are high *(top left).* CD45RA and intracellular expression of FOXP3 enables the definition of three distinct subsets within FOXP3$^+$CD4$^+$ T cells: CD45RA$^-$ effector Treg cells with high expression of FOXP3 *(blue box),* CD45RA$^+$ naïve Treg cells with low expression of FOXP3 *(red box)*, and CD45RA$^-$ non-Treg cells with low expression of FOXP3 *(top right, purple box;).* Effector FOXP3^{high} Treg cells correspond to actively proliferating Treg cells *in vivo* as they express Ki-67 *(bottom left, purple box).* The thymus produces CD45RA$^+$FOXP3^{low} naïve Tregs as well as naïve CD45RA$^+$ non-Treg cells. Upon antigenic stimulation, naïve Tregs differentiate to CD45RA$^+$FOXP3^{high} effector Tregs, which are potently suppressive and capable of suppressing the proliferation of other Tregs as well as non-Tregs *in vitro (bottom right).*

CD25$^+$CD4$^+$ T cells and CD25$^+$CD4$^+$CD8$^-$ thymocytes specifically express *Foxp3* mRNA in contrast to the cell surface markers used until now. In addition, other thymocytes/T cells, Th1, or Th2 cells scarcely express *Foxp3* even after stimulation.[9] Intranuclear staining of the Foxp3 protein shows that although the majority of Foxp3$^+$ cells in mice reside in the CD4$^+$CD25$^+$ T-cell population, some can also be found in the CD4$^+$CD25$^-$ population (see Fig. 18.3). Importantly, retroviral transduction of *Foxp3* in naïve CD25$^-$ T cells can convert them to regulatory cells with at least some of the suppressive functions of true Tregs. However, although it is essential, it has also become clear that Foxp3 alone is not sufficient to stably maintain the full Treg identity. Another critical factor is the presence of a Treg-type epigenetic pattern in which genes, such as *Foxp3, CTLA-4,* and *GITR,* have stably demethylated CpG residues and a permissive chromatin structure allowing them to be constitutively expressed by Tregs. These epigenetic modifications occur independently of Foxp3 expression and maintain a significant proportion of the *Treg* gene expression even in the absence of Foxp3 itself.[10] However, at the same time, Foxp3 expression is still essential, as shown by the severe diseases seen in humans or mice lacking functional Foxp3. A similar pattern of FOXP3 expression can be observed in humans, with most FOXP3$^+$ cells among CD4$^+$CD25^{high} T cells, and a few being CD25$^-$ or CD25^{low} (see Fig. 18.3). However, in humans, but not in mice, low levels of FOXP3 can be transiently induced by TCR stimulation in conventional T cells. These T cells can be detected directly in blood as CD4$^+$ T cells with a memory phenotype and a weak expression of FOXP3, but with no suppressive function.[8] Human FOXP3$^+$ Tregs with suppressive function can be divided into two subsets: CD45RA$^+$FOXP3^{low} naïve Tregs (nTregs) and CD45RA$^-$FOXP3^{high} effector Tregs (eTregs) (see Fig. 18.3).

In addition to tTregs, there is abundant evidence from mouse studies supporting the peripheral development of T cells with suppressive properties. For example, Foxp3-expressing CD25$^+$CD4$^+$ Tregs, functionally and phenotypically similar to tTregs, can be induced from naïve T cells by *in vitro* or *in vivo* antigenic stimulation in the presence of TGF-β.[11] However, it should be noted that *in vitro*–induced Tregs lack the Treg-type epigenetic pattern and so may not be stable Tregs, making it important to differentiate between *in vivo* peripherally induced pTregs and *in vitro*-induced iTregs.[10] Recent findings indicate that both murine and human thymus-derived Treg cells express Helios, an Ikaros family transcription factor, and Neuropilin-1, whereas most induced Foxp3-expressing CD4 T cells do not. However, some highly activated pTregs and Foxp3$^-$ T cells express these markers to some extent, making them useful, but not of themselves conclusive, to differentiate between tTregs and pTregs.[12] Recent work has demonstrated that tTregs are sufficient for the prevention of widespread autoimmunity but that pTregs have a more specialized function in the prevention of type-2 immune responses in mucosal sites, such as the gastrointestinal tract and the lungs.[11]

CLINICAL RELEVANCE

Infections and Immune Dysfunction/Polyendocrinopathy/Enteropathy/X-Linked (IPEX) Syndrome Is a Result of FOXP3$^+$ Treg Deficiency

When the *Foxp3/FOXP3* gene has a loss-of-function mutation, FOXP3$^+$ regulatory T cells (Tregs) fail to develop, or Foxp3 protein is dysfunctional, and a fatal autoimmune/autoinflammatory disease develops. This monogenic X-linked disease directly demonstrates how crucial FOXP3$^+$ Tregs are for maintaining self-tolerance and immune homeostasis.

Cardinal features of IPEX are:

- Autoimmune diseases (type 1 diabetes, thyroiditis, hemolytic anemia)
- Allergy (dermatitis, hyperimmunoglobulinemia E, food allergy)
- Inflammatory bowel disease

Maintenance of Foxp3$^+$ Tregs

In addition to TCR interaction, it seems that accessory signals, such as costimulation through CD28-B7 or CD40-CD40L, play an important role in the production of Foxp3$^+$ Tregs in the thymus, since animals that lack CD28 or CD40 expression generate only minute numbers of Foxp3$^+$ T cells in the thymus (Table 18.2).[6]

In the periphery, the maintenance of Foxp3$^+$ Tregs requires antigenic priming and cytokines. It is vital that Foxp3$^+$ Tregs encounter specific antigens to remain in the Treg pool. For example, cell transfer experiments in mice thymectomized on day 3 (d3Tx) have demonstrated that Tregs from donors of the same sex are better at protecting against orchitis or oophoritis compared with Tregs from donors of the opposite sex and that Tregs from ovariectomized mice are less competent in preventing oophoritis compared with those from normal females.[5]

IL-2 is vital for the maintenance of natural Tregs, and accordingly, CD25 is not only a marker but also a functionally indispensable molecule for Tregs as a key component of the high-affinity IL-2 receptor. Mice genetically deficient in IL-2 or IL-2 receptor α chain (CD25) or β chain (CD122) develop severe lymphoproliferative disease with lymphocyte infiltration

TABLE 18.2 Signals With Impact on FOXP3$^+$ Treg Induction, Maintenance, and Suppression

	Development	Maintenance/Survival	Suppressive Function
Peptide MHC II interaction	Yes (high affinity)	Yes	Yes, at least initially
CD28	Yes (crucial)	Yes	Not crucial for induction of suppression but high expression on APCs breaks suppression
CD40	Yes	No	No
CTLA-4	No	No	Yes
GITR	No	Modest positive effect	Breaks suppression
TLR ligands	No	Yes	TLR ligands initially break suppression, but this is followed by induction of enhanced suppression
IL-2	Yes (but not crucial)	Yes (crucial)	High levels break suppression
TGF-β	Not required for thymic differentiation but may be involved in peripheral induction	Yes	Yes (not crucial)

Treg, regulatory T cell; MHC II, major histocompatibility complex II; IL-2, interleukin 2; APC, antigen-presenting cell; TGF-β, transforming growth factor-β; CTLA-4, cytotoxic T lymphocyte antigen 4; GITR, glucocorticoid-induced tumor necrosis factor receptor protein; TLR, toll-like receptor.

in multiple organs, resulting in early death.[13] Moreover, genetic deficiencies of CD25 in humans generate a comparable clinical and pathological pattern. It is now known that IL-2–deficient animals have substantially reduced, although not completely depleted, numbers of Foxp3$^+$ T cells and that disease can be prevented by adoptive transfer of normal Foxp3$^+$ Tregs (see Table 18.2).

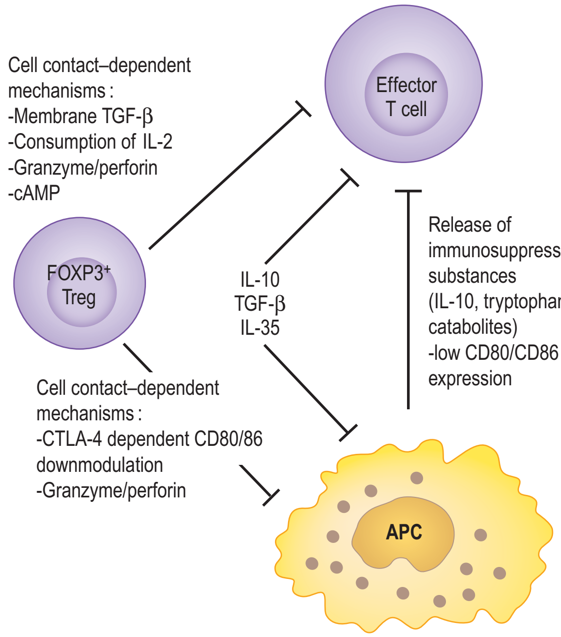
In addition to antigen recognition and cytokines, Foxp3$^+$ Tregs require appropriate interactions with antigen-presenting cells (APCs) for their function and survival. Several molecules of cell adhesion and costimulation are important for function and homeostasis of Tregs, including CD18/CD11a, GITR, CD28, and CTLA-4.

Effector CD4 T cells differentiate into various subpopulations, such as Th1, Th2, Th17, and Tfh, in response to specific stimulation and cytokine milieus (Chapter 16). It has become clear that Tregs mirror this process to some extent and can also differentiate in response to the same stimuli into a subpopulation specialized to control the matching effector population. As a result, Tregs express transcription factors linked to these fates, such as T-bet (Th1), RORγt (Th17), and BCL6 (Tfh), and this allows Tregs to gain expression of relevant chemokine receptors, such as CXCR5, in the case of T-follicular regulatory (Tfr) cells, enabling these cells to traverse to the germinal center, where they are able to suppress T-follicular helper (Tfh) cells and the germinal center reaction. Similarly, expression of CCR6 and CXCR3 allows a similar process to occur for Th17-Tregs and Th1-Tregs, respectively. This process lets Tregs respond to the environment and specifically travel to and suppress Th1, Th2, Th17, and Tfh-cell responses.[14] Further to the development of Tregs that specifically mirror effector T-cell subsets, it has also been recently demonstrated that Tregs travel to nonlymphoid sites, such as skin, adipose tissue, and skeletal muscles, to suppress inflammation. Tregs from these sites may represent specialized subtypes of Tregs with adapted transcriptional signatures, such as adipose tissue Tregs, expressing the transcription factor peroxisome proliferator-activated receptor-γ (PPAR-γ), which regulates fatty acid metabolism and allows their homeostasis and survival in this environment.[15]

Another important aspect of Treg responsiveness to the environment is that Tregs are affected by the microbiota (Chapter 14). Recently, it has been demonstrated that certain commensal organisms, such as *Clostridium* spp. present in the gut, have large effects on Treg differentiation in these environments. In some cases, this may be indirect via induction of TGF-β production leading to induction of Tregs from naïve T cells, whereas in other cases, microbial metabolites, such as short-chain fatty acids, directly induce Treg proliferation.[11]

Suppressive Function of Foxp3$^+$ Tregs

The standard assay to analyze the suppressive function of Tregs is to coculture purified cell fractions of T cells with Tregs and then measure the proliferative response upon antigenic stimulation in the presence of APCs. Such assays show that freshly isolated Foxp3$^+$CD25$^+$ Tregs are not able to suppress T-cell responses *in vitro* unless they are first stimulated via the TCR. Once activated, they suppress other CD4 and CD8 T cells, irrespective of their antigen specificities.[7] Foxp3$^+$ Tregs can inhibit proliferation and cytokine production of naïve T cells. They can also suppress the function of already differentiated Th1 and Th2 cells *in vitro* and have been shown to reverse ongoing immunopathology, such as colitis, *in vivo*.[11] In addition to suppressing T-cell function, Foxp3$^+$ Tregs are also able to suppress B cells, NK cells, and NKT cells.



Cell contact–dependent mechanisms:
-Membrane TGF-β
-Consumption of IL-2
-Granzyme/perforin
-cAMP
Effector T cell
FOXP3+ Treg
IL-10
TGF-β
IL-35
Release of immunosuppressive substances
(IL-10, tryptophan catabolites)
-low CD80/CD86 expression
Cell contact–dependent mechanisms:
-CTLA-4 dependent CD80/86 downmodulation
-Granzyme/perforin
APC

FIG 18.4 Proposed Suppressive Mechanisms of Foxp3$^+$ Regulatory T Cells (Tregs). Foxp3$^+$CD25$^+$ Tregs can inhibit many different types of effector cells and can also suppress immune responses at multiple stages, including the initial priming in the lymph node and effector actions at the site of inflammation. The precise mechanism is not known, but numerous theories have been proposed, and it is likely that Foxp3$^+$CD25$^+$ Tregs suppress by several different mechanisms. *In vivo* Tregs can act in a cell contact–dependent manner by competing directly for stimulatory ligands on the antigen-presenting cell (APC), by absorbing essential growth factors, such as interleukin-2 (IL-2), or by directly transmitting an as-yet uncharacterized negative signal to either the T cell or the APC. Alternatively, Tregs can use long-range suppressive mechanisms by means of the cytokines IL-10, IL-35, and transforming growth factor-β (TGF-β).

Foxp3$^+$ Tregs likely suppress by multiple mechanisms, including both soluble and cell surface–bound mediators (Fig. 18.4). *In vitro* studies have shown that Foxp3$^+$ Tregs need direct cell-to-cell contact with responder cells and that suppression does not occur if Tregs are separated from effector T cells by a semipermeable membrane, even if this allows the passage of soluble factors.[7] Moreover, Foxp3$^+$CD25$^+$ Tregs are not prominent producers of either IL-10 or TGF-β *in vitro*. These features are quite different from those of Tr1 or Th3 cells, which primarily rely on soluble immunosuppressive cytokines, such as IL-10 and TGF-β, for their inhibitory function.

Although Foxp3$^+$ Tregs have been shown to suppress effector T cells under APC-free conditions *in vitro*, presumably by absorbing IL-2, it is reasonable that Foxp3$^+$ Tregs *in vivo* control immune responses also by regulating APCs. Indeed, by using two-photon laser-scanning microscopy, it has been shown *in vivo* that although there are limited contacts between Foxp3$^+$ Tregs and effector T cells, stable interactions exist between Foxp3$^+$ Tregs and dendritic cells (DCs) during ongoing suppression in lymph nodes. One way that Foxp3$^+$ Tregs regulate immune responses may be through competition with effector T cells for access to APCs. Foxp3$^+$ Tregs have, relative to conventional T cells, a more activated phenotype (*e.g.*, high expression of adhesion molecules, such as LFA-1) in normal healthy individuals, which gives an advantage when engaging with APCs and results in the prevention of naïve T-cell priming. Interestingly, Foxp3$^+$ Tregs have been shown to modify the function of the APC. APCs cultured with Foxp3$^+$ Tregs downregulate CD80 and CD86 via a CTLA-4–dependent mechanism and become impaired in their ability to stimulate T cells.[16] Additionally, CTLA-4–expressing Tregs can induce production of the enzyme indoleamine dioxygenase (IDO), which catalyzes the amino acid tryptophan to the metabolite kynurenine that represses T-cell responses. Importantly, CTLA-4 expression by Foxp3$^+$ Tregs has been shown to be critical for tolerance *in vivo,* since mice with deletion of this coinhibitory molecule only in Foxp3-expressing cells develop lethal autoimmunity. Other proposed suppressive mechanisms that involve close contact between Foxp3$^+$ Tregs and target cells include surface-bound TGF-β, which is inhibitory at a close range; perforin; and granzyme B, which kills target cells (see Fig. 18.4).[7]

Despite the fact that immunosuppressive cytokines are redundant for suppression *in vitro,* the *in vivo* situation seems somewhat different. Recently, the immune suppressive cytokine IL-35 has been implicated in Treg-mediated suppression, and both TGF-β and IL-10 expressed by Foxp3$^+$ Treg are important in the prevention of IBD in mice. Curiously, adoptive transfer of IL-10–deficient CD25$^+$ Tregs failed to protect against colitis, although it could inhibit the development of gastritis. Furthermore, although perforin- or granzyme B–expressing Foxp3$^+$ Tregs are rare in the spleen, they are abundant in a tumor environment. Taken together, Foxp3$^+$ Tregs can use several different mechanisms of suppression, and one seems to play a more prominent role than another, depending on the local cytokine milieu and the strength and type of immune response.[7]

Tr1 Cells

Some Foxp3$^-$ suppressive T cells have also been identified. The best characterized are IL-10–secreting Tr1 cells, which have been shown to be present and functional in humans following bone marrow transplantation and in response to allergens (see Table 18.1).

Tr1 cells were initially generated *in vitro* from CD4 T cells rendered anergic by chronic stimulation in the presence of IL-10, which is a potent negative regulator of inflammation and lymphoproliferation.[17] T cells obtained in such a fashion produce a unique pattern of cytokines distinct from Th1 or Th2 cells, with IL-10 as their signature cytokine. In addition, Tr1 cells secrete some TGF-β, interferon-γ (IFN-γ), and IL-5, but not IL-4 or IL-2. Tr1 cells can be identified on the basis of surface expression of CD49b and LAG-3, but lacking Foxp3 expression.[17] In addition, antigenic stimulation with immature DCs (*i.e.,* low levels of costimulatory molecules) or with DCs pretreated with IL-10/TGF-β confers on naïve CD4 T cells an anergic and suppressive phenotype both *in vitro* and *in vivo.*[17,18]

Several investigations have shown that Tr1 cells take part in the tolerance process in humans. For example, the presence of Tr1 cells can be correlated with lack of graft-versus-host disease (GvHD) in bone marrow transplantation, and Tr1 cells are also induced after specific immunotherapy in patients with allergies. Experimental data from a murine model shows that Tr1 cells can prevent IBD. Interestingly, Tr1 cells specific for *Escherichia coli* proteins can be isolated from the intestinal mucosa of healthy donors. In pemphigus vulgaris, which is an autoimmune skin disorder with circulating autoantibodies against desmoglein-3 (Chapter 63), Tr1 cells specific for desmoglein-3 can be isolated from pemphigus vulgaris–prone but apparently healthy individuals, whereas patients with pemphigus rarely have such cells. Collectively, Tr1 cells can be induced by autoantigens as well as foreign antigens as a component of the mechanisms that maintain tolerance to both self and nonself.[18]

OTHER SUBSETS OF FOXP3$^-$ REGULATORY T CELLS

Th3 cells were identified in mice during investigations of the mechanisms of oral tolerance. Oral tolerance has presumably evolved to prevent hypersensitivity reactions to food and microbial antigens present in the mucosal flora. It was found that mice fed with myelin basic protein, a neuronal autoantigen, developed T cells that preferentially produced TGF-β together with varying amounts of IL-4 and IL-10. These T cells had suppressive properties, mediated by TGF-β, and could prevent the induction of experimental allergic encephalomyelitis (EAE), the murine equivalent of multiple sclerosis (MS) (Chapter 66). Th3 cells can be identified by their surface expression of latency-associated peptide (LAP), which binds inactive TGF-β. Recently, LAP$^+$ Tregs have been shown to be induced after oral or nasal administration of tolerogenic CD3 monoclonal antibodies. Th3 cells can also be generated *in vitro* if grown in the presence of TGF-β, IL-4, and IL-10, although some of them may become Foxp3$^+$ iTregs. Since the intestinal mucosa has high basal levels of all these cytokines, which are upregulated after antigen administration, it is conceivable that this particular environment drives the formation of Th3 cells whereas a different setting may produce Tregs of another phenotype.[19,20]

In addition to CD4 Tregs, other types of T cells with immunosuppressive properties have also been found; these recognize antigens different from those typically presented to CD4 T cells via MHC class II and may therefore serve to induce tolerance in other settings (see Table 18.1). One example is CD8 T cells with TCRs that recognize antigen presented by the mouse MHC class lb Qa-1 molecule (HLA-E in humans; Chapter 5). Qa-1 has limited polymorphisms and can present both foreign and self-peptides. Since Qa-1 peptide complexes on, for example, CD4 T cells can bind to both the inhibitory CD94-NKG2 receptor complex and the TCR on CD8 T cells, total loss of Qa-1 does not lead to development of spontaneous autoimmunity, since loss of CD94-NKG2 inhibitory signaling is largely compensated for by loss of TCR signaling.[21] However, specific mutation of Qa-1 leading to its loss of CD94-NKG2, but not TCR binding, results in severe lupus-like autoimmunity underpinned by dysregulated Tfh-cell responses. The function of Qa-1–restricted CD8 appears to be largely dependent on perforin expression as perforin-deficient CD8 T cells fail to mediate the suppression of Tfh cells.[21]

Another subset of regulatory CD8 T cells are CD8$^+$CD28$^-$ Tregs, which can suppress immune responses by direct interaction with APCs. These cells are generated by multiple rounds of *in vitro* stimulation with alloantigen and can downregulate costimulatory molecules or upregulate the inhibitory immunoglobulin-like transcript 3 (ILT3) and ILT4 receptors on DCs, leading to the impaired activation of effector T cells.[22]

Double-negative T cells are a class of αβ TCRs expressing cells that lack both CD4 and CD8 and make up around 1% of the TCR αβ cells in mice and humans.[22] Much is still unknown about the action of these cells, but it seems that they may be able to suppress CD4 and CD8 T cells by taking up antigen–MHC complexes from APCs via trogocytosis, capturing plasma membrane fragments from the immunological synapse and then presenting them to other T cells in the absence of costimulatory signaling and possibly a signal-inducing apoptosis, such as Fas. They may also suppress APCs in a manner similar to Foxp3$^+$ Tregs by expression of CTLA-4.[22]

γδ T cells with a regulatory phenotype exist as a subset of the epithelial γδ T cells, which can be found in mice. Mice deficient in γδ T cells do not appropriately regulate responses to various pathogens. This inappropriate regulation manifests as immunopathology in conjunction with the robust development of immunity. γδ T cell–deficient mice also show accelerated autoimmune responses in models of systemic lupus erythematosus (SLE) and spontaneously develop dermatitis when bred on certain genetic backgrounds. Commonly, these conditions are driven by αβ T cells, and γδ T cells will inhibit αβ T cells predominantly in the local environment. In humans, who lack an equivalent population of intraepithelial γδ cells, it is plausible that this immune regulation is provided by other types of suppressive cells.[23]

NKT cells respond to CD1d, the nonclassic class I antigen-presenting molecule, which binds glycolipids rather than peptides. NKT cells can induce either proinflammatory (IFN-γ) or anti-inflammatory (IL-4, IL-10, IL-13) immune responses, but the prerequisites for this choice are ill defined. Nevertheless, under appropriate conditions, NKT cells clearly promote tolerance, which is illustrated in studies of transplantation and oral tolerance (see Table 18.1).[24]

Suppressive Non–T Cells

Recently, interest has also been focused on non–T-cell subsets with suppressive functions. One example of this is B cells with regulatory function (known as *Breg* or *B10 cells*). Breg cells produce the suppressive cytokine IL-10 and have been identified in both mice and humans. Experiments in mice have demonstrated that these cells have suppressive capacity and can influence the development of autoimmune diseases, such as EAE, collagen-induced arthritis, and colitis. Breg cells appear to be induced in the periphery; to date, a clear transcriptional controller providing a clear transcriptional program has not been identified. This, together with the finding that various subsets of Breg cells differentiate from a wide variety of different B-cell populations (marginal zone, plasma blasts, plasma cells, CD5+CD1d^{high} B10 cells), has led to the suggestion that Breg cells may not be a lineage in themselves but, rather, a suppressive state that can be induced in all B cells when given the correct stimuli.[25] The suppressive function of Breg cells has largely been attributed to production of IL-10, TGF-β, and IL-35; this may either be via direct action on effector CD4 and CD8 T cells or indirectly by induction of other suppressive populations, such as Foxp3$^+$Tregs and Tr1 cells.[25]

Myeloid-derived suppressor cells (MDSCs) are broadly divided into polymorphonuclear MDSCs, which are closely related to neutrophils, and monocytic MDSCs, which are related to monocytes. MDSCs are generated in bone marrow and can be differentiated from other myeloid cells by the high levels of expression of NADPH oxidase (Nox2) and nitric oxide synthase 2 (*nos2*), leading to production of reactive oxygen species (ROS) and nitric oxide (NO) and the transcription factor c/EBPβ. MDSCs have decreased phagocytic capacity, which, in combination with their production of suppressive cytokines, such as IL-10 and TGF-β, leads them to have a suppressive effect on T-cell responses. MDSCs are often associated with tumor progression and are believed to play an important role in the establishment of the immunosuppressive tumor environment.[26]

DCs have also been demonstrated to have tolerogenic properties in certain circumstances. It is unclear if tolerogenic DCs are of a stable lineage or, perhaps like Bregs, represent a particular state of differentiation. Antigen presentation by immature DCs may, indeed, be tolerogenic because of lack of costimulation, but antigen presentation by the same cells may be immunogenic once mature and expressing greater levels of costimulatory molecules. Additionally, both pDCs found in the tumor microenvironment and CD103$^+$ conventional DCs in the lamina propria produce the immune suppressive molecule indoleamine 2,3-dioxygenase (IDO), which has been demonstrated to aid in the induction of pTreg cells.[27]

CLINICAL RELEVANCE OF REGULATORY T CELLS

Abundant evidence strongly supports Tregs as key controllers of self-tolerance, and Tregs of various subsets play an active role in the control of almost all types of physiological and pathological immune responses, which also makes them suitable targets for immunotherapy (see Table 18.1; Table 18.3).

THERAPEUTIC PRINCIPLES

Adjustment of the Immune Response by FOXP3$^+$ Regulatory T Cell (Treg)

- Reduction of FOXP3$^+$ Treg suppression or reducing Treg numbers
  - Enhancement of tumor immunity
  - Clearance of infections
  - Improvement of responses to vaccines
- Boosting of FOXP3$^+$ Treg function or increasing Treg numbers
  - Treatment of autoimmunity
  - Treatment of allergic responses
  - Induction of transplantation tolerance
  - Control of excessive immunopathology to foreign antigens (*i.e.*, pathogens)
  - Maintenance of fetomaternal tolerance in pregnancy

TABLE 18.3 Potential Therapeutic Approaches for Treg-Based Therapy

Increase of Treg Numbers or Function	Reduction of Treg Numbers or Function
Ex vivo expansion of pure FOXP3$^+$ Tregs with allo- or autoantigens plus growth factors, such as IL-2, and chemicals, such as rapamycin	Transient reduction of FOXP3$^+$ Treg and/or perturbation of suppression *in vivo* (anti-CD25 antibody, anti-CTLA-4 antibody, or anti-IL-2 antibody)
Ex vivo induction of Treg from conventional T cells by cytokines (IL-10, TGF-β), pharmacological agents or modified DCs	Render effector T cells resistant to suppression (GITR signaling)
In vivo promotion of Tregs, rather than effector T cells, using monoclonal antibody treatment or pharmacological agents (anti-CD3 antibody, anti-CD40L antibody, etc.)	

Treg, regulatory T cell; IL-2, interleukin-2; IL-10, interleukin-10; TGF-β, transforming growth factor-β; DC, dendritic cell; CTLA-4, cytotoxic T lymphocyte antigen-4; GITR, glucocorticoid-induced tumor necrosis factor receptor protein.

Autoimmunity

As discussed above, natural Foxp3$^+$CD4$^+$ Tregs are engaged in active suppression of autoimmune disease, since their depletion results in spontaneous development of autoimmune diseases in rodents. Furthermore, genetic anomaly of Foxp3 function can be a direct cause of autoimmune diseases in humans, as exemplified in IPEX syndrome.[6] A reduction of Foxp3$^+$ Tregs in number or function has been reported in systemic autoimmune diseases, such as SLE, Sjögren syndrome, antineutrophil cytoplasmic antibody (ANCA)–associated vasculitis, Kawasaki disease, systemic sclerosis, psoriasis, autoimmune hepatitis, myasthenia gravis, and IBD.[28] Of note, type II autoimmune polyglandular syndrome, which resembles the systemic disease induced in nude mice reconstituted with splenocytes devoid of CD4$^+$CD25$^+$ T cells, is also characterized by Treg functional deficiency. However, studies of MS and type 1 diabetes did not detect any differences between patients and controls, and conflicting data have been reported in rheumatoid arthritis (RA) with regard to both function and numbers of CD25^{high} Tregs.[28] The accuracy of the identification of Tregs must be taken into account in these human studies, since CD25 and Foxp3 are also expressed to some extent by activated non-Treg T cells in humans.

A general observation is that FOXP3$^+$ Tregs increase in number at the site of inflammation. In the case of RA, synovial fluid from patients with ongoing RA was found to contain increased numbers of Foxp3$^+$CD25$^+$ Tregs compared with the levels in peripheral blood. CD25$^+$ Tregs from the synovial fluid of patients with RA are largely functional, although their numbers or suppressive function is apparently not enough to halt the inflammatory process. In contrast, CD25$^+$ Tregs obtained from the blood of patients with MS reportedly have decreased abilities to suppress proliferation of effector T cells. In summary, reduced levels of FOXP3$^+$CD25$^+$ Tregs in peripheral blood are not a general finding in autoimmune diseases and may not necessarily reflect the actual conditions at the site of inflammation. However, if Treg subsets defined by expression levels of CD45RA and Foxp3 are assessed, cytokine secreting Foxp3^{low} non-Tregs increase in active SLE.[8] Dynamic changes of Treg subsets in various autoimmune states remain to be investigated.

Allergic Disease

CD25$^+$ natural Tregs play an important role in suppressing the development of allergic reactions to innocuous environmental substances. This is best illustrated by IPEX syndrome, which is accompanied not only by organ-specific autoimmune diseases but also by severe eczematous dermatitis, high levels of serum immunoglobulin E (IgE), and sometimes eosinophilia.[6] Indeed, FOXP3$^+$CD25$^+$ Tregs from the blood of healthy donors without allergies suppress both proliferation and production of Th2 cytokines when challenged with specific allergens *in vitro*. If the same experiment is performed with Tregs from individuals with allergies, a marked difference is seen, as these Tregs fail to downregulate Th2-related responses to allergens. IL-10 production by the FOXP3$^+$ Tregs, Tr1 and Breg, has been implicated in the control of allergic responses.[29]

Since the suppressive ability for polyclonal stimuli is retained in patients with allergies, this deficiency is directly related to the allergen the individual is sensitized to and thus probably does not reflect a general Treg deficiency. The inability to suppress Th2 responses induced by birch or grass pollen is aggravated when the allergic reaction is ongoing and effector cells are fully activated, as during spring and summer compared with wintertime. Addition of IL-4 can attenuate the CD25$^+$ Treg-mediated suppression of Th2 clones *in vitro* in the same way as IL-2, which may provide an explanation for the insufficient control of ongoing allergic responses by Tregs. Individuals with or without allergies harbor allergen-specific, IL-4–producing effector T cells, IL-10–producing Tr1 cells, and CD25$^+$ Tregs, but in different proportions. The balance between Th2 and certain Treg populations may, therefore, dictate whether clinical allergy will develop. Indeed, in the setting of curative specific allergy immunotherapy (SIT), allergen-specific IL-10–producing T cells can be induced. Furthermore, children who “grow out” of their allergy to cow’s milk have higher numbers of CD4$^+$CD25$^+$ T cells specific for β-lactoglobulin compared with children with clinically active allergies. This suggests that certain allergies can be cured by the induction or expansion of antigen-specific Tregs and that the balance between Tregs and effector T cells is of importance to prevent allergeis.[30]

Transplantation

The ultimate goal of organ transplantation is to establish tolerance to allogeneic organ grafts as effectively and stably as to self-tissues, but without the need for continuous general immunosuppression (Chapter 81).[31] Needless to say, Tregs have sparked a lot of attention in this area of research. CD25$^+$ Tregs were first shown to suppress GvHD in murine models of allogeneic bone marrow transplantation. Similarly, nude mice transplanted with allogeneic skin rejected the graft when reconstituted with CD4$^+$CD25$^-$ T cells alone but retained the graft when large enough numbers of CD25$^+$ Tregs were cotransferred. In humans, attempts have been made to prevent GvHD in bone marrow transplantation and induce graft tolerance in organ transplantation with the use of purified CD25$^+$ Tregs.[17] Another potential way to promote the induction of Tregs in organ transplantation is to evaluate the effects of various immunosuppressants in terms of altering the balance between Tregs and effector T cells. Different immunosuppressants target different pathways in cell metabolism and can therefore have different effects on cell populations that behave in dissimilar ways, such as effector T cells and Tregs. Dosage and timing of administration, as well as specific drug combinations, seem to be a promising angle of transplantation immunotherapy with the purpose of inducing graft tolerance and preventing graft rejection. Tregs have been shown to home to, and reside within, the graft, which is stably accepted once a dominance of Tregs has become established. Treg-mediated transplantation tolerance is not a systemic phenomenon but, rather, is localized to the graft, and as such, it would not incur the dangers that accompany general immunosuppression.[31]

Tumor Immunity

It is now well known that many of the tumor-associated antigens recognized by a patient’s T cells are normal self-constituents, indicating that antitumor immune responses are within the range of FOXP3$^+$ Treg control. Therefore the presence of natural Tregs in the normal immune system may not only prevent autoimmunity but also hamper immune surveillance of cancer.[32] In fact, FOXP3$^+$ Tregs, in particular, highly suppressive FOXP3^{high} effector Tregs, are abundant in the tumor mass where they likely block any immune response targeting malignant cells. Studies on human malignancies have shown that the frequency of FOXP3$^+$ Tregs is increased in tumors of, for example, metastatic melanoma or pancreatic and lung cancers. Moreover, high levels of FOXP3$^+$

Tregs in the tumor are correlated with a poor prognosis and survival. Treg cells are not only involved in solid tumors but also in hematological malignancies.[32] For example, the architectural pattern of Treg cells in follicular lymphomas is associated with the prognosis of the disease. Whether the elevated levels result from migration of Tregs into the tumor or from an expansion on the site is not clear, but evidence exists in support of both events. For example, ovarian tumor cells and infiltrating macrophages secrete the Treg-recruiting chemokine CCL22, which binds to CCR4 expressed by Tregs, and, in addition, many tumors produce TGF-β, which contributes to the maintenance of FOXP3$^+$ Tregs and may also induce FOXP3 expression in non-Treg cells within the tumor microenvironment. It is now evident that both effector T cells and Tregs must be assessed in monitoring the efficacy of anticancer immunotherapy.[32]

The involvement of Tregs in tumor immunity indicates that antitumor immune responses can be provoked or enhanced by depleting Tregs in a host that is otherwise responding poorly. Experimental mouse models have, indeed, demonstrated that simple depletion of CD25$^+$ Tregs with anti-CD25 antibody results in tumor eradication, and similar effects can be achieved with *in vivo* administration of agonistic anti-GITR, anti-CTLA-4–blocking antibodies or anti-CCR4 cell–depleting antibodies.[32] Depletion of CD25$^+$ T cells also enhances the effect of vaccination with tumor antigens.

Pharmacological agents are another possible way of altering the effector T cell/Tregs ratio. For example, fludarabine was shown to selectively decrease the frequency of CD25$^+$ Tregs in patients receiving chemotherapy. Conversely, previously used regimens, such as administration of exogenous IL-2, are now being reevaluated, since IL-2 may expand Tregs. As expected from the role of Tregs in self-tolerance, a caveat of Treg-based therapies of cancer is the possible development of autoimmunity that may depend on the degree and period of *in vivo* systemic Tregs depletion, as well as the genetic make-up of the host.[32]

In addition to Foxp3-expressing Tregs, MSDCs are believed to have an important role in the establishment and maintenance of the tumor immunosuppressive environment, largely through their production of immunosuppressive cytokines, such as IL-10 and TGF-β, and reactive nitrogen and oxygen species.[26]

Infectious Disease

Immune responses to infectious agents, such as bacteria and viruses, often result in tissue damage, which might be more severe if it were not for the involvement of Tregs. On the downside, in many cases, Tregs can contribute to the development of chronic infections. As previously discussed, Tregs have the potential to directly respond to microbial products and are believed to be engaged in suppressing responses to infectious agents. A number of studies have shown that the outcome of an infection partly hinges on the proper balance between effector T cells and Tregs.[33] Adoptive transfer of Tregs prevents lethal pneumonia in T cell–deficient mice infected with *Pneumocystis jiroveci,* but at the expense of a deficient protective response and microbial clearance. Similarly, Tregs suppress Th1 responses in mice infected with *Helicobacter pylori,* thereby limiting the mucosal inflammation but resulting in a higher bacterial load. Human studies have shown that Tregs from carriers of *H. pylori* suppress responses to *H. pylori* antigens *in vitro* and have increased frequencies of CD25$^{\text{high}}$ T cells in both the stomach and the duodenal mucosa compared with Tregs from healthy controls. Taken together, modulation of the infectious response by Tregs can limit tissue damage but may enhance pathogen survival. This sort of compromise may not always be disadvantageous to the host. For example, in murine *Leishmania major* infection, Tregs prevent complete eradication of the parasites, which results in the persistence of low numbers of microbes that have been proven to be essential for the development of T-cell memory and prevention of reinfection. However, this delicate balance can be tipped in favor of the pathogen, which can be seen in the case of malaria and various viral infections such as human immunodeficiency virus (HIV). For example, HIV-specific CD4 and CD8 T-cell responses are substantially suppressed by Tregs *in vitro* in most individuals with HIV infection. Taken together, future treatments, as well as vaccine design, will need to take Tregs into account, and depending on the pathogen in question, it might be necessary to reduce or enhance the activity of Tregs to achieve a favorable outcome (see Table 18.3).[33]

TRANSLATIONAL RESEARCH

Manipulations of Foxp3$^+$ Tregs in animal models of, for example, autoimmune disease, cancer, transplantation, and infection, have shown a great potential for modulation of immunological diseases by this subset. The findings in animals have already started to make their way into clinical practice and more is likely to come within the next 5–10 years.[2] In cases when immunity needs to be boosted, such as in cancer and during infection, the approach is to identify molecules that inhibit function and differentiation of Tregs as well as molecules that locally deplete them. Particularly, cancer immunotherapy has proven to be successful[34] (Chapter 77). Such examples in current therapy are CTLA-4–specific blocking antibody (ipilimumab; MDX-010/Yervoy; Bristol-Myers Squibb, N.Y.); although CTLA-4 expression is not exclusive to Tregs, it is much more highly expressed and critical to their suppressive function. In addition, recent studies have suggested that in addition to blocking the function of CTLA-4, anti-CTLA-4 antibodies may also deplete Tregs in the tumor environment, but not in the periphery, because of antibody-dependent, cell-mediated cytotoxicity. This depletions specificity to the tumor environment may be attributed to a combination of high levels of CTLA-4 expression and the presence of large numbers of phagocytic cells on the local area.[32] Furthermore, other checkpoint blockade strategies, such as those targeting the cell intrinsic immunosuppressive molecule PD-1 or its ligand PD-L1, have proven to be effective in early clinical trials.[34] Additionally, combination therapies are of great interest. It has been found that anti-CTLA-4 treatment can lead to increased expression of PD-L1 by the tumor itself, which may dampen the effect. Thus adding both anti-CTLA-4 and anti-PD1 or PD-L1 may have greater benefits, as demonstrated by a recent phase I trial of anti-CTLA-4 (ipilimumab) plus anti-PD-1 (nivolumab) in patients with melanoma.[35] Certain combinations may prove particularly effective, since they target different pathways. Again, in this case, CTLA-4 may be acting primarily as a cell extrinsic suppressive molecule on Tregs, and PD-1 may be acting in *cis* to suppress PD-1–expressing CD4 or CD8 effector cells, and as a result, the combination of the two may provide synergistic effects. As might be predicted, these types of immunomodulatory treatments can lead to severe autoimmune adverse events; however, further studies on both CTLA-4 and PD-1 and other potential checkpoints, such as B- and T-lymphocyte attenuator (BTLA), inducible T-cell costimulator (ICOS), and a range of other inhibitor or stimulatory molecules,[34] either as monotherapies or in combination, may help boost efficacy while reducing adverse events.[34]

Conversely, in cases when tolerance should be reinforced (autoimmunity, transplantation, allergy, fetomaternal tolerance) molecules that either mimic or enhance Tregs function and survival are under investigation. In the former case, CTLA-4-Ig (abatacept; Orencia, Bristol-Myers Squibb, N.Y.), a solubilized version of CTLA-4 that, in part, mimics the effect of Tregs on APCs by blocking their expression of B7.1 and B7.2, is currently being used for the treatment of, for example, RA. In addition, cellular therapy, by infusion of *ex vivo* or manipulated expanded Tregs, is in small-scale use in patients with GvHD after hematopoietic stem cell transplantation,[17] and early trials of Treg transfer in recent-onset type 1 diabetes are underway. Further to this, transfer of Tr1 cells in patients with Crohn disease is also under investigation.[17] Cell-based therapies are, indeed, a promising strategy for managing various immunological diseases and immune responses; however, several challenges still remain, particularly those relating to the functional stability of *ex vivo*–expanded or –induced Tregs.[2]

ON THE HORIZON

- It is clear that regulatory T cells (Tregs) in different sites have phenotypic differences, a greater understanding of Treg heterogeneity is critical to clarification of their role in human autoimmunity.
- Specific targeting of tumor-resident Tregs without depletion of peripheral Tregs is critical to enhancing antitumor therapy while avoiding adverse events.
- Expansion and control of Treg subsets, such as T-follicular regulatory (Tfr) or muscle-resident Tregs, may be critical to fine control of specific immunological disorders.

MULTIPLE-CHOICE QUESTIONS

1. What are the symptoms of loss of FOXP3 function?
   A. Inflammatory bowel disease
   B. Allergic disease (allergic dermatitis, food allergy, hyperimmunoglobulinemia E)
   C. Type 1 diabetes
   D. All of the above

2. A cell is Helios$^+$ Neuropilin$^+$ Foxp3$^+$ CD4$^+$. What is it most likely to be?
   A. tTreg
   B. pTreg
   C. iTreg
   D. Tr1

3. What is the primary suppressive mechanism used by Tr1 cells?
   A. Granzyme B
   B. IL-35
   C. CTLA-4
   D. IL-10

4. What extracellular marker is most commonly used to identify Foxp3 expressing Tregs?
   A. CD27
   B. CD69
   C. CD25
   D. CD28

Host Defenses in Skin

Hui Xu, Laura Timares, Craig A. Elmets

Skin, which is the largest organ in the body, is the major interface between the individual and the environment. It comprises 12–16% of the body's weight and chiefly functions to protect against environmental threats. It also plays an important homeostatic role in maintaining body temperature, water and electrolyte balance, and vitamin D production. It acts as a barrier against invading pathogens, exogenous chemicals, and the destructive effects of physical agents, such as the sun, wind, and heat. To perform these various functions, skin consists of three self-regenerating specialized compartments that are layered on top of each other (Fig. 19.1). Adnexal tissues, which include hair, nails, sebaceous glands, and eccrine and apocrine sweat glands, are embedded within these tissues to provide specialized protective functions.

KEY CONCEPT

Primary Functions of Skin

- It is the body's largest organ representing 12–15% of body weight, and spans a surface area of ≈ 2 m^2.
- Because of skin's large surface area, it serves as the principal organ for homeostatic thermoregulation and regulation of fluid retention and evaporation.
- It provides a tactile interface with our environment through an array of specialized sensory cells, which are distributed at very high densities at critical points of the skin surface (*e.g.*, finger tips have up to 2500 sensory cells/cm^2).
- It serves as a photosynthetic surface, utilizing the energy of ultraviolet radiation (UVR) to transform 7-dehydrocholesterol to cholecalciferol (vitamin D3), vitamin D$_3$, an essential step in the biosynthetic pathway of vitamin D.
- It provides a strong physical barrier to withstand physical stresses engendered by exposure to the forces of nature. These include shear forces, extreme temperatures, wind, water, and solar radiation. Granular layer keratinocytes are bound together through tight junctions, providing an effective seal that blocks entry of small molecules and microbes.
- It provides a pharmacological barrier by means of enzymes that detoxify or repair damage caused by chemicals and other carcinogens, such as UVR and ionizing radiation.
- It serves as a regenerative organ that continuously replaces older, damaged skin cells, which are eliminated and shed from skin as anucleated squames.
- It provides an immunological barrier by means of a complex integration of innate and adaptive immune mechanisms that serve to protect against entry by microbial pathogens and to neutralize or eliminate potentially harmful exogenous antigens and endogenous neoplastic cells.

The outermost layer of skin is the epidermis. Blood and lymphatic vessels are absent. However, oxygen and nutrients diffuse to epidermal cells from the microvasculature that is housed in the dermal layer that lies under the epidermis. Approximately 95% of cells within the epidermis are keratinocytes. These form a self-renewing stratified squamous epithelium, which differentiates from bottom to top from a regenerating basal layer containing cuboidal cells to the outer most superficial layer, called the *stratum corneum*, composed of flat, anucleate, compact scales. Keratin intermediate filaments are the major proteins produced by keratinocytes. The type of heterodimer keratins that are made during differentiation impacts the cytoskeletal structure and cell morphology.

Keratinocytes bind to one another through specialized adherence junctions called *desmosomes*. Keratin filaments attach to desmosomal proteins to provide structural, tensile strength. During the differentiation process, the composition of the keratin and desmosomal proteins changes. For example, basal layer keratinocytes synthesize keratins 5 and 14, and the desmosomal protein desmoglein 3 is more abundant than desmoglein 1. In the stratum corneum, keratins 1 and 10 and desmoglein 1 are all highly expressed, but keratins 5 and 14 and desmoglein 3 are absent. Finally, the compact tough outer scales (squames) of the stratum corneum are cross-linked with keratin filaments.

The differences in protein localization between the epidermal layers have consequences for immunologically mediated skin diseases.[1] Pemphigus vulgaris, a disease in which autoantibodies are formed against desmogleins 1 and 3, presents with blisters that originate in the suprabasal layer of the epidermis. Conversely, the closely related disease pemphigus foliaceus, in which autoantibodies recognize only desmoglein 1, results in blisters located exclusively in the upper epidermis.

The remaining cells located in the epidermis are pigment-producing melanocytes, neuroendocrine Merkel cells (important for mechanoreception), and Langerhans cells (LCs) (specialized epidermal antigen presenting cells). Melanocytes are derived from the neural crest, and progenitors seed the epidermis early in development. They synthesize melanin pigment in organelles called *melanosomes*, which mature into the melanin-filled granules, which are then transferred and internalized by keratinocytes. Melanin absorbs the damaging effects of ultraviolet radiation (UVR) and protects skin keratinocytes. When stimulated by cytokines, melanocytes may express several immunologically relevant proteins, including intracellular adhesion molecule 1 (ICAM-1; CD54), costimulatory receptor CD40, and major histocompatibility complex (MHC) class I and II molecules[2] (Chapter 5).

Malignant melanomas arise from melanocytes. These tumors evade the host immune response, at least in part, through expression of programmed death ligand 1 (PD-L1). PD-L1 is an immune

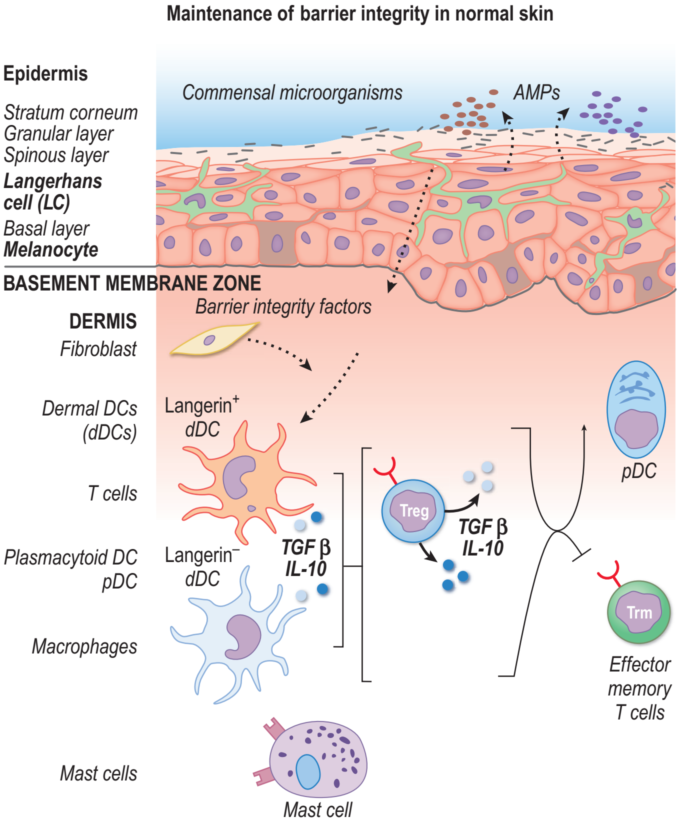

FIG 19.1 Histological Features of Normal Skin. The epidermis is made up of keratinocytes organized into stratified layers. The most superficial layer is the stratum corneum (light pink). The granular layer cells are connected through tight junctions (dark grey). Granular layer cells also secrete antimicrobial peptides (AMPs). The basal layer (tan) contains the proliferative cells that give rise to all the differentiated suprabasal keratinocytes. Basal cells are bound to the basement membrane (black line) and share that scaffold with interspersed melanocytes (brown). Langerhans cells (LCs) (green) are epidermal antigen-presenting cells (APCs) that reside in the suprabasal layer of the epidermis. The dermis contains a number of DC subsets which, under resting conditions, are conditioned by barrier integrity factors. Two of the dermal DC subsets that have been described are langerin$^+$ (orange) and langerin$^-$ (light blue) DCs. Plasmacytoid DCs (pDCs) are also present in the dermis and secrete type I interferons (aqua). Resident memory T cells (T_{RM}) (green) represent previously primed T cells in many lineages (Th1, CTL, Th17, Tc17, Treg) poised to respond when their specific antigens are presented locally, but remain quiescent in uninfected skin. Mast cells (purple) reside near endothelial venules (not shown).

checkpoint molecule that can be found on tumor cells and myeloid suppressor cells. Interaction of PD-L1 with PD-1 receptors on T cells inhibits their antitumor activity. Monoclonal antibodies (mAbs) that block PD-1 interaction with PD-L1 (pembrolizumab and nivolumab) can restore antitumor responses. In clinical trials, these antibodies have shown objective responses and prolonged survival. Ipilimumab, which blocks cytotoxic T lymphocyte antigen-4 (CTLA-4), another immune checkpoint molecule, has comparable efficacy.

The dermis lies beneath the epidermis and serves as a connective tissue layer that provides elasticity and tensile strength to skin. It is filled with a matrix of collagen bundles, elastic fibers, glycoproteins, proteoglycans, and glycosaminoglycans, all of which are produced by dermal fibroblasts. The production of collagen is a dynamic process that involves continual remodeling. Fibroblasts must balance ongoing synthesis of matrix components with the production of matrix metalloproteinases (MMPs) that degrade the matrix. Scleroderma and morphea (localized scleroderma) (Chapter 55) are inflammatory disorders that lead to the overproduction of collagen in the dermis, thus hardening skin.

Other cell types normally found in the dermis are mast cells and diverse sets of tissue macrophages and dendritic cells (DCs).[3] The dermis supports the microvasculature of skin. Endothelial cells of dermal arterioles, capillaries, and postcapillary venules behave differently from those in larger vessels. They express E- and P-selectins, which enable circulating skin-homing T cells to bind through their homing receptors cutaneous lymphocyte-associated antigen (CLA) and P-selectin glycoprotein ligand (PSGL), respectively.[4]

Both homeostatic T-cell trafficking and recruitment of inflammatory leukocytes into skin from the circulation require dermal endothelial cell-specific expression of E- and P-selectins. The egress of leukocytes from blood occurs primarily through postcapillary venules. Egress is regulated, in part, by endothelial responses to cutaneous cytokines and chemokines.

New vessels can also develop in skin. The new vessels can worsen immunologically mediated dermatological diseases and promote tumor development.

The dermis is separated from the epidermis by the basement membrane. This membrane creates a scaffold to which basal keratinocytes and melanocytes are attached. It acts as a selective diffusion barrier that permits passage of necessary small molecule nutrients while retarding entry of macromolecules and inflammatory cells. In patients with systemic lupus erythematosus (SLE) (Chapter 51), antigen–antibody complexes tend to accumulate at the basement membrane. Skin-specific proteins in the dermal–epidermal junction (DEJ) are targets of autoimmune blistering diseases, such as bullous pemphigoid and epidermolysis bullosa acquisita (Chapter 63).

The hypodermis lies beneath the dermis and attaches skin to underlying muscle. It is composed mainly of adipose tissue, which cushions skin impacts. Adipose cells produce leptin, which is implicated in a variety of inflammatory skin diseases, including psoriasis (Chapter 64).

The protective functions of skin are supported by three major barriers: *(i)* physical, *(ii)* pharmacological or detoxifying, and *(iii)* immunological. The physical barrier includes the hair and stratum corneum. The stratum corneum provides an impermeable hydrophobic cover of protein-filled squames that hinders the entry of invading microorganisms or toxic chemicals into the body. It also reflects and scatters UVR to impede the damaging energy from reaching the deeper, regenerating layers of skin. The pharmacological barrier includes detoxifying and repair enzymes synthesized by epidermal cells. Some metabolize chemicals and xenobiotics, whereas others repair DNA damage resulting from UVR or environmental mutagens.

The immunological barrier includes cells and molecules that are unique to skin and are historically referred to as "skin associated lymphoid tissue."[5] They include elements of both innate immunity and acquired immunity. Together, these elements

TABLE 19.1 Immunodermatological Disorders That Affect the Skin

- Papulosquamous disorders
  - Psoriasis
  - Lichen planus
  - Cutaneous graft-versus-host disease
  - Acute, subacute, and discoid lupus erythematosus
- Eczematous disorders
  - Atopic dermatitis
  - Allergic contact dermatitis
- Urticarial disorders
  - Urticaria and angioedema
  - Erythema multiforme
  - Stevens Johnson syndrome
  - Toxic epidermal necrolysis
  - Cryopyrin-associated periodic syndromes
  - Muckle-Wells syndrome
  - Familial cold urticaria
  - Neonatal-onset multisystem inflammatory disease (NOMID)
  - Deficiency of the interleukin-1–receptor antagonist (DIRA)
  - Tumor necrosis factor receptor–associated periodic syndrome (TRAPS)
- Purpuric disorders
  - Leukocytoclastic vasculitis
  - Medium vessel vasculitides (polyarteritis nodosa, Wegener granulomatosis, Churg-Strauss vasculitis)
- Vesiculobullous diseases
  - Pemphigus
  - Bullous pemphigoid
  - Paraneoplastic pemphigus
  - Epidermolysis bullosa acquisita
  - Dermatitis herpetiformis
  - Linear immunoglobulin A (IgA) bullous dermatoses
  - Pemphigus gestationis
- Pigmentary disorders
  - Vitiligo
- Hair disorders
  - Alopecia areata
- Autoimmune disorders
  - Dermatomyositis
  - Mixed connective tissue disease
  - Scleroderma and morphea
- Photodermatoses
  - Polymorphous light eruption
  - Solar urticaria
  - Chronic actinic dermatitis
  - Photoallergic contact dermatitis
- Allergic drug eruptions
- Disorders of subcutaneous tissues
  - Erythema nodosum
  - Erythema induratum
- Immunodeficiencies
  - Ataxia telangiectasia
  - Chronic mucocutaneous candidiasis
  - Chronic granulomatous disease
  - Hyperimmunoglobulin E (IgE) syndrome (HIES)
  - Leukocyte adhesion molecule deficiency
  - Severe combined immunodeficiency
  - Warts–hypogammaglobulinemia–infections–myelokathexis syndrome (WHIM syndrome)
  - Wiskott-Aldrich syndrome
  - Organ transplant recipients on immunosuppressive medications

promote both local and systemic responses to protect against invading pathogens and neoplastic cells. Locally they act to enhance protective mechanisms in affected skin. Systemically they alert the rest of the body to build and expand host defenses. Although these protective measures work exceedingly well, they do not work perfectly. Disturbances in these protective mechanisms can result in increased infections and malignancies when deficient or in immunologically mediated skin diseases when excessive (Table 19.1).

INNATE IMMUNITY AND SKIN

Pattern Recognition Receptors

By rapidly sensing and responding to microbial pathogens and environmental toxins, epidermal keratinocytes act as innate first responders (Chapter 3). Keratinocyte pattern recognition receptors (PRRs) recognize highly conserved sequences in macromolecular components of microbial pathogens and host-derived danger indicators. The identification of pathogen-associated molecular

KEY CONCEPTS

Immunological Defenses of Skin

- The innate defenses of skin provide the first line of defense against environmental antigens and invading pathogens.
- In response to pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs), granular layer keratinocytes produce cutaneous microbicidal peptides β defensin and cathelicidin, and proinflammatory mediators, such as interleukin (IL)-1α, IL-1β, IL-6, and tumor necrosis factor-α (TNF-α).
- Tricellulin molecules are specialized tight junction proteins that regulate sampling of the external microbial environment by protruding dendrites of Langerhans cells (LCs) residing in the suprabasal layer of the epidermis.
- At initial skin breach, mediators derived from a variety of cells activate neighboring keratinocytes and LCs to perpetuate a proinflammatory signal cascade throughout the epidermal layers and lead to the activation of dermal cells and dermal microvasculature.
- Immune cells that are resident in healthy skin include epidermal LCs; dermal leukocytes, such as mast cells; macrophages; and dendritic cells (DCs).
- LCs internalize microbes and produce IL-1β, IL-6, and other cytokines; become activated in response to a combination of signals (Toll-like receptors [TLRs], NOD-like receptors [NLRs], IL-1β, and TNF-α); and migrate from skin to reach regional lymph nodes (LNs), where they mature into potent antigen-presenting cells (APCs).
- In LNs, LCs activate T cells and deliver antigens and other information from affected skin to LN resident DCs to initiate and amplify skin-specific immunity.
- Keratinocyte-derived proinflammatory mediators and chemokines (CXCL8/IL-8) act on post endothelial venules to promote extravasation of inflammatory cells from the circulation into the dermis, including neutrophils, monocytes/macrophages, plasmacytoid DCs (pDCs), natural killer (NK) cells, and memory T cells.
- Inflammatory leukocytes enter the epidermis and attach to keratinocytes through interactions with CD54 (intercellular adhesion molecule 1 [ICAM-1]) proteins on activated keratinocytes to clear affected epidermis of invading pathogens and cellular debris.

patterns (PAMPs) and danger-associated molecular patterns (DAMPs) is principally undertaken by an array of PPRs. Membrane-bound Toll-like receptors (TLRs) are present at the cell surface (TLRs 1, 2, 4–6) and intracellular endosomes (TLRs 3, 7–9). Also present are cytosolic nucleotide-binding domain, leucine-rich repeat containing receptors (NLRs) (formerly termed *NOD-like receptors*).[6] TLR and NLR expression profiles are differentially expressed (often with partial overlap) on epidermal and leukocyte cell subsets.

Of the 10 TLRs that humans express, messenger RNA (mRNA) for all have been detected in keratinocytes. However, receptor proteins and activities have been detected for only eight (TLR1-7 and 9).[6] Human melanocytes constitutively express mRNA for TLRs 1–4, 6, 7, and 9, and abundant functional protein is detected for TLRs 2–4, 7, and 9. Human and murine DC subsets also show differential TLR expression profiles. For example, conventional DCs (DCs) express combinations of TLRs 1–5 and 8, whereas TLR expression is restricted to virus-detecting endosomal TLRs 7 and 9 in plasmacytoid DCs (pDCs). The latter is consistent with their primary function as major interferon-α (IFN-α) producers.

NLRs have over 20 members in humans and over 30 in mice, reflecting the broad spectrum of PAMPs and DAMPs they can recognize. Structurally, NLRs can be divided into four subfamilies: *(i)* NOD, caspase recruitment domain (CARD)-containing NLRCs; *(ii)* NALP, pyrin domain (PYD)-containing NLRPs; *(iii)* NLRB, NLR apoptosis inhibitory protein NAIP; and *(iv)* NLRA, the transcription factor CIITA. Primary human keratinocytes express mRNA transcripts for 11 of 14 NALP family genes.[7] NOD1 is expressed in many tissues, including skin keratinocytes. NLRs act independently, but in synergy with TLR signals, to trigger fast-acting potent innate immune responses against microbes. They can either promote nuclear factor-κB (NF-κB) activation or form inflammasomes that generate interleukin-1 (IL-1) family proinflammatory mediators.

TLR ligands are derived from conserved microbial products, such as lipopolysaccharides (LPS) from gram-negative bacteria, lipoteichoic acid and peptidoglycans from gram-positive bacteria, mannans of yeast and fungi, and nucleic acids from viral and bacterial pathogens. Endogenous DNA derived from stressed host cells can be recognized by TLRs. DAMPs are recognized by NLRs. The set of TLRs and NLRs that are triggered determines what types of immunomodulatory or inflammatory responses will be elaborated. Acting as adjuvants, they can also influence the magnitude of the response. In the clinic, a drug known as a TLR7 agonist (imiquimod) is used as an effective topical agent for eliminating human papillomavirus (HPV)–induced genital warts and nonmelanoma skin tumors.

Keratinocytes, DCs, and monocytes also express the PRR dectin-1. Dectin-1 is a membrane-associated glycoprotein that recognizes β-glucan, a polysaccharide component of several species of fungi. Dectin-1 activation results in the production of IL-1β, IL-6, and IL-23 (Chapter 9), which promotes the development of T-helper type 17 (Th17) cells—important antifungal effector cells (Chapter 16). Patients lacking dectin-1 exhibit Th17-cell deficiency, which leads to recurrent vulvovaginal *Candida albicans* infections and onychomycosis[5] (Chapter 29). Mutations in Card9, a mediator of dectin-1 signal transduction, also lead to a Th17 deficiency associated with chronic mucocutaneous candidiasis.[8]

Cutaneous Production of Cytokines and Chemokines

Types of Cytokines and Chemokines

Skin is a rich source of cytokines (Chapter 9) and chemokines (Chapter 10) that influence the magnitude and type of cutaneous immune response that is generated.[9] They are also important in driving nonimmunological processes, such as activating systemic responses to injury, wound healing, carcinogenesis, and pigmentation. Production of these mediators in skin involve several different cell types and environmental stimuli.

Keratinocytes produce a variety of immune mediators during different phases of immune reactions: proinflammatory cytokines IL-1, IL-6, IL-33, and tumor necrosis factor-α (TNF-α); immunosuppressive and antiinflammatory cytokines IL-10, TGF-αβ, and IL-1 receptor antagonist (IL-1RA); colony-stimulating factors GM-CSF, G-CSF, and M-CSF; immunomodulatory cytokines IL-7, IL-12, IL-15, IL-18, IL-19, IL-20, and IL-23; and chemokines CXCL8/IL-8, CCL2/MCP-1, CCL20/MIP3α, and CCL5/RANTES. LCs produce IL-1αβ, IL-12, and IL-23, CCL3/MIP1α, CCL4/MIP1αβ, and CCL5/RANTES. Melanocytes produce cytokines IL-1β, IL-6, IL-8, TNF-αα, type I interferons (IFN-αα and IFN-β), and chemokines CCL2, CCL3, and CCL5.

Although cytokines and chemokines produced in skin are functionally identical to those secreted by nonskin cells, in skin they can have unique effects. For example, IL-1 can remodel the dermis by inducing MMP production and augmenting collagen production. Mutant forms of cytokines can also cause cutaneous diseases. For example, a deficiency of IL-1–receptor antagonist (DIRA) is associated with a mutation in the gene that encodes the IL-1–receptor antagonist. This mutation can cause severe pustulosis, ichthyosiform lesions, psoriasis-like changes, and nail abnormalities.[10]

Phases of Active Cutaneous Cytokine Secretion

In response to immunological and inflammatory stimuli, keratinocytes produce different sets of immune mediators in three sequential phases: initiation, amplification, and resolution.

Initiation. The initial set of cytokines that are generated include proinflammatory IL-1, IL-6, TNF-α, and many others. Keratinocytes constitutively produce a pool of inactive proinflammatory precursors: pro–IL-1α, pro–IL-1β, and pro–IL-18. These molecules can be immediately processed into active mediators by inflammasomes, which are rapidly formed in the presence of DAMPs.[7] IL-1β, a potent stimulator of endothelial cell activation, permits rapid infiltration of inflammatory leukocytes and T cells from blood into the dermis. TNF-α contributes to dermal microvascular endothelial cell activation and augments expression of ICAM-1 (CD54) on keratinocytes and endothelial cells. Infiltrating T cells express the β_2 integrin molecule leukocyte function–associated antigen-1 (LFA-1), which binds to ICAM-1 expressed on affected dermal and epidermal layers. IL-6 helps drive the development of IL-17–producing Th-17 cells. IL-6 can also perpetuate chronic inflammation.

Amplification. Activated keratinocytes respond to the first wave of proinflammatory mediators by generating of a second set of cytokines and chemokines (including GM-CSF, TNF-α, and CXCL8/IL-8) with autocrine and paracrine effects. They can activate unaffected neighboring keratinocytes to amplify proinflammatory signals. These cytokines are key to triggering adaptive immune responses by activating cutaneous LCs and DCs to become mature potent antigen-presenting cells (APCs). APC interaction with antigen-specific, skin-resident memory T cells stimulates the proliferation and expansion of differentiated effector T cells at the affected skin site. Keratinocyte-derived IL-8 is a potent chemoattractant for neutrophils. The influx of leukocytes further amplify local immune responses, inflammation, and associated tissue damage. Stimulation of TLRs 7 and 9 within small numbers of resident dermal pDCs leads to abundant production of type I interferons (IFN-α), inducible nitric oxide synthase (iNOS), and arginase, which aid in the eradication of viral infection and other invading organisms.

Resolution. After the pathogen is eliminated, keratinocytes switch their cytokine production program in response to IL-6 and generate anti-inflammatory factors, such as IL-10 and IL-1 receptor antagonist (IL-1RA). During this phase, recruited leukocytes can also produce IL-10. IL-10 is a potent inhibitor of adaptive and inflammatory cellular responses, whereas IL-1RA effectively blocks the activity of IL-1β. Both activities function to return skin to its normal resting state. In addition, macrophages and certain DC subsets can inhibit ongoing adaptive immune responses through their expression of indoleamine 2,3 dioxygenase (IDO), an enzyme that alters tryptophan metabolism in T cells.

Antimicrobial Peptides

Skin is a production site for antimicrobial peptides, which are important components of the innate immune response.[11] Over 20 antimicrobial peptides have been described. They function at the earliest stages of infection by microorganisms that breach the stratum corneum. These antimicrobial peptides have the ability to disrupt bacterial and fungal membranes, as well as viral envelopes. These peptides have broad effects on innate and adaptive immune responses. The two best characterized skin antimicrobial peptides are the cathelicidins and β-defensins. They are synthesized by keratinocytes, cells of the epidermal sebaceous and eccrine glands, and dermal mast cells. Cathelicidins are secreted as precursor proteins (*e.g.,* hCAP18), which are then processed to an active form (*e.g.,* IL-37). They are detected at low levels in unperturbed skin but are strongly increased following infection or disruption of the epidermal barrier.

Cathelicidins interact with a variety of cell-surface receptors, including TLR-like and endothelial growth factor (EGF) receptors. They enhance leukocyte migration, stimulate the secretion of cytokines and chemokines, and promote angiogenesis. Interestingly, vitamin D_3, the synthesis of which is initiated in skin by UVR, plays an important role in regulating cathelicidin production through epigenetic mechanisms.[12]

Abnormalities in antimicrobial peptides have been implicated in a variety of immunological and nonimmunological skin diseases.[10] Deficiencies in antimicrobial peptide levels have been found in atopic dermatitis (Chapter 44), which may explain why patients with these deficiencies are at greater risk for viral (herpes simplex, HPV-induced warts, and poxvirus-induced molluscum contagiosum) and bacterial (*Staphylococcus aureus*) skin infections. Rosacea manifests as an acneiform eruption with erythema, telangiectasias, and flushing of the face. In rosacea, excessive amounts of cathelicidins are associated with characteristic inflammation and angiogenesis.[13] In psoriasis (Chapter 64), cathelicidins are postulated to combine with self DNA from damaged keratinocytes. This stimulates type I IFN production by pDCs, which is a key to the development of pathogenic Th17 cells.[14]

Nonimmune mechanisms that cause physical disruption of the skin barrier (*e.g.,* shear forces, chemical, thermal, or UV damage) stimulate "sterile" inflammatory responses that produce similar proinflammatory mediators and antimicrobial peptides to protect vulnerable sites during wound healing.

KEY CONCEPTS

- Skin is the major interface between an individual and his or her environment. Skin-resident and recirculating immunocompetent cells and immune mediators are used to defend against intrusion by microorganisms, noxious exogenous chemicals, and mutant cells that arise within it.
- When the immune system overperforms, it can give rise to autoimmune skin diseases. Pemphigus, for example, is a blistering disease in which antibodies are directed at desmogleins-1 and -3.
- When the immune system underperforms, cutaneous immunodeficiency occurs. For example, patients taking immunosuppressive medications suffer an increased risk of developing squamous cell carcinomas of skin.
- Skin-specific immune system components provide targets for new therapies. For instance, T-helper type 17 (Th17) cells play a dominant role in psoriasis, and neutralizing antibodies to IL-17 have recently been approved as a highly effective treatment for this disease.

ADAPTIVE IMMUNITY AND SKIN

Although the innate immune response forms the first line of defense against microbial threats in an antigen-nonspecific manner, the host's adaptive immune response provides antigen-specific protection against intracellular and extracellular pathogens. In contrast to innate immunity, adaptive immunity is able to distinguish self from nonself to eliminate microbial-infected or mutated cancer cells without damaging normal cells. The adaptive immune response in skin is carried out primarily by T cells and by immunoglobulin E (IgE) antibodies that are bound to mast cells. T cell–mediated immunity is dependent on activation by antigen-presenting DCs.

Dendritic Cells

DCs are a heterogeneous group of leukocytes that typically exhibit a DC surface, providing a large surface area for interaction with T cells (Fig. 19.2) (Chapters 5 and 6). LCs are specialized epidermal DCs originally discovered by Paul Langerhans in 1868. Under resting conditions, two different types of DCs are typically found in the dermis–myeloid derived conventional DCs (cDCs) and lymphoid plasmacytoid DCs (pDCs). cDCs are the most potent APC type. pDCs are less dendritic and less potent APCs but are still potent producers of IFN-α.[15] In perturbed skin, inflammatory DCs (iDCs) accumulate to produce abundant levels of TNFα and iNOS. They are derived from circulating monocytes that differentiate into DCs upon transendothelial migration into inflamed dermis.

To perform APC function, LCs and DCs express a wide array of antigen capture receptors that internalize bound microbes and antigens into processing endosomes, where antigens are cleaved and trimmed into short peptides and then loaded into the peptide-binding groove of MHC (or human leukocyte antigen [HLA]) molecules (Chapters 5 and 6). Peptide–MHC molecular complexes are presented at the surface of DCs for recognition by antigen-specific T-cell receptors (TCRs) (Chapter 4) on naïve and/or memory T cells. Through integration of environmental signals, LCs and DCs are able to program naive T cells to differentiate into appropriate, functionally distinct subsets of skin-homing effector cells that can eradicate a particular pathogen.

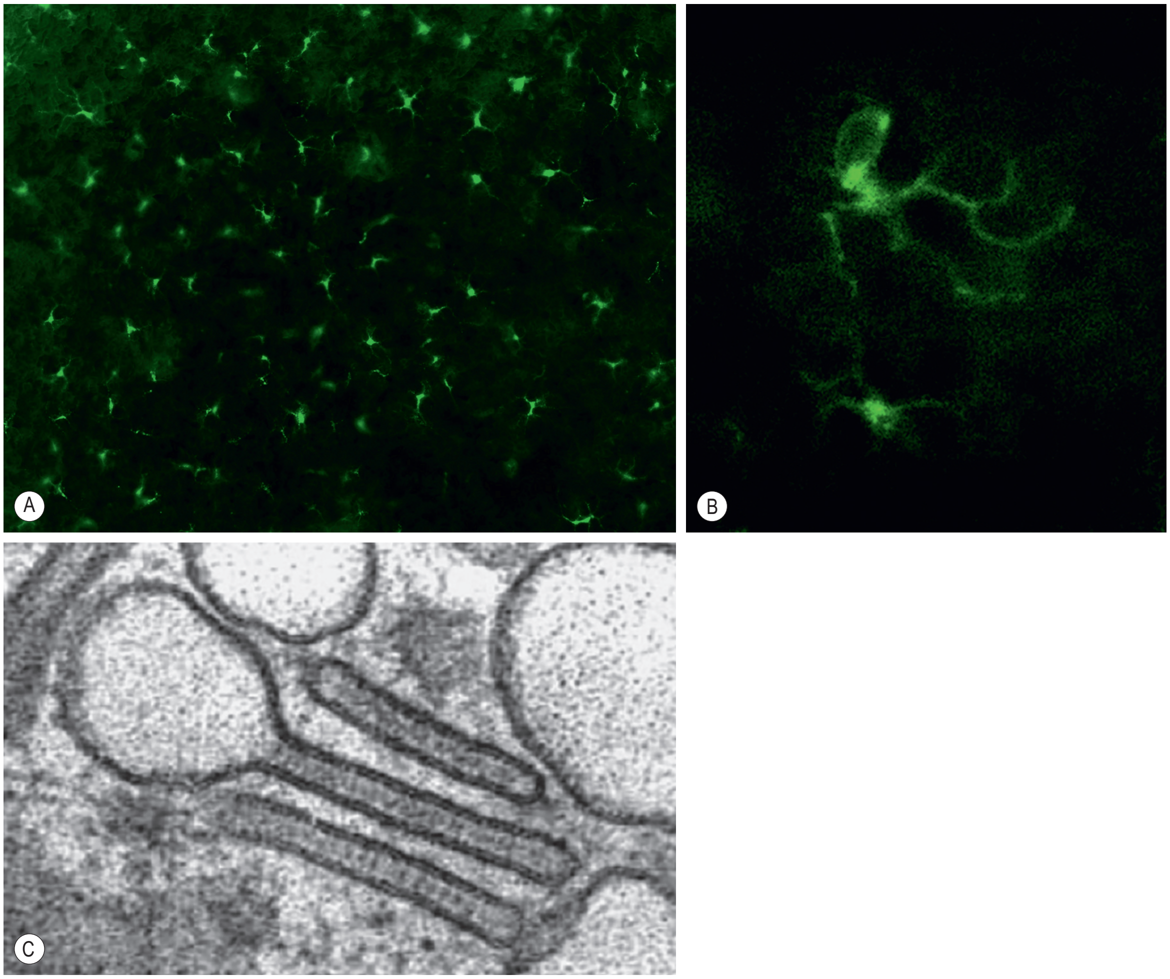

FIG 19.2 Langerhans Cells (LCs). (A) A horizontal view of epidermis (murine) stained with an antibody to major histocompatibility complex (MHC) class II molecules, of which only LCs are positive. Dendritic shaped LCs are spaced throughout the epidermis with dendrites stretching out to meet and communicate with neighboring LCs. (B) High-power view of an LC. Note contact between adjacent LCs. (C) Transmission electron microscopy of Birbeck granules in LCs from human epidermis. The Birbeck granule has a "tennis racket" morphology and is formed by internalized langerin molecules. (From: Romani N. et al. Langerhans cells and more: langerin-expressing dendritic cell subsets in the skin. Immunol Rev 2010:234(1):120–41.)

Epidermal Langerhans Cells

In normal skin, resting LCs reside in the suprabasal layer of the epidermis, where they cover the entire skin surface in a net-like structure. They represent 1–3% of all cells in the epidermis. They are poised to sense and respond to the earliest stages of a microbial or physical breach of epidermal integrity (see Fig. 19.2). LCs are identified by selective expression of antigen capture receptor langerin (CD207), a C-type lectin. Langerin internalizes to form a definitive "tennis racket–shaped" organelle called the *Birbeck granule,* which is thought to be a specialized antigen-processing compartment (see Fig. 19.2). Human LCs are also identified by their expression of CD1a, a protein structurally similar to MHC/HLA class I molecules that present lipid and glycolipid microbial antigens, rather than peptides. *In vivo* studies of mouse LCs reveal that they can extrude their dendritic processes across the skin tight junction, present in the granular layer, through a specialized pore, called *tricellulin,* to sample the microbial environment in the stratum corneum. Langerin receptors concentrate at the tips of the extruded dendrites to aid in the capture of external pathogens.

LCs have long been considered the paradigm-defining conventional DCs that transfer site-specific antigens to the lymph node, where they inform and activate CD4 and CD8 T cells (Chapter 8) to develop into differentiated skin-homing helper and cytotoxic effector effectors to eliminate the invading threat. Limited studies of primary human LCs indicate they are potent at inducing cytotoxic CD8 T cells and CD4 Th2 cells.[16] This is in contrast to relatively recent *in vivo* studies of mouse LCs that appear unable to activate CD8 T cells. Thus mouse and human LCs differ with regard to their division of labor.

In addition to their potent cross-presenting activity to CD8 T cells (Chapter 17); human LCs, like mouse LCs, also favor development of CD4 regulatory T cells (Tregs) (Chapter 18), antimicrobial Th17 cells, and follicular helper T (Tfh) cells for antibody development[17,18] (Chapter 16). LCs that emigrate from the epidermis leave a hole in the skin surface network, which is subsequently replenished, under inflammatory conditions by iDCs for the short term and by resident LC-committed stem cells that seed the epidermis during fetal development for the long term.[17,19]

Dermal Dendritic Cells

Dermal DCs efficiently present antigens that have reached the dermis to T cells. In normal skin, multiple subpopulations of resident dermal DCs can be detected.[19] In mice, dermal langerin positive and negative DCs are found, both of which are developmentally distinct from LCs. In humans, most dermal DCs are langerin negative; only a small number of langerin-dull dermal DCs can be detected. Nevertheless, human langerin negative dermal DCs share functional characteristics with mouse langerin-positive dermal DCs. They are able to cross-present captured intracellular bacterial or viral antigen from infected skin cell debris to activate CD8 T cells without being infected themselves. Thus they are able to forgo the canonical MHC class I–antigen processing pathway, which requires infection for endogenous expression of the pathogen antigens. Mouse langerin positive dermal DCs are also critical for activating Tfh cells for IgG2a/c and IgG2b isotype antibody production. In the resting state, all DCs are poor stimulators of T cells. Interaction with so-called immature DCs can generate unresponsive antigen-specific T cells, a key mechanism for maintaining immune tolerance, which is needed to prevent the immune system from attacking self tissues.

T Cells and Immune Responses in Skin

Phases of the Cell-Mediated Immune Response in Skin

The adaptive immune response in skin occurs in two phases: *(i)* sensitization (or immunization phase) by first exposure to antigen and *(ii)* elicitation (or effector phase) in response to re-exposure to antigen (Fig. 19.3).

FIG 19.3 Phases for the Development of Immune Responses in Skin. During the sensitization phase, dendritic cells (DCs) capture pathogens in skin and migrate through afferent lymphatics to the skin draining lymph nodes (LNs), where they present the antigens to naïve T cells. T cell differentiation is induced by activated cutaneous DCs, and they develop into resident memory T (T_{RM}) cells and central memory T (T_{CM}) cells representing different lineages (Th1, CTL, Th17, Tc17), depending on DC programming. Activated T_{CM} that leave the LN and migrate to skin become skin resident $T_{RM,}$ whereas nonactivated T_{CM} stay in lymph nodes. The effector phase occurs in response to a second exposure to antigen, which activates DCs, which, in turn, activates local T_{RM} to become effector cells *in situ.* Activated cutaneous DCs that reach the draining LN activate T_{CM} to become skin-homing T effector cells that are recruited to the inflamed dermal site. T effector cells, in concert with recruited cells, will enter into the epidermal layer by binding intercellular adhesion molecule 1 (ICAM-1) molecules present on activated keratinocytes, to clear infection, eliminate pathogen-infected cells, remove debris, and repair the skin barrier.

Sensitization/immunization phase. Epidermal LCs and dermal DCs are responsible for carrying antigens from the affected skin site to draining lymph nodes, where they present those antigens to activate and expand antigen-specific T cells. To emigrate from the epidermis, activated LCs downregulate E-cadherin to detach from their surrounding keratinocytes. During migration to the draining lymph node, LCs and DCs undergo a maturation process that stops antigen capture activity (by downregulation of antigen capture receptors) and increases expression of T-cell interactive molecules: MHC class I and II molecules, costimulatory molecules CD80 and CD86, and ICAM-1 (CD54).

Naïve T cells in the lymph nodes that express TCRs for presented antigens form long-term APC–T cell conjugates (on the order of 30 minutes) during which T cells are programmed to differentiate into functionally distinct T-cell subsets. These new T cells leave the lymph node by downregulating their lymph node–homing receptors, CCR7, and L-selectin (CD62L) and then upregulating the skin-specific homing receptor CLA and chemokine receptors CCR4 and CCR10 to enter the affected skin site.[20] Unless antigen is present in skin for an extended period, the sensitization phase does not cause an inflammatory reaction and therefore often goes unnoticed.

Elicitation/effector phase. In the dermis of resting skin, a large number of resident memory T cells (T_{RM}), previously activated during the sensitization phase, persist in the absence of antigens and are readily capable of effector functions. They provide rapid on-site immune protection to secondary antigen exposure.[20] Central memory T cells (T_{CM}) reside in lymph nodes and differ from T_{RM}, as they do not express high levels of skin-homing receptors CLA and CCR4 or exhibit immediate robust responses to antigen restimulation. T_{CM} in lymph nodes or spleen can be activated by secondary presentation of Ag by skin-draining LCs or DCs. Activated T_{CM} enter the circulation, express skin-homing receptors, and extravasate into the affected skin site, where they can contribute to the elicitation response. CD4 and CD8 T_{RM} and recruited T_{CM} that interact with antigen-activated LCs and DCs in the dermis are further stimulated to proliferate *in situ* to amplify *(i)* effector cell numbers, *(ii)* cytokine and chemokine production, and *(iii)* further recruitment of inflammatory leukocytes, which act in concert to eradicate microorganisms, chemically modified, or neoplastic cells.

Skin Resident T-Cell Subpopulations

In response to instructional cues from cutaneous DCs, antigen-specific T cells differentiate into specialized subsets, each with functions that focus on eliminating specific types of pathogens (Table 19.2). These presensitized, functionally committed T cells that home to skin remain in the dermis as long-lived T_{RM}s. The

TABLE 19.2 T-Cell Subsets and Trafficking in Skin

Twenty billion T cells are resident in healthy dermal tissue, representing twice the number of circulating T cells present in the entire circulation (T-cell distribution density in skin ≈1 million T cells/cm^2).

[a] Homing-R – an adhesion molecule on leukocytes that recognizes and binds site-specific adhesion molecules expressed on high endothelial venules in the lymph node (LN) and activated postcapillary venules in the dermis and other organs. L-selectin is the lymph node homing receptor, whereas CLA is the skin-homing receptor.

[b] HEV – high endothelial venules; these are postcapillary venous swellings in LNs and most secondary lymphoid organs.

skin of a healthy adult contains nearly 20 billion T_{RM} cells, about twice the number present in the entire blood volume.[20] Among the best-characterized differentiated T-cell subsets are CD4 Th1, Th2, Th17, and Tregs, each of which produces a distinct profile of cytokines. The Th22 subset has recently been discovered and is implicated in human inflammatory skin diseases.[21] CD8 T cells primarily function as cytotoxic effector cells, but they also express cytokine profiles analogous to CD4 subsets, termed *Tc1, Tc2,* and *Tc17.*[22]

Th1 responses. Th1 cells preferentially produce IFN-α and IL-2 and are the principal regulators of type 1 immunity, which eradicates intracellular pathogens and tumors. The major effector cytokine produced by Th1 cells is IFN-α. Macrophages are stimulated by IFN-α to phagocytose and generate oxidative bursts that aid intracellular killing of microbes. IFN-α also upregulates expression of class I and class II MHC molecules and ICAM-1 (CD54) on keratinocytes, dermal microvascular endothelial cells and fibroblasts, and induces them to secrete proinflammatory cytokines and chemokines.[23] In animal models, deficiencies in IFN-α render them more susceptible to cutaneous microbial infections and tumors. Th1 cells develop cutaneous delayed-type hypersensitivity responses, such as the tuberculosis skin test reaction, and allergic contact dermatitis to haptens. Haptens are small compounds that penetrate skin and bind to epidermal proteins, generating "modified self" proteins as immunogenic antigens. Examples include urushiol in poison ivy and nickel.

Th2 responses. Th2 cells are involved in type 2 immune responses, which are important for eradication of extracellular parasites and bacterial infection. They produce IL-4, IL-5, IL-10, and IL-13, which are important for the induction and development of humoral immune responses. IL-4 and IL-13 activate B-cell proliferation, Ig class-switching, and antibody production. Th2 cell-mediated inflammation is characterized by the presence of eosinophils and basophils, as well as extensive mast cell degranulation—a process dependent on cross-linking surface-bound IgE.[24] IL-5 is a potent hematopoietic cytokine, which stimulates bone marrow production of eosinophils as well as activation and chemotaxis of eosinophils and basophils to affected tissue. In mice, Th2-cell deficiency profoundly increases susceptibility to Leishmania infection in skin. In humans, Th2 cells appear to play a critical role in the pathogenesis of atopic dermatitis (Chapter 44). A recent clinical trial with dupilumab, a fully human mAb that targets the IL-4 receptor-αα and blocks IL-4 and IL-13 signaling, improved atopic symptoms .

Th17 responses. Th17 cells produce IL-17A, IL-17F, IL-21, and IL-22. (IL-17A is commonly called IL-17.) Th17 cells have protective effects against extracellular bacterial and fungal infections in skin. Both IL-17A and IL-17F enhance protective immune responses by inducing the production of CXC chemokines, G-CSF, and antimicrobial peptides by keratinocytes and epithelial cells of other organ systems. Mice deficient in IL-17A are highly susceptible to *Staphylococcus aureus* infections in skin. IL-17 and IL-22 are important mediators of psoriasis and have been implicated in other autoimmune skin disorders. In clinical trials testing anti-human IL-17A antibodies (secukinumab and ixekizumab), three-quarters of patients with psoriasis exhibited reduced symptoms. Brodalumab, an IL-17 receptor antagonist, has shown efficacy in psoriasis. IL-17 may also promote tumor development and UVR-induced immune suppression in skin.[25]

Regulatory T cells. The principal aim of the immune system is to establish a balance between defense against pathogens and avoidance of autoimmune responses. This balance is achieved partly through the action of Tregs (Chapter 18). Natural Tregs (nTregs) develop in the thymus in response to self antigens, whereas induced Tregs (iTregs) develop in the periphery in response to foreign antigens. Both are commonly characterized as $CD4^+/CD25^+/Foxp3^+$, and both produce immunosuppressive cytokines (IL-10 and/or TGF-β). They can also express immunoregulatory surface molecules, such as CTLA-4, PD-1, glucocorticoid-induced TNFR family–related gene (GITR), and lymphocyte activation gene 3 (LAG-3). They can directly inhibit the activation and function of T cells and suppress the activity of antigen-presenting DCs. A defect in Treg function will result in autoimmune and inflammatory diseases. About 5–10% of the T cells resident in normal human skin are Tregs. Tregs diminish immune responses in skin, an important function for dampening immune and inflammatory responses and limit tissue damage.[26] Conversely, increased Treg suppression can impair host immunosurveillance against tumors. UVR-induced immunosuppression is considered a critical mechanism for development of UVR-induced tumors, and this is, to a great extent, mediated by UVR-induced Tregs.[27]

CD8 T-cell immunity. CD8 T cells differentiate into cytotoxic T lymphocytes (CTLs), which are essential for the elimination of viral infections and cancerous cells (Chapter 17). The CD8 T-cell subsets Tc1, Tc2, and Tc17 also express cytokines analogous to CD4 helper subsets.[22] Tc1 cells express the killer molecules Fas-L, perforin, and granzyme B, as well as large amounts of IFN-α, all of which act to eradicate virally infected and neoplastic cells. Since CD8 T cells are important effectors of immune surveillance,[28] their presence in tumor tissues is a good prognostic factor for certain types of cancer.[29] Diminished CD8 T-cell function increases the susceptibility to squamous cell and basal cell carcinomas in the skin of humans and animal models. Tc1 and Tc17 cells, producing IFN-α and IL-17 respectively, are key mediators in allergic contact dermatitis[30] (Chapter 44). Tissue damage by cytotoxic CD8 T cells also contributes to the pathology of allergic contact dermatitis.

γδ T cells. Dendritic epidermal T cells (DETCs) bridge innate first line of defense and acquired immune mechanisms. In place of conventional αβ chain TCRs, they express a more restricted repertoire of γ and δ chain TCRs and reside in epithelial tissues of skin, the gut, lungs, and the reproductive tract.[31] In humans, γδ T cells account for at least 10% of the T cells in the epithelium. Epithelium-resident γδ T cells differ from circulating γδ T cells with respect to their development, selection, TCR diversity, and effector functions. Epithelial γδ T-cell activation is not restricted by MHC class I or class II molecules. Instead they recognize PAMP and DAMP molecules presented by nonclassic MHC molecules, such as CD1. They use alternate sets of costimulatory molecules, such as the junctional adhesion molecule–like protein (JAML) and its ligand, the coxsackievirus and adenovirus receptor (CAR). They are thought to be partially activated under static conditions. This enables them to rapidly mount responses to pathogenic stimuli. DETCs are involved in epidermal wound repair, can influence DC activation, and can directly present antigens.

Cytokines and Chemokines and the Adaptive Immune Response in Skin

A number of proinflammatory mediators are intimately involved in adaptive immunity in skin. IL-1 activates LC and dermal DC migration and maturation processes. Mature DCs produce T-cell differentiation factors IL-12 and IL-23, which are critical for the development of Th1 and Th17 cells, respectively.[32]

Chemokines facilitate leukocyte migration and thus skin inflammation and antigen-specific responses (see Table 19.2).[9,33] Secondary lymphoid chemokine (SLC, CCL21) attracts CCR7$^+$ DCs and T cells to lymph nodes, and stromal cell-derived factor 1 (SDF1; CXCL12) facilitates DC migration out of skin. CCL17 and CCL27, produced by keratinocytes and dermal cells, facilitate transmigration of circulating skin-homing T cells (expressing the chemokine receptors CCR4 and CCR10). Human skin–resident T cells are retained through interaction of their chemokine receptor CCR8 and its ligand CCL1 bound to the dermal matrix, which is produced by cutaneous cells.[33] During inflammation, CXCL1 and CXCL8/IL-8 expedite infiltration of granulocytes and monocytes into skin.

Cutaneous T-cell lymphoma (Chapter 79) is a disease in which a malignant population of skin-homing T cells accumulate in skin. Clinical manifestations include erythematous, pruritic patches, plaques, and skin tumors. The malignant T cells express CCR4 chemokine receptor. Clinical trials of humanized mAbs directed against the CCR4 receptor on T-cells (mogamulizumab) have shown promise.

MAST CELLS AND SKIN

Skin is a rich source of mast cells[22] (Chapter 23). These cells are derived from CD34$^+$ progenitors in bone marrow and migrate into many different tissues in the body, especially those at environmental interfaces. In skin, they are found in the dermis at a density of up to 20 000/mm^2. They are typically concentrated around the dermal microvasculature, appendages, and nerves. Metachromatic stains, such as toluidine blue and Giemsa, stain mast-cell granules purple, a distinguishing feature. Their cytoplasmic granules contain a plethora of preformed mediators that include histamine and heparin; the proteases tryptase, chymase, carboxypeptidase, arylsulfatase A, β-hexosaminodase, and β-glucuronidase; and the cytokines TNF-α, GM-CSF, IL-3, IL-4, IL-5, IL-6, IL-8, and IL-13.

Mast cells express the high affinity surface receptor for the Fc portion of the IgE molecule (FcεRI), which bind and retain IgE for long periods. Antigen-induced cross-linking of IgE bound to FcεRI initiates a sequence of calcium- and energy-dependent events that culminate in the fusion of granules to the plasma membrane and the release of granule contents. Degranulation releases potent prostanoids, histamines, and inflammatory cytokines that rapidly recruit inflammatory cells. Nonantigenic stimuli, such as opiates, C5a, anaphylatoxin, stem cell factor, and substance P, can activate degranulation through FcR-independent opioid, adenosine, and β-adrenergic receptors. The products and contents of mast-cell granules are causative agents of acute vasodilatation, edema, pruritus, and rapid influx of leukocytes and eosinophils into skin. Eosinophils are especially important for fighting parasitic infections (Chapter 24). Mast-cell activation is implicated in the pathogenesis of bullous pemphigoid, leukocytoclastic vasculitis, atopic dermatitis, allergic contact dermatitis, and mastocytosis (urticaria pigmentosa) and plays a prominent role in the pathogenesis of urticaria and angioedema.

ANTIBODIES AND SKIN

Less is known regarding B cells in skin. Although the role of IgG, IgA, and IgE antibodies in normal skin homeostasis is less certain, Igs play key roles in the pathogenesis of several different dermatological diseases. IgE-dependent skin diseases include urticaria and angioedema and bullous pemphigoid. Hyper-IgE syndrome (HIES) is an autosomal dominant disease that develops cutaneous manifestations of severe dermatitis, recurrent infections of staphylococcal abscesses, and, to a lower extent, cutaneous candidiasis.[33] Dominant negative mutations in the signal transducer and activator of transcription 3 (STAT3) gene are associated with this disease. Deficient STAT3 signaling leads to impaired β-defensin expression, which may explain some of the clinical manifestations of HIES.[34] Pathogenic IgG causes blistering disorders, including pemphigus, bullous pemphigoid, epidermolysis bullosa acquisita, and paraneoplastic pemphigus, as well as leukocytoclastic vasculitis. IgA is key to the pathogenesis of dermatitis herpetiformis, linear IgA bullous dermatosis, and IgA-mediated cutaneous vasculitis.

ULTRAVIOLET RADIATION AND CUTANEOUS IMMUNITY

Sunlight is the major environmental agent to which skin is exposed. Although the presence of sunlight is essential for life, injudicious exposure to wavelengths in the ultraviolet (UV) spectrum can lead to sunburn, aging of skin, skin cancers, and a variety of photosensitivity diseases, many of which have an immunological pathogenesis. Although much of the investigation into the immunological effects of UVR has been conducted in animal models, many of the observations have been corroborated in humans.

In mice, as in humans, chronic exposure to UVR results in the development of highly antigenic skin cancers that are capable of stimulating a vigorous antitumor response in untreated mice. Despite their antigenic nature, these tumors grow progressively in their original host. This apparent paradox was resolved in studies that showed that in addition to producing mutant neoplastic cells, UVR also impairs cell-mediated immune surveillance that normally eliminate mutant cells before they develop into clinically apparent tumors. Thus mutant cells develop tumors only in an environment of immune suppression. In fact, organ transplant recipients who are treated with immunosuppressive medications have a greatly increased risk of developing UV-induced skin cancers, and those tumors tend to behave more aggressively.[35]

Studies have shown that UVR mediates its effects, in part, by perturbing the function of skin APCs. UV-irradiated APCs are poor stimulators of Th1 cells but are able to activate Tregs, which promote antigen-specific immunological tolerance. The immunosuppressive effect is mediated, at least in part, through UV-induced enhanced production of the suppressive cytokine IL-10 and reduction of the Th1 activation cytokine IL-12. It may seem surprising that an environmental carcinogen, such as UVR, suppresses immunological function in skin. One proposed explanation is that altered epithelial proteins are constantly generated by UVR exposure, necessitating chronic induction of immune tolerance to UV-damaged proteins to preserve the integrity of the skin barrier.

The immunosuppressive effect of UVR has been exploited for therapeutic purposes. UVR phototherapy is used to manage pathogenic immune responses that cause certain skin diseases, such as psoriasis and atopic dermatitis.[36]

ON THE HORIZON

- Identification of T-helper type 17 (Th17) cells as important mediators of the inflammatory response has provided the impetus for development of interleukin-17 (IL-17) inhibitory antibodies for the treatment of psoriasis. Because IL-23 promotes Th17-cell development, antibodies that block that molecule are being evaluated as therapeutic agents as well.
- The availability of cytokine inhibitors provides an opportunity for physicians to broaden the spectrum of skin diseases for which they can be used. Agents that inhibit tumor necrosis factor-α (TNF-α), for example, are being evaluated for the management of immunologically mediated skin diseases, including hidradenitis suppurativa.
- Cell-surface receptors have been detected that allow specific subpopulations of T cells to migrate into skin. Agents that block these receptors are being evaluated as a treatment for cutaneous T-cell lymphoma and inflammatory diseases of skin, in which skin-homing T cells are fundamental to the disease process. This provides enhanced treatment specificity leaving the functions of those T cells that circulate to other parts of the body intact.
- Several different types of dendritic cells (DCs) are present in skin that are specialized in the subpopulations of T cells that they activate. Recognition of this fact provides the basis for methods to improve vaccination procedures. It is likely that in the next several years cutaneous DCs will be employed for vaccination against tumors, such as melanoma and selected infectious agents.
- As involvement of cytokines in cutaneous diseases continues to be clarified, they will be employed to manipulate the immune response in an expanding list of immunologically mediated skin diseases, such as vitiligo, alopecia areata, cutaneous lupus erythematosus, and dermatomyositis.

MULTIPLE-CHOICE QUESTIONS

1. Pembrolizumab and nivolumab are neutralizing antibodies directed at the programmed death ligand type 1 (PD-L1) and ipilimumab is an antibody that neutralizes cytotoxic T lymphocyte antigen-4 (CTLA-4). They are used to treat which of the following cutaneous malignancies?
   A. Basal cell carcinoma
   B. Fibrosarcoma
   C. Kaposi sarcoma
   D. Melanoma
   E. Sebaceous gland carcinoma

2. Skin is a rich source of cytokines and chemokines. Which cell type does not produce them in skin?
   A. Fibroblasts
   B. Keratinocytes
   C. Mast cells
   D. Melanocytes
   E. All of the above produce cytokines in the skin

3. Cathelicidins are antimicrobial peptides that are produced by skin. They have been implicated in which of the following diseases?
   A. Atopic dermatitis
   B. Cutaneous T-cell lymphoma
   C. Dermatitis herpetiformis
   D. Hyper-IgE syndrome (HIES)
   E. Pemphigus

4. In a normal healthy individual, which of the following has the largest number of lymphocytes?
   A. Blood
   B. Brain
   C. Kidney
   D. Liver
   E. Skin

5. Which of the following is *true* about epidermal Langerhans cells?
   A. They possess a specialized organelle called the *Birbeck granule.*
   B. They are a type of myeloid dendritic cell (DC).
   C. Following cutaneous exposure to danger signals, they extrude their processes to capture external antigens.
   D. After cutaneous antigen exposure, they migrate to draining lymph nodes.
   E. All of the above are true.

20

Host Defenses at Mucosal Surfaces

Prosper N. Boyaka, Kohtaro Fujihashi

Mammals have evolved a sophisticated network of cells and molecules that serves to maintain homeostasis on exposed mucosal surfaces. This system is anatomically and functionally distinct from its bloodborne counterpart and is strategically located at the portals through which most pathogenic microorganisms enter the body. This specific branch of the immune system may have developed in response to the size of the mucosal surfaces, which cover an area of ≈70 m^2 in the airways and ≈400 m^2 in the gut of an adult human, and the large numbers of commensal bacteria and exogenous antigens to which mucosa are exposed.[1,2]

THE INNATE MUCOSAL DEFENSE SYSTEM

Cells and molecules that contribute to innate defense of the mucosa include the physical barrier provided by epithelial cells, the movement of the epithelial cilia, the production of mucus by goblet cells, the secretion of molecules with innate antimicrobial activity, and the cytolytic activity of natural killer (NK) cells (Fig. 20.1A). Innate lymphoid cells (ILCs; Chapter 3) were identified recently as key players in innate mucosal immunity (see Fig. 20.1B). In concert with the commensal microbiota (Chapter 14), these innate mechanisms provide a first line of defense against exogenous antigens and invading pathogens.

KEY CONCEPTS

Innate Defenses of the Mucosal Immune System

The innate defenses of the mucosal immune system provide a first line of defense against exogenous antigens and invading pathogens. These defenses include:

- *Physical barriers:* the epithelium, the epithelial cilia, goblet cell mucus production
- *Mucosal antimicrobial molecules:* Paneth cell production of α defensins in the small intestine; epithelial cell production of β defensins in the oral mucosa, trachea, bronchi, mammary glands, and salivary glands; lactoferrin, lysozyme, lactoperoxidase, and secretory leukocyte protease inhibitor (SLPI)
- *Cellular innate immunity:* mucosal natural killer (NK) cells, innate lymphoid cells (ILCs), dendritic cells (DCs). and polymorphonuclear neutrophils (PMNs).

Epithelial Cells and Other Effectors of the Mucosal Physical Barrier

All mucosal surfaces are covered by epithelial cells, which contribute to their selective barrier function. In the gastrointestinal (GI) tract, tightly joined enterocytes constitute the cellular component of the physical barrier and are covered by a blanket of mucus. Mucus consists of glycoproteins secreted into the lumen by goblet cells. This layer of glycoproteins interferes with the attachment of microorganisms to the mucosal surface. The replacement of damaged or infected enterocytes by crypt epithelial cells, which differentiate into enterocytes as they migrate toward the desquamation zone at the villus tip, ensures the integrity of this barrier. Multilayered squamous epithelial cells cover other mucosal surfaces, including the oral cavity, pharynx, tonsils, urethra, and vagina. These epithelia lack tight junctions. Instead, mucus coats the intercellular space between the lower stratified epithelial cell layers. Polymeric immunoglobulin A (pIgA) and commensal microbes support the physical barrier function of mucosal tissues. Perturbation of the commensal microbiome, which is present in the mucus ecosystem, facilitates opportunist infections by pathogens, such as *Clostridium difficile.*

Defensins and Other Mucosal Antimicrobial Peptides

Selected epithelial cell subsets contribute to innate responses through the production of antimicrobial peptides, iron transporters, and enzymes. Defensins are 30–40 amino acid β-sheet peptides with antiviral activity and antimicrobial effects similar to those of antibiotics. Defensins are structurally segregated into α and β categories. α-Defensins are secreted by tracheal epithelial cells and by Paneth cells in intestinal crypts. α-Defensins are homologous to peptide mediators of nonoxidative microbial cell killing in neutrophils (termed *human neutrophil peptides* [HNPs]).[3] Human β-defensin 1 (HBD-1) is expressed in the epithelial cells of the oral mucosa, trachea, bronchi, mammary glands, and salivary glands, whereas HBD-5 is expressed in the gut. Inflammatory cytokines (Chapter 9), including interleukin-1 (IL-1), IL-17, tumor necrosis factor-α (TNF-α) and bacterial lipopolysaccharide (LPS), regulate defensin production.

Other antimicrobial products of the epithelium include lactoferrin, lysozyme, peroxidases, secretory phospholipase A2 (S-PLA2), and cathelin-associated peptides. Lactoferrin, a member of the transferrin family, is found in exocrine secretions. High concentrations of lysozyme (1209–1325 μg/mL) are found in tears, saliva, colostrum, serum, and urine. Human milk contains lysozyme in concentrations ranging from 20 to 245 μg/mL, depending on the lactation period. Milk leukocytes produce myeloperoxidase (MPO), and mammary gland cells produce human lactoperoxidase (hLPO). Both peroxidases display properties similar to those of human salivary peroxidases (hSPO). S-PLA2 is released by Paneth cells. Secretory leukocyte protease inhibitor (SLPI) is found in human saliva, nasal secretions, tears, cervical mucus, and seminal fluid. It is believed to be responsible for the anti–human immunodeficiency virus (HIV) properties of external secretions.

FIG 20.1 Innate Mucosal Host Defense Factors. (A) A thick coat of mucus prevents penetration of exogenous macromolecules, commensal microbes, and potential pathogens. The epithelial cell barrier is connected via tight junctions and contains both αβ and γδ intraepithelial T lymphocytes (IELs). The crypt regions contain Paneth cells, which produce cryptins (α defensins). β defensins are products of epithelial cells and form a defensin network. Other innate factors, such as lysozyme, lactoperoxidase, lactoferrin, and phospholipases, also serve in antimicrobial defense. (B) Three types of innate lymphoid cells are identified based on their cytokine production.

Mucosal Innate Lymphoid Cells

ILCs constitute recently described groups of lymphoid cells that are predominantly found in mucosal tissues. ILCs lack T- or B-cell receptors. They contribute to innate regulation of homeostasis through their ability to rapidly produce cytokines. Similar to CD4 T helper (Th) cells (Chapter 16), ILCs can be divided into three major groups according to cytokines they produce.[4,5] Group 1 ILCs (ILC1) produce interferon-γ (IFN-γ) and are considered similar to Th1 cells. Cells with ILC1 phenotypes express CD103/CD160 and CD127 and include NK cells, which are large granular lymphocytes found in the lamina propria and the intraepithelial compartment. Group 2 ILCs are similar to Th2 cells and produce IL-5, IL-9, IL-13, and amphiregulin. ILC2 are responsible for innate responses in allergies and asthma. As with Th17 cells, group 3 ILCs (ILC3) secrete IL-17 and/or IL-22. Although lymphoid tissue inducer (LTi) cells are ILC3, functional properties of these cells are distinct from other mucosal ILC3.[4,5]

Two types of ILC1 occur in tonsils and the mucosa of the GI tract. $CD103^+$ $CD160^+$ ILCs are found in the intraepithelium of the intestines and produce perforin and granzyme like NK cells. This ILC1 subset requires Nfil3 and T-bet transcription factors for its development. An ILC1 population expressing low levels of RORγt and aryl hydrocarbon receptor (Ahr) similar to ILC3 was identified in humans. These ILCs express IL-7Rα (CD127), but not conventional lymphocyte lineage or NK cell markers. Both subsets of ILC1 may be involved in the induction of inflammatory bowel disease (IBD).[4] ILC2 are seen in the lungs, upper respiratory mucosa, gut, and skin. By producing IL-5, IL-13, and amphiregulin, they play key roles in the clearance of parasites, including *Nippostrongylus brasiliensis* and *Trichuris muris.* ILC2 are also important in the development of asthma and allergies, including atopic dermatitis. Although ILC2 were reported to promote airway hypersensitivity during acute influenza virus infection, the amphiregulin they produce could also help maintain lung epithelial cell homeostasis.[4]

ILC3 in both humans and mice showed heterogenic cytokine profiles. Thus human ILC3 bearing NKp44 and CCR6 produce IL-22 alone. However, human ILC3 isolated from patients with Crohn disease produce IL-17 and IFN-γ. Mouse LTi and LTi-like ILC3 produce both IL-17 and IL-22. $NKp46^+$ ILC3 secrete IL-22, as well as IFN-γ under certain conditions, but not IL-17. Another subset of mouse ILC3 that produces IFN-γ, IL-17, and IL-22 can be found in the large intestine. ILC3-derived IL-22 induces antimicrobial peptide responses by intestinal epithelial cells (IECs). Furthermore, IL-22 from ILC3 was reported to enhance innate immunity against *Salmonella* and bacterial infection secondary to influenza virus infection.[4,5] Since ILC3 are also involved in the induction of colonic inflammation and colorectal cancer, they may act as a double-edged sword in the mucosal immune system.[4,5]

A COMMON MUCOSAL ADAPTIVE IMMUNE SYSTEM

Higher-order mammals have developed an organized secondary lymphoid tissue system in the GI and upper respiratory tracts. Gut-associated lymphoreticular tissues (GALTs) include Peyer patches (PPs), the appendix, and solitary lymphoid nodules in the GI tract (Chapter 2). Tonsils and adenoids comprise nasal-associated lymphoid tissues (NALTs). Experimental animals, such as rabbits, rats, and guinea pigs, exhibit organized bronchus-associated lymphoid tissues (BALTs) that rarely occur in human airway branches.[1] Together, GALTs and NALTs in humans and GALTs, BALTs, and NALTs in experimental species are termed *mucosa-associated lymphoreticular tissue* (MALT).

The vast areas of the mucosal immune system characterized by diffuse collections of lymphoid cells are termed *effector tissues.* These include the interstitial tissues of the mammary, lacrimal, salivary, sweat, and all other exocrine glands, as well as the lamina propria and the epithelium of the GI tract. The lamina propria areas of the upper respiratory and genitourinary tracts are also lymphoid effector sites. MALT is connected with effector sites through the migratory patterns of effector cells.

KEY CONCEPTS

The Common Mucosal Immune System

The term *mucosa-associated lymphoreticular tissue* (MALT) comprises discrete and diffuse collections of lymphoid tissues that share distinctive features, including a unique type of epithelium, a distinct architecture, a unique set of antigen-presenting cells (APCs), and B cells, where switching to immunoglobulin A (IgA) predominates. The involved tissues include:

- *Gut-associated lymphoid tissues (GALTs):* Peyer patches (PPs), the appendix, and solitary lymphoid nodules in the gastrointestinal (GI) tract
- *Nasal-associated lymphoid tissues (NALTs):* tonsils and adenoids
- *Effector tissues:* the interstitial tissues of the mammary, lacrimal, salivary, sweat, and all other exocrine glands; the lamina propria and the epithelium of the GI tract; and the lamina propria areas of the upper respiratory and genitourinary tracts.

MALT as an Inductive Site

MALT has a unique type of epithelium for antigen uptake. Its features include a characteristic architecture, antigen-presenting–cell (APC) and B cell areas with germinal centers where switches to IgA predominate. The columnar epithelium that covers MALT is infiltrated with lymphocytes and APCs, leading to the term follicle-associated epithelium (FAE). Lacking goblet cells, the FAE is covered with far less mucus than normal enterocytes. Soluble and particulate luminal antigens are taken up by microfold (M) cells and are delivered to adjacent APCs. M cells have been described in PPs, the appendix, and tonsils and represent 10–15% of cells within the FAE.[6] M cells are also found in isolated lymphoid follicles (ILFs) and at the tips of the villus, where they are termed *villous M cells.*[7] The microvilli of these cells, which are less dense than those of adjacent enterocytes, offer a portal of entry into MALT (Fig. 20.2). The M cell is often identified by an invagination of the basolateral membrane into a "pocket" normally occupied by lymphocytes and APCs (Fig. 20.3).

M cells appear ideal for antigen uptake owing to a well-developed microvesicle system that contains endosomes. However, it remains unclear whether M cells act as classic APCs. M cells also provide a portal of entry for some pathogens, such as invasive strains of *Salmonella typhimurium*, but not for noninvasive strains of *S. typhimurium* and reoviruses.

Gut-Associated Lymphoreticular Tissues

Each PP contains a dome region that is positioned under the FAE. This dome region is populated by T cells, B cells, macrophages (MØs), and dendritic cells (DCs). It includes follicles that contain germinal centers. The presence of all three major APC types in the dome (*i.e.*, memory B cells, MØs, and DCs) makes it likely that antigen uptake occurs immediately following

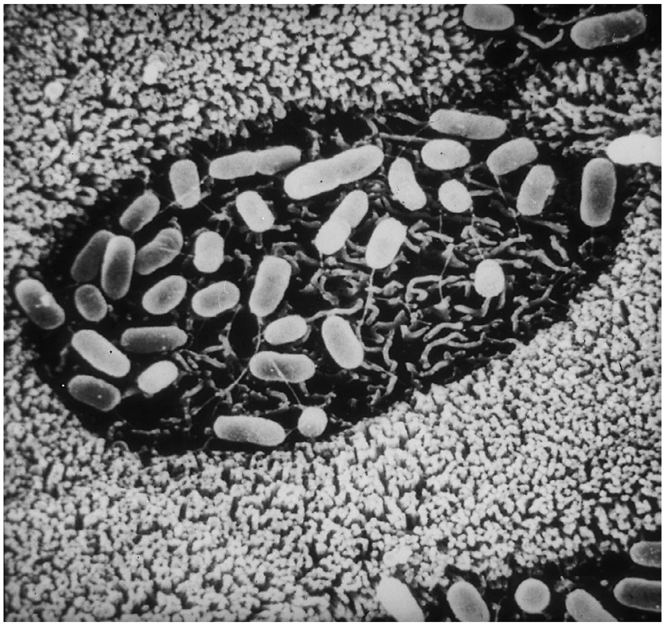

FIG 20.2 **The Microfold (M) Cell.** A scanning electron micrograph of an M cell with adjacent enterocytes. The M cell has selectively bound *Escherichia coli* 0157. Note that a thick brush border is lacking, facilitating the binding and uptake of microparticles. (Courtesy of Dr. Tatsuo Yamamoto, Niigata University.)

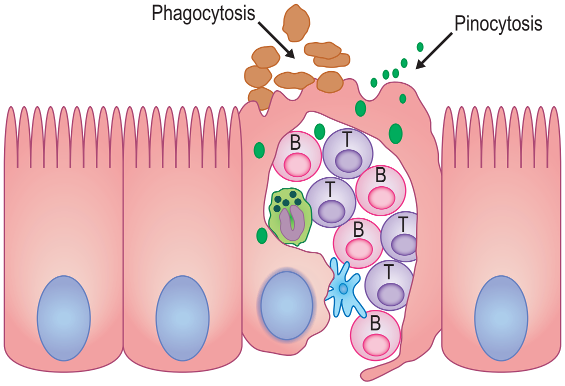

FIG 20.3 **Microanatomical Features of Microfold (M) Cells.** The M cell forms a "pocket" containing memory lymphocytes. It actively pinocytoses soluble antigens and phagocytoses particulates such as viruses, bacteria, and microspheres. (Courtesy of Dr. Svein Steinsvoll, University of Oslo.)

release from M cells (Fig. 20.4A). M cell pockets in PPs contain approximately equal numbers of T and B cells, but fewer MØs. Approximately 75% of the T cells are Th cells.

GALT B-cell follicles are enriched in IgA-bearing B cells,[8] suggesting that they are major sites for B-cell μ to α switching (Chapters 4 and 7). The interfollicular regions of PPs contain high endothelial venules (HEVs) (Chapter 2, 11). Both CD4 and CD8 TCR$\alpha\beta$ T cells are found in these interfollicular regions, with CD4 T cells representing the predominant phenotype. Both naïve and memory T cells are present in PPs, with one-third in cell cycle (see Fig. 20.4; Table 20.1). Lymphotoxin-α (LT-α), lymphotoxin-β (LT-β), and TNF-α (Chapter 9) are critical for lymphoid tissue organogenesis (Chapter 2). LT-$\alpha^{-/-}$ mice are deficient in secondary lymph nodes,[9,10] whereas LT-$\beta^{-/-}$ mice have mesenteric and cervical lymph nodes but lack peripheral lymph nodes and PPs. Tumor necrosis factor–receptor I (TNF-RI)$^{-/-}$ mice lack or display abnormal PP structures, whereas TNF-$\alpha^{-/-}$ mice exhibit normal patches.

TABLE 20.1 **Major T-Cell Subpopulations Associated With Murine Peyer Patches**

T-Cell Phenotype	Percentage of Total T Cells
CD3$^+\alpha\beta$ T-cell receptor (TCR)$^+$	95–97
CD3$^+\gamma\delta$ TCR$^+$	3–5
CD3$^+$, CD4$^+$ (precursors of T-helper [Th] cells)	65–70
CD3$^+$, CD8$^+$ (precursors of cytotoxic T lymphocytes [CTLs])	30–35
Naïve (CD45RB^{Hi})	50–60
Memory (CD45RB^{Lo}, CD45RO^{Hi})	40–50
Blasts (in cell cycle)	30–35

Nasal-Associated Lymphoid Tissues

Strategically positioned at the entry of the respiratory and the digestive tracts are the accumulations of lymphoid tissues that comprise the palatine, lingual, and nasopharyngeal tonsils, which collectively form the Waldeyer ring. These tissues resemble both lymph nodes and PPs, including an FAE with M cells in the tonsillar crypts that is essential for selective antigen uptake (see Fig. 20.3). Germinal centers containing B and T cells, plasma cells, and APCs are also present. Tonsillar tissues can serve as a source of precursors of IgA plasma cells found in the upper aerodigestive tracts, as well as inductive sites for systemic and mucosal immune responses.[11] The LT$\alpha_1\beta_2$ signaling pathway is essential for the maintenance, but not the initiation, of NALT organogenesis.[7] Signaling via the IL-7/IL-7R and the L-selectin/peripheral lymph node addressin (PNAd) adhesion molecules both play important roles in the organization of NALTs.[7]

Other Sites for Mucosal Induction of an Immune Response

The follicular structures analogous to PPs in the large intestine are known as rectal-associated lymphoid tissues (RALTs). Unlike most other mucosal tissues, the large intestine lamina propria is home to more IgA2- than IgA1-producing cells.[8] Eye drop administration of antigen elicits secretory immunoglobulin A (SIgA) antibody responses in ocular and nasal mucosae. Thus both tear-duct associated lymphoid tissue (TALT) and conjunctiva-associated lymphoid tissue (CALT) take up antigens for the initiation of mucosal immune responses as a component of MALT.[12,13] Immunization via the epicutaneous and sublingual routes is emerging as a potential method for induction of mucosal immunity, and structures facilitating these responses are being investigated.

LYMPHOCYTE HOMING INTO MUCOSAL COMPARTMENTS

Mesenteric lymph node cells of orally immunized animals can repopulate the lamina propria of the gut, mammary glands, lacrimal glands, and salivary glands with antigen-specific IgA plasma cells (see Fig. 20.4B),[1] pointing to the existence of a "common" mucosal immune system. This concept has undergone

FIG 20.4 Structural Features and Cellular Components of Gut-Associated Lymphoreticular Tissues (GALTs). (A) The dome region is covered by the follicle-associated epithelium (FAE) with its characteristic microfold or microfold (M) cells. Major features of the dome include M cells with lymphocyte pockets, scattered plasma cells, and immature dendritic cells (DCs). The B-cell area contains five or more germinal centers with high frequencies of surface immunoglobulin (Ig) A$^+$ B cells. The adjacent T-cell area contains mature interdigitating DCs and precursors of CD4$^+$ Th and CD8$^+$ CTL. (B) Structural features and cellular characteristics of mucosal effector sites. The lamina propria is equally populated by B1 and B2 cells, both of which differentiate into IgA$^+$ plasma cells. Note that memory B and T lymphocytes are also both present in this compartment. Although intraepithelial lymphocytes (IELs) in human are mainly T-cell receptor (TCR)αβ$^+$, significant numbers of TCRγδ$^+$ T cells are also found in this compartment.

FIG 20.5 Structural Features and Lymphocyte Homing to Gut-Associated Lymphoreticular Tissues (GALTs). (A) High endothelial venules (HEVs) occur in T-cell areas and express the ligands mucosal addressin cell adhesion molecule-1 (MAdCAM-1), intercellular adhesion molecule 1 (ICAM-1), and CCR7. Naïve T and B cells, which are L-selectin$^+$, $\alpha_4\beta_7^+$, and leukocyte function–associated antigen-1 (LFA-1)$^+$, all participate in rolling, binding activation, arrest, and diapedesis in the HEV. Memory B and T cells express $\alpha_4\beta_7$ and LFA-1 at a higher level. (B) Lymphocyte receptors and addressin ligands involved in homing to mucosal effector sites of the gastrointestinal (GI) tract. The majority of B and T cells exhibit a memory phenotype with coexpression of high levels of $\alpha_4\beta_7$ and LFA-1. The expression of the G-protein–coupled receptor CCR9 allows the homing steps that occur on lamina propria venules.

further refinement, with evidence that migration of cells into and from NALTs follows rules different from those for GALTs and the GI tract.

Lymphocyte Homing in the GI Tract

Naïve lymphocytes enter mucosal or systemic lymphoid tissues from blood through specialized HEVs (Fig. 20.5A) (Chapter 11). In GALTs, HEVs are present in the interfollicular T-cell zones.[14] In effector sites, such as the lamina propria of the gut, the HEVs tend to occur near villi crypts (see Fig. 20.5B). Mucosal addressin cell adhesion molecule-1 (MAdCAM-1) is the most important addressin expressed by PP HEVs or lamina propria venules (LPVs). PNAd and vascular cell adhesion molecule 1 (VCAM-1) are the principal addressins expressed by peripheral lymph node and skin HEVs, respectively (Chapter 11).

Integrins are a large class of homing receptors characterized by heterodimeric α and β chains (Chapter 11). In general, the β_1 integrin characterizes the homing receptor for skin, whereas the β_7 integrin characterizes the receptor for the gut. The pairing of α_4 with β_7 is thus responsible for lymphocyte binding to MAdCAM-1, which is expressed on HEVs in PPs and gut LPVs (see Fig. 20.5).[14] The C-type lectins—L-, E-, and P-selectins (Chapter 11)—also serve as homing receptors. For example, L-selectin can bind to carbohydrate-decorated MAdCAM-1 and is an important initial receptor for homing into GALT HEVs.

Chemokines (Chapter 10) are also involved in immune-cell homing in mucosal tissues. For example, loss of secondary lymphoid tissue chemokine (SLC) results in lack of naïve T-cell or DC migration into the spleen or PPs. Conversely, memory $\alpha_4\beta_7^{hi}$ T cells that express the receptor for thymus-expressed chemokine (TECK), CCR9, migrate into the lamina propria of the GI tract. Both human $\alpha_E\beta_7^+$ and $\alpha_4\beta_7^{hi}$ CD8 T cells express CCR9, suggesting that TECK-CCR9 is also involved in lymphocyte homing and the arrest of IELs in the GI tract epithelium (see Fig. 20.4) (Chapters 10, 11).

PPs and GALTs contain both naïve and memory T- and B-cell subsets, whereas the lamina propria consists of memory T and B cells and terminally differentiated plasma cells (see Table 20.1 and Fig. 20.4). Naïve lymphocytes destined for GALTs express L-selectin, moderate levels of $\alpha_4\beta_7$ ($\alpha_4\beta_7^+$) and lymphocyte function–associated antigen-1 (LFA-1). Memory lymphocytes destined for lamina propria express higher levels of $\alpha_4\beta_7$ ($\alpha_4\beta_7^{hi}$) and lack L-selectin. Initial rolling is dependent on $\alpha_4\beta_7$ interactions with LPV MAdCAM-1. Activation-dependent binding and extravasation require LFA-1–ICAM binding. $\alpha_4\beta_7$ also mediates binding to E-cadherin, and CCR9 expression can result in activation-dependent entry into the epithelial cell compartment.

Cryosections of human tissues have revealed naïve lymphocytes in HEVs that express both L-selectin and $\alpha_4\beta_7$, whereas memory lymphocytes in efferent lymphatics express $\alpha_4\beta_7$, but not L-selectin. The majority of cells in mesenteric lymph nodes, including B-cell blasts, tend to be of the memory phenotype and are $\alpha_4\beta_7^{hi}$, L-selectin^{lo}. Ig-containing B-cell blasts also express high levels of $\alpha_4\beta_7$. This separation of naïve and memory T and B cells for entry into GALT HEVs or LPVs has important implications in vaccine development (Chapter 90).

An oral cholera vaccine was reported to elicit transient IgA antibody-forming cells (AFCs) in blood and subsequent IgA anticholera toxin AFCs in duodenal tissues.[15,16] In a separate study, peripheral blood AFCs induced after parenteral immunization were L-selectin$^+$, whereas those induced after oral and rectal immunization were predominantly $\alpha_4\beta_7^+$ AFCs.[15,16] In the latter study, most of the AFCs produced IgA, but some also expressed IgG. After nasal immunization, AFCs expressed both L-selectin and $\alpha_4\beta_7$ homing receptors. The APCs in GALTs were shown to produce high levels of retinoic acid, which promotes expression of $\alpha_4\beta_7$. Thus enteric immunization of GALTs more effectively triggers $\alpha_4\beta_7$ memory IgA and IgG B cells, which can then migrate into the bloodstream.

Lymphocyte Homing in NALTs and Lung-Associated Tissues

Unlike PP HEVs, which are found in T-cell zones, murine NALT HEVs are found in B-cell zones and express PNAd, either alone or associated with MAdCAM-1. Moreover, anti–L-selectin antibodies—but not anti–MAdCAM-1 antibodies—block the binding of naïve lymphocytes to NALT HEVs, suggesting a role for L-selectin and PNAd in the binding of naïve lymphocytes to these HEVs.[17]

During pulmonary immune responses, induction of VCAM-1, E-selectin, and P-selectin in the pulmonary vasculature is matched by increased expression of P-selectin ligand on peripheral blood CD4$^+$ and CD8$^+$ T cells.[18] As the cells accumulate in the bronchoalveolar lavage (BAL) fluid, the number of cells that express P-selectin ligand in blood declines. Very late antigen-4 (VLA-4) appears to be involved, as migration of VLA-4$^+$ T cells into BAL fluid is impaired following treatment with anti-α_4 antibody. Following systemic immunization, most NALT effector B cells express L-selectin, with only a few cells expressing $\alpha_4\beta_7$.[19] Effector B cells induced by nasal immunization display a more promiscuous pattern of adhesion molecules, with a large majority expressing both L-selectin and $\alpha_4\beta_7$.

The Common Mucosal Immune System Revisited

The homing pattern that has been elucidated in the GI tract after immunization of GALTs has been the model for all mucosal immune sites. As summarized above, the specific set of homing receptors and ligand addressins expressed in the GI tract are absent in NALTs and associated lymph nodes. It remains possible, and even likely, that memory lymphocytes from the gut may enter NALTs for additional priming and reprogramming of homing receptors. Likewise, memory lymphocytes induced in NALTs may traffic to lung and genitourinary tract tissues as well as to the GI tract. Thus the rules for the homing of naïve lymphocytes precursors to NALTs need to be more clearly defined.

INDUCTION OF MUCOSAL IMMUNITY

Mucosal Immune responses are typified by SIgA antibodies, the predominant Ig isotype in external secretions. The resistance of SIgA to endogenous proteases makes them uniquely suited to protect mucosal surfaces. The development of mucosal adaptive immunity requires cytokine signals from CD4, as well as from CD8, T cells; DCs, MØs, and B cells; and nonclassic APCs (*e.g.*, epithelial cells). B cell commitment (Cμ to Cα switching) and B-/T-cell interactions are of central importance for induction of pIgA-producing cells.

Mucosal Antigen-Presenting Cells

Large macromolecules are taken up by M cells in the GI tract. N418$^+$, 2A1$^+$, NLDC-145$^-$, M342$^-$ DCs form a dense layer of cells in the subepithelial dome (SED) just beneath the follicle epithelium, where CD4 T cells can be found,[20] whereas N418$^+$, 2A1$^+$, NLDC-145$^+$, and M342$^+$ DCs populate the interfollicular T-cell regions, where both CD4 and CD8 T cells reside. DCs in the dome region are immature, highly endocytic, and express low levels of major histocompatibility complex (MHC) (Chapter 5) and B7 molecules. DCs in the T-cell area are mature, with low endocytic activity and high levels of MHC class I and II molecules and B7 molecule expression (see Fig. 20.4A). DCs are also found in NALTs, where they play essentially the same role as in GALTs.

IECs express MHC class II and class I molecules and present peptides to primed CD4 and CD8 T cells. Human and murine IECs also express CD1d, a nonclassic MHC class I molecule involved in the presentation of lipid and glycolipid antigens (Chapter 5).

CD4 T-Helper Cell Subsets in Mucosal Immunity

Th cells are classified as Th1, Th2, Th17, regulatory T cells (Tregs), or follicular Th (Tfh) cells according to the cytokines they produce (Chapter 16). Th1 cells produce IFN-γ, LT-α,

FIG 20.6 **T-Helper (Th) Cell Subset Development in Mucosal Tissues.** The cellular and cytokine environment induces Th0 cells to develop into Th1, Th2, or Th17 subsets that can be discriminated based upon their cytokine production. Antigen-presenting cells (APCs) produce IL-12 in response to microbial assault and, together with interferon (IFN)-γ produced by natural killer (NK) cells and group 1 innate lymphoid cells (ILC1), induce mature Th1 cells. Th1 cells express select chemokine receptors and, through IFN-γ synthesis, activate macrophages (MØs) and induce B cells to produce opsonizing antibodies. Other cells, such as NK1.1, mast cells, and ILC2, respond to parasite/antigen/allergen with IL-4 production. IL-4 induces Th0 to Th2 differentiation. Epithelial cells (ECs) also produce cytokines that facilitate Th2 cell differentiation. Th2 cells produce IL-4, -5, -6, -9, -10, and -13, which help regulate mucosal secretory immunoglobulin A (SIgA) antibody responses. Transforming growth factor (TGF)-β, IL-6, and IL-23 produced by epithelial cells, MØs, and other cells help promote the differentiation of Th17 cells. The cytokines produced by Th17 cells contribute to several functions for the host response to commensal bacteria and protection against fungal infections. Follicular T helper cells (Tfh) are a subset of Th cells that help germinal center formation and the development of high-affinity antibodies.

LT-β, and TNF-α, whereas Th2 cells produce IL-4, IL-5, IL-6, IL-9, IL-10, and IL-13 (Fig. 20.6). In mice, mucosal Th1-type responses are associated with cell-mediated immunity and B-cell responses with characteristic IgG2a antibodies. Th2 cells support the production of IgA, as well as IgG1, IgG2b, and IgE. In humans and mice, Th1 and Th2 cells regulate the development of the opposite subset reciprocally through IFN-γ and IL-4 secretion, respectively (see Fig. 20.6). Human Th1 cells and IFN-γ responses are associated with IgG1 and IgG3 C-fixing antibodies with low IgG2 and undetectable IgG4 antibody levels,[21] suggesting that in humans IL-4 promotes IgG4 and IFN-γ promotes IgG1 (see Fig. 20.6).

Tregs and Th17 cells play a role in mucosal homeostasis and inflammatory responses (Chapter 18). Human tonsil CD4 T cells expressing the B-cell follicle homing receptor CXCR5 are identified as Tfh cells that help B-cell differentiation.[22] Foxp3$^+$ Tregs in PPs can apparently differentiate into Tfh cells, which express the chemokine CXCR5, the transcription factor Bcl-6, and the cytokine IL-21, to promote germinal center formation and IgA synthesis in the gut.[23,24]

B-Cell Isotype Switching and IgA Plasma Cell Differentiation

Isotype switching is preceded by transcriptional activation of the isotype in question (Chapter 4). IL-4 and TGF-β induce surface IgM-positive (sIgM$^+$) B cells to switch to IgE and IgA. TGF-β_1 can induce sIgM$^+$ to sIgA$^+$ B-cell switches, and addition of TGF-β_1 to LPS-triggered mouse B-cell cultures increased IgA synthesis. In humans, anti-CD40 stimulation of tonsillar B cells, together with TGF-β_1 in the presence of IL-10, stimulates IgA synthesis.[1] Cα_1 transcripts can also be induced by B-cell mitogen plus TGF-β, and Cα_2 transcripts can be induced by TGF-β together with IL-10.

DCs can also induce surface IgA$^+$ B cells via direct stimulation of B cells with B-cell activation factor of the TNF family (BAFF) and a proliferation-inducing ligand (APRIL).[25] APRIL–transmembrane activator and CAML interactor (TACI) signaling plays a key role in CD40-independent IgA class switching in mice.[25] In humans, functional mutations in TACI can result in IgA deficiency (IgAD; Chapter 34). Differentiation of sIgA$^+$ B cells into IgA-producing plasma cells is dependent on IL-5 and IL-6.[26]

VACCINE DEVELOPMENT AND MUCOSAL IMMUNE RESPONSES

Mucosal sIgA antibodies, as well as Th cell and cytotoxic T lymphocyte (CTL) responses, can be induced by pathogens triggering the organized mucosal inductive sites. Effective protection against virulent mucosal pathogens requires prophylactic immune responses that can be achieved through mucosal vaccines. In contrast to conventional injected vaccines, those administered via mucosal routes can trigger both mucosal immune responses as a first line of defense at the portal of pathogen entry and systemic immune responses that neutralize pathogens that have penetrated that barrier. Thus safe adjuvants boosting SIgA antibodies and mucosal immunity are being developed for mucosal vaccines. These efforts are in large part as a result of knowledge gained from studies of bacterial enterotoxins and nontoxic derivatives (Fig. 20.7).

Lessons From Studies of Bacterial Enterotoxins

Earlier studies of cholera toxin (CT) and heat-labile toxin I (LT-I) from *Escherichia coli* helped establish that mucosal (*i.e.,* oral or nasal) administration of vaccines was an effective approach for the induction of both mucosal and systemic immunity to coadministered vaccine antigens (Chapter 90). These closely related molecules are AB-type toxins consisting of two structurally and functionally separate enzymatic A subunits and binding B subunits (see Fig. 20.7). The B subunit of cholera toxin (CT-B) binds to GM1 gangliosides, whereas the B subunit of heat-labile toxin I (LT-B) binds to GM1 as well as GM2 asialo-GM1 gangliosides. The A subunits of these toxins are adenosine diphosphate (ADP)–ribosyl transferases. Binding of the B subunits to ganglioside receptors on target cells allows the A subunits to reach the cytosol where they elevate cyclic adenosine monophosphate (cAMP) levels.

Cellular Targets of Vaccine Adjuvants Can Shape the Immune Response

Studies with CT and LT-I revealed the importance of the cellular targets for shaping the profile of immune responses induced by mucosal adjuvants. In fact, CT promotes CD4 Th2 and Th17 responses, whereas LT-I also induces a CD4 Th1 (*i.e.,* IFN-γ) response.[27] As discussed below, studies with mutants of these enterotoxins and other toxins (*e.g., Bacillus anthracis* edema toxin[28]) have shown that their enzymatic activity are dispensable for vaccination.

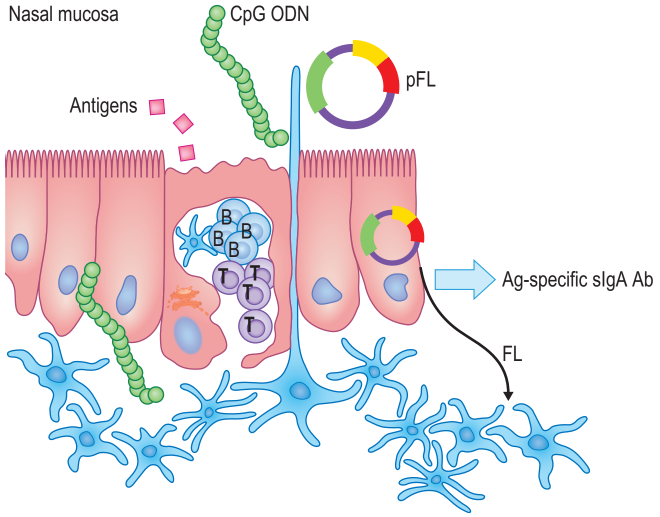

FIG 20.7 **Dendritic Cell (DC) Targeting With a Nasal Adjuvant.** Nasal administration of CpG oligodeoxynucleotide (ODN) and plasmid expressing FLT3 ligand cDNA (pFL) specifically target DCs in nasal-associated lymphoid tissues (NALTs). These nasal DC-targeting vaccines successfully elicit protective antigen-specific secretory immunoglobulin A (SIgA) antibody responses in older adults.

Central Nervous System Targeting Is a Safety Concern With Nasal Vaccines

Cholera induces diarrhea as a result of its ability to elevate cAMP in epithelial cells, thereby promoting secretion of water and chloride ions into the intestinal lumen. Diarrhea is thus the primary limiting factor for the use of oral enterotoxin as an adjuvant in humans. The olfactory neuroepithelium in the nasopharynx constitutes approximately 50% of the nasal surface and has direct neuronal connection to the olfactory bulbs (OBs) in the central nervous system (CNS). Nasally delivered enterotoxins can enter and/or target olfactory neurons and therefore gain access to OBs and deeper structures in the brain parenchyma. These adverse effects are, in large part, mediated by the ADP–ribosyl transferase activity and the nature of the cellular receptors targeted. Both CT and LT-I bind to GM1 on epithelial cells and require endocytosis followed by transport across the epithelial cell to reach the basolateral membrane. GM1 gangliosides are also abundantly expressed by the neuronal and microglial cells of the CNS.[29] CT or CT-B, when administered nasally to mice, enters the olfactory nerves and epithelium (ON/E) and OBs by mechanisms that are selectively dependent on GM1.[30] The targeting of CNS tissues by nasally administered bacterial enterotoxins is clearly related to a higher incidence of Bell palsy (facial paresis) among volunteers of a nasal vaccination trial given LT-I as mucosal adjuvant. Bell palsy among study subjects that in 2000 received nonliving nasal influenza vaccine (Nasalflu) led to its withdrawal from the market (www.niaid.nih.gov/dmid/enteric/intranasal.htm).

New Mucosal Adjuvants and Delivery Systems

CLINICAL RELEVANCE

Examples of Mucosal Adjuvants and Delivery Systems for the Induction of Targeted Immunity

Genetically Engineered Bacterial Toxins

- Examples are derivatives of the enterotoxin cholera toxin (CT) and heat-labile toxin (LT-I) from *Escherichia coli.*

Nucleic Acid Toll-Like Receptor (TLR) Ligands

- These sequences typically contain a transcription unit designed to express the antigen in question that is coupled to an adjuvant/mitogen unit, such as CpG motifs.

Mucosal Cytokines and Innate Factors as Adjuvants

- Mucosal delivery of specific cytokines or innate factors can reduce the risk of adverse systemic effects while targeting the immune response to the mucosa.

Transgenic Plants

- Plants, such as potatoes, bananas, and rice, can be engineered to express both B- and T-cell antigen epitopes, providing a simple delivery system for oral vaccination or oral tolerance induction.

Nontoxic Derivatives of Bacterial Enterotoxins

To circumvent the toxicity of enterotoxins, mutants of CT (mCT) and LT (mLT) molecules were generated by site-directed mutagenesis in the active site of the A subunit of CT or LT, or in the protease sensitive loop of LT. These mutants induced comparable levels of antigen-specific serum IgG and sIgA antibodies as wild-type CT and significantly higher levels than those induced by recombinant CT-B.[31] One of the mutants also induces Th2-type responses through a preferential inhibition of Th1-type CD4 T cells. mLT molecules, whether possessing a residual ADP–ribosyltransferase activity (*e.g.,* LT-72R) or totally devoid of it (*e.g.,* LT-7 K and LT-6 K3), can also function as mucosal adjuvants for nasal vaccine antigen in mice.[32] As LT induces a mixed CD4 Th1- and Th2-type response,[27] one might envisage the use of mLTs when both Th1- and Th2-type responses are desired.

The use of GM1-receptor binding holotoxins as nasal mucosal adjuvants is currently not recommended because of the risk for their accumulation in the CNS. However, nontoxic mCT could overcome these potential problems. To this end, a model adjuvant has been developed by combining the ADP-ribosylating ability of native CT (nCT) with a dimer of an Ig-binding fragment, D, of *Staphylococcus aureus* protein A.[33] This CTA1-DD molecule directly binds to B cells of all isotypes, but not to MØs or DCs. Despite the lack of a mucosal binding element, the B cell–targeted CTA1-DD molecule is as strong an adjuvant as nCT. Notably, CTA1-DD promoted a balanced Th1/Th2 response with little effect on IgE antibody production. CTA1-DD did not induce inflammatory changes in the nasal mucosa and, most importantly, did not bind to or accumulate in the OBs or the CNS.[33] CTA1-DD is an example of the use of nonganglioside targeting adjuvants and delivery systems as new tools for the development of safe and effective nasal vaccines.

Nucleic Acid Toll-Like Receptor Ligands

Toll-like receptor 3 (TLR3) and TLR9 recognize the pathogen-associated microbial pattern double-stranded RNA (dsRNA) and unmethylated DNA, respectively (Chapter 3). The latter contains immunostimulatory sequences consisting of short palindromic nucleotides located around a CpG dinucleotide core (*e.g.,* CpG motifs). CpG motifs bind to intracellular TLR9 and induce cytokine secretion (*i.e.,* IL-6, IFN-α, IFN-β, IFN-γ, IL-12, and IL-18) by a variety of immune cells. CpG motifs can enhance both systemic and mucosal immune responses when given nasally to mice,[34] and injection of bacterial DNA or CpG motifs with a DNA vaccine or with a protein antigen promotes Th1-type responses even in mice with preexisting Th2-type immunity.

Stimulation of TLR3 by dsRNA results in the production of type I IFNs (*i.e.,* IFN-α/β), which stimulate antibody responses to injected vaccines.[35] The synthetic TLR3 ligand polyinosinic–polycytidylic acid (poly I:C) has been shown to enhance CD8 responses to an experimental nasal influenza vaccine in mice and promote heterosubtypic protection via stimulation of TLR3 signaling by nonhematopoietic radioresistant cells.[36]

Mucosal Cytokines and Innate Factors as Adjuvants

Mucosal delivery of cytokines offers a means to prevent the adverse effects associated with the large and repeated parenteral doses often required for the effective targeting of tissues and organs. For example, nasal delivery permits acquisition of significant serum levels of IL-12 at one-tenth the dose required for inhibition of serum IFN-γ by parenteral administration.[1] Earlier studies have shown that nasal administration of tetanus toxoid with IL-12 as adjuvant induced high titers of sIgA antibody responses in the GI tract, vaginal washes, and saliva.[37] Similar results were reported when mice were nasally immunized with soluble influenza H1 and N1 proteins and IL-12. Related studies showed that mucosally administered IL-12 can redirect antigen-specific Th2-type responses toward the Th1 type or promote mixed Th1- and Th2-type responses, depending on the mucosal route and timing of delivery.[1]

FMS-like tyrosine kinase 3 ligand (FL) binds to the FMS-like tyrosine kinase receptor Flt3/Flk2. FL mobilizes and stimulates myeloid and lymphoid progenitor cells, DCs, and NK cells. Although FL dramatically augments numbers of DCs *in vivo,* it fails to induce their activation. Treatment of mice by systemic FL injection can induce marked increases in the numbers of DCs in both systemic *(i.e.,* spleen) and mucosal lymphoid tissues (*i.e.,* iLP, PPs, and mesenteric lymph nodes). Although this increase in mucosal DCs can, in some cases, initially enhance induction of oral tolerance,[38] it favors the induction of immune responses by mucosal or systemic vaccines. Nasal administration of plasmid or adenovirus encoding FL cDNA (pFL or Ad-FL) with protein antigens was shown to induce antigen-specific sIgA and protective immunity.[39-41] Thus FL cDNA may be an alternative to costly treatments with FL protein.

Transgenic Plants

Edible plants have been engineered to synthesize and assemble one or more antigens that retain both T- and B-cell epitopes, thereby inducing systemic and mucosal immune responses in both mice and humans.[42,43] To circumvent potential denaturation of the plant antigen during cooking, recombinant bananas that can accumulate up to 1 mg of vaccine antigen per 10 g of banana were developed. Most recently, the CT-B subunit has been expressed under the control of the rice seed storage protein glutelin promoter (MucoRice-CT-B). Oral feeding of powdered MucoRice-CT-B to mice and nonhuman primates resulted in the induction of both systemic and mucosal antibody responses for protection against CT.[44-46]

ON THE HORIZON

Development of Transgenic Plants as Vehicle for Vaccine Administration

- The MucoRice system is a novel strategy for vaccine development.
- The MucoRice system may also be used as a passive neutralizing antibody delivery system.

SYNTHESIS AND FUNCTIONS OF SECRETORY ANTIBODIES

Mucosal sIgA differs from serum IgA in both molecular composition and specific antibody activity. Humans possess two $C\alpha$ gene segments, $C\alpha 1$ and $C\alpha 2$ (Chapter 4), the use of which defines the two IgA subclasses, IgA1 and IgA2.[8] These IgA subtypes differ primarily in their hinge regions (Chapter 15). IgA1 antibodies contain an additional 13 amino acids in the hinge region, and this renders them more flexible and susceptible to IgA1-specific proteases produced by certain bacteria. IgA1-secreting cells are prevalent in most human mucosal tissues, especially the small intestine and the respiratory tract, whereas the human colon and genital tract are enriched by IgA2-secreting cells. SIgA are mostly viewed as a barrier at mucosal surfaces to prevent adhesion and colonization of pathogens, as well as an effective means to neutralize viruses and toxins, although these antibodies confer the additional advantage of providing antiinflammatory properties.[8]

In external secretions, adult levels of sIgA are reached considerably earlier (1 month to 2 years) than in the serum (adolescence). Approximately 98% of SIgA antibodies are produced locally in mucosal tissues, with only a minor fraction deriving from the circulation.

KEY CONCEPTS

Secretory Immunoglobulin A (SIgA)

- Unlike serum IgA, mucosal secretion of IgA reaches adult levels early in life (1 month to 2 years after birth).
- The polymeric Ig receptor (pIgR) is expressed on the basolateral surface of epithelial cells and facilitates the active transport of secretory IgA, as well as pentameric IgM, into mucosal secretions.
- SIgA protects the host by inhibiting microbial adherence; neutralizing viruses, enzymes, and toxins; and engaging in antiinflammatory activities by means of inhibiting IgM and IgG complement activation.
- Clinically, selective IgA deficiency, which is the most common primary immune deficiency, is characterized by recurrent mucosal infections, including sinusitis, otitis media, bronchitis, and pneumonias of viral or bacterial origin, as well as acute diarrhea caused by viruses, bacteria, or parasites, such as *Giardia lamblia.*

Polymeric Immunoglobulin Receptor and pIgA Transport

The polymeric Ig receptor (pIgR) is synthesized as a transmembrane protein by epithelial cells and is found on the basolateral surface of epithelial cells. It acts as a receptor for the endocytosis of pIgA and pentameric IgM, both of which contain a J-chain. The pIgR is produced by bronchial epithelial cells, renal tubules, glands, and the epithelia of the small and large intestines.[1] The pIgR is not expressed by the FAE (including M cells) of PPs, but only by the adjacent columnar epithelial cells. Further, pIgR is expressed in the upper respiratory tract, which includes the nasal cavity, tonsils, trachea, bronchi, and tracheobronchial glands. Expression in the lower lungs is restricted to the pulmonary alveolar cells.

In female reproductive tissues, the expression of pIgR is influenced by the sex hormones. It is low in the vagina, absent in the ovary and myometrium, and very high in the fallopian tubes and uterus. Normal kidneys do not express pIgR, whereas epithelial cells in the lower urinary tract may normally express pIgR and transport pIgA into urine. The expression of pIgR can be upregulated by cytokines, such as IFN-γ, TNF-α, IL-1α, IL-1β, and TGF-β.

IgA-Mediated Inhibition of Microbial Adherence

The inhibition of microbial adherence plays a critical initial role in the protection of the host. This inhibition is mediated by both specific and nonspecific mechanisms. The surface of microorganisms interacting with sIgA becomes less hydrophobic and thus more likely to be entrapped in mucus. SIgA and pIgA are more effective at agglutinating microorganisms than is membrane-bound IgA, and the agglutinating ability of sIgA specific for capsular polysaccharides of *Haemophilus influenzae* appears to be crucial to preventing colonization by *H. influenzae.*[47]

Neutralization by sIgA of Viruses, Enzymes, and Toxins

SIgA antibodies have been shown to be effective at neutralizing viruses in several experimental systems (*e.g.,* influenza virus, Epstein-Barr virus [EBV], HIV, etc.) and at different steps in the infectious process. SIgA specific for influenza hemagglutinin can interfere with the initial binding of influenza virus to target cells or with the internalization and the intracellular replication of the virus. *In vitro* experiments employing polarized murine epithelial cells have demonstrated that antibodies specific to rotavirus and hepatitis virus can neutralize the viruses inside epithelial cells. Finally, sIgA can neutralize the catalytic activity of many enzymes of microbial origin.

Antiinflammatory Actions Mediated by SIgA Antibodies

IgA antibodies are unable to activate complement by either the classical or the alternative pathway (Chapter 21). Nevertheless, they can interfere with IgM- and IgG-mediated complement activation.[8] SIgA can inhibit phagocytosis, bactericidal activity, and chemotaxis by polymorphonuclear neutrophils (PMNs), monocytes, and MØs. IgA can downregulate the synthesis of TNF-α and IL-6, as well as enhancing the production of IL-1R antagonists by LPS-activated human monocytes. Thus the antiinflammatory properties of IgA are of significant importance for the integrity of the mucosa in that IgA can limit bystander tissue damage that may result from the continuous interactions of the mucosa with myriad dietary and environmental antigens. Systemically, circulating IgA also appears to help limit inflammatory reactions that result from complement fixation and phagocyte activation, and it contributes to the inhibition of IgE-dependent anaphylactic responses.

IgA Deficiency

Selective IgAD is the most common primary immune deficiency (PID) in individuals of European descent (Chapter 34). The clinical diagnosis of IgAD depends on the relative absence of IgA in the serum. However, the most important manifestations of the disorder primarily reflect the absence of both sIgA1 and sIgA2 in the external secretions. Thus IgAD affects both the mucosal and systemic immune compartments, with only rare individuals exhibiting a superselective loss of either IgA1 or IgA2 alone.[48]

MUCOSAL CTLS

M cells have specific receptors for mucosal virus that allow certain viruses, such as reoviruses, to enter the cells in both NALTs and GALTs. It is likely that enteric viruses, such as rotavirus, and respiratory pathogens, such as influenza virus and respiratory syncytial virus (RSV), also enter the mucosal inductive pathway via M cells.[49] After enteric infection or immunization, antigen-stimulated CTLs are disseminated from PPs into mesenteric lymph nodes via the lymphatic drainage. Oral immunization with live virus can thus induce antigen-specific CTLs in both mucosal and systemic lymphoid tissues.

KEY CONCEPTS

Mucosal Cytotoxic T Cells (CTLs)

- After enteric infection or immunization, antigen-stimulated CTLs are disseminated from Peyer patches into mesenteric lymph nodes via the lymphatic drainage.
- Oral immunization with live virus can induce antigen-specific CTLs in both mucosal inductive and effector tissues for mucosal immune responses, as well as in systemic lymphoid tissues for serum immune responses.

Enteric Viruses and Mucosal CTLs

CD8 CTLs (Chapter 17) play a central role in rotavirus and reovirus immunity.[50,51] Reovirus-induced CTL precursors (pCTLs) in GALTs migrate to the systemic compartment. Reovirus-specific CD8 CTLs associated with the $\alpha\beta$ T cell population are also observed in intraepithelial T lymphocytes. Oral delivery of rotavirus increases pCTLs in GALTs and results in their dissemination throughout the murine lymphoid system within 3 weeks. Moreover, adoptively transferred CD8 T cells mediate the clearance of rotavirus infection in severe combined immunodeficiency mice.

Respiratory Viruses and Mucosal CTLs

Studies of immune responses after intranasal infection with influenza virus in CD4-coreceptor knock-outs or other mice in which this subset had been depleted have shown that CD4 T cells do not affect the induction of pCTLs or significantly alter clearance of infection.[52] Clearance of influenza is unaltered by the use of β_2 microglobulin knock-out mice, which lack CD8 T cells, or of mice that have been treated with monoclonal anti-CD8. $\gamma\delta$ T cells with several Vδ chain specificities increase in the infected site as clearance occurs, which suggests a regulatory role for $\gamma\delta$ T cells in antiviral immunity.[53]

Mucosal AIDS Models for CTL Responses

Approximately 80% of new HIV-1 infections result from sexual transmission (Chapter 39). Studies using the rhesus macaque and the simian immunodeficiency virus (SIV) vaginal infection model have provided evidence that pCTLs occur in female macaque reproductive tissues and that infection with SIV induces CTL responses. This important finding was extended to vaginal infection with an SIV/HIV-1 chimeric virus (SHIV) containing the HIV-1 89.6 *env* gene.[54] Other work has shown that intranasal immunization with SIV/HIV components induces antibody responses in vaginal secretions.

Other Mucosal CTL Systems

Salmonella can elicit CD8 T-cell responses, including CTLs, to expressed proteins, and CD8 T cells induced to the parasite *Toxoplasma gondii* have been shown to be protective. Thus mucosal CD8 CTLs can also be induced in nonviral situations. Significant questions remain as to the mechanism by which naïve CD8 T cells can be triggered to expand into pCTLs and to the rules for expression of effector CTLs and memory in the actual mucosal compartment that manifests the infection. pCTLs accumulate in immunologically privileged sites, but they do not develop a cytotoxic function until they encounter infected class I MHC-presenting target cells. It is possible that this mechanism protects the common mucosal immune system network from inadvertent cytotoxic inflammatory events.

MUCOSAL IMMUNE RESPONSES IN EARLY LIFE AND AGING

Although most of its structures are present at birth, the mucosal immune system requires further postnatal development and maturation before becoming fully functional (Chapter 38). GALTs, NALTs, and tonsils are present in humans at birth. The bacterial colonization after birth increases the number of immune cells and germinal centers in these sites and the number of secondary lymph nodes (*e.g.,* mesenteric lymph nodes and cervical lymph nodes; Chapter 2) and generate innate lymphoid follicles (ILFs). Significant changes that occur after bacterial colonization include an increase in SIgA levels and in the numbers of IgA secreting cells, Tregs, and Th17 cells. BALT only develops after birth. It is clear that the immature mucosal immune system in early life cannot protect against infectious pathogens entering mucosal surfaces. This gap is filled by maternal antibodies, which are acquired either before birth through the placenta or after birth via ingestion of milk.

KEY CONCEPTS

Mucosal Immunosenescence

- Early mucosal aging is evident in the gastrointestinal (GI) tract immune system.
- Nasal immunization is an effective route for the induction of mucosal and systemic immune responses in aging mice.
- Dendritic cell (DC)–targeting mucosal adjuvants are able to elicit protective pathogen-specific secretory immunoglobulin A (SIgA) antibody responses in aged mice.

Immune functions are known to deteriorate as a result of aging in several species (Chapter 38). The risk and severity of infections are higher, and the susceptibility to certain types of autoimmune diseases and cancer are greater in older adults,[55] and responses to vaccination are diminished. Aging-associated alterations of the systemic immune compartments have been studied extensively. Dysfunctions occur in both B and T cells, although the latter are considered more susceptible to immunosenescence.

In humans, older subjects were reported to have significantly higher concentrations of salivary sIgA antibodies compared with younger subjects, whereas whole gut lavages of aged and young subjects contain similar amounts of antibodies.[56] Analogous results have also been obtained for total IgA antibody responses in the serum of aged animals and humans. These results indicate an absence of aging-associated impairment in total IgA antibody levels in external secretions.

The GI tract in older adults is particularly susceptible to infectious diseases. Antigen-specific mucosal IgA antibody responses are diminished in aged animals, especially those in GALTs.[56] In older humans, pathogens that invade through mucosal surfaces, such as influenza virus and the bacterial pathogen *Streptococcus pneumoniae,* cause more severe and more frequently lethal infections. The development of effective vaccines for older adults remains a largely unmet goal. To provide effective protection against influenza and *S. pneumoniae* for this population, one should strongly consider developing a new generation of vaccines that could induce pathogen-specific immunity in the respiratory tract. Although it has been shown that effective protection can be provided by pathogen-specific systemic IgG without mucosal IgA responses, pathogen-specific sIgA responses are a necessary component for providing a first line of effective immunity against these respiratory pathogens at their entry site.

MULTIPLE-CHOICE QUESTIONS

1. The following are major characteristics of mucosal effector sites:
   - **A.** Essentially all of the T and B cells present are of a memory phenotype.
   - **B.** Most of the plasma cells are producing polymeric immunoglobulin A (pIgA).
   - **C.** The majority of T cells are $CD4^+$ and have characteristics either T-helper 1 (Th1)- or Th2-type helper cells.
   - **D.** Significant numbers of functional $CD8^+$ cytotoxic T lymphocytes (CTLs) are present.
   - **E.** All of the above.

2. Two IgA subclasses occur in humans, IgA1 and IgA2. However, their distribution in mucosal effector sites is remarkably different. For example:
   _____ predominates in tissues from the waist up, whereas _____ is prevalent in the lower gastrointestinal (GI) tract. In this regard, ______ predominates in the upper respiratory tract and nasal mucosa. On the other hand, ______ predominates in the lower ileum and colon.

   Correct Order:
   - **A.** IgA1→IgA2→IgA2→IgA1
   - **B.** IgA2 →IgA1→IgA1→IgA2
   - **C.** IgA1→IgA2→IgA1→IgA2
   - **D.** IgA2→IgA1→IgA2→IgA1

3. The existence of a "common mucosal immune" system suggests that mucosal tissues are connected. This means that:
   - **A.** Nerves connect distant mucosal sites.
   - **B.** Immune cells freely move between mucosal sites.
   - **C.** Selected homing receptors and addressins control homing to selected tissues.
   - **D.** Homing receptors and addressins play no role in homing to effectors sites.

The Human Complement System: Basic Concepts and Clinical Relevance

John P. Atkinson, Terry W. Du Clos, Carolyn Mold, Hrishikesh Kulkarni,
Dennis Hourcade, Xiaobo Wu

OVERVIEW: AN EVOLUTIONARY AND HISTORICAL PERSPECTIVE

The complement system arose early in evolution, possibly even in single-cell organisms. In vertebrates, it features a proteolytic cascade to coat microorganisms with cleavage fragments that are recognized by receptors on phagocytic cells.[1-4] This phenomenon, known as *opsonization,* leads to immune adherence followed by internalization. A related strategy employed by primates is to express a complement receptor on erythrocytes. In blood, the opsonized pathogen becomes adherent to the abundant erythrocytes and then, like a taxi, is taken by them to the liver and/or the spleen for transfer to monocytes and macrophages. In this manner, bacteria are both immobilized and prevented from traveling free in the circulation to such sites as the brain.

To mediate opsonization, the complement system needed to develop a system to transfer a plasma component onto the pathogen. Lectins and, subsequently in evolution, antibodies (Abs) faced this same challenge. Of note, both of the latter eventually utilized the complement system (lectin pathway and classical pathway [CP]) to "complement" their attachment strategies. In contrast to lectins and antibodies, the alternative pathway (AP) earlier solved this problem creatively through development of a thioester bond in C3. C3's homologous cousin, α_2-macroglobulin, also utilizes cleavage of a thioester bond to covalently attach to and thereby inactivate proteases. The parallels are apparent—upon its generation following C3 activation, C3b can transiently (within microseconds) attach to nearby hydroxyl or amino groups to form an ester or amide linkage, respectively. This mechanism creates essentially an almost unbreakable bond and places this complement fragment irreversibly on the pathogen's surface (Table 21.1).

To summarize, the major function of the complement system is to modulate the membrane of a microbial target, leading to immune adherence and internalization of the opsonized antigen. The target is selected by lectins in the lectin pathway and predominantly by antibodies in the CP. However, the ancient AP does not feature selective or specific recognition. Instead, 1–2% of C3 "ticks over" each hour, serving as a surveillance system. The activated C3b has a few microseconds to bind to a target, such as bacteria, or it will be inactivated by water. If C3b lands on a pathogen, C3b can rapidly amplify to put several million copies of C3b on a single *Escherichia coli* in 2–3 minutes. If C3b remains in the fluid phase, it is promptly inactivated by plasma regulators. If it binds to healthy self, it is inactivated by ubiquitously expressed membrane complement inhibitors. To summarize, the AP initially formed the original complement system and likely consisted of three elemental proteins (C3 and two proteases known as *factor B* and *factor D*). These three were sufficient to generate a C3 convertase (splitting) enzyme and also to form a feedback loop. The positive regulator of this remarkable enzymatic feedback/amplification loop, known as *properdin,* probably came later in evolution (as did lectins and antibodies).

Later to arise in evolution is the membrane attack complex (MAC, often called the *terminal pathway*) that is common to all three cascades. The goal of its five sequentially interacting, nonenzymatic proteins (C5b, C6, C7, C8, and C9) is also to attach to and then alter the surface of a pathogen by membrane perturbation, often ending in lysis. In humans, a deficiency of any one of these five proteins leads to meningococcal infections. Interestingly, properdin deficiency also predisposes to recurrent meningococcemia. Thus such infections likely drove specialization of this terminal wing of the complement system.

In contrast to the rapidly acting AP, a major limitation with the lectin and Ab systems is that the triggers of these two pathways are slow! It takes several days to ramp up synthesis of a particular lectin (acute phase type response) and at least a week to develop an appropriate immunoglobulin M (IgM) and even longer for an IgG immune response. For a host with an opportunistic pathogen invading the bloodstream, this time delay for an adaptive humoral immune response is far from adequate. Consequently, the complement system is often called the "guardian of the intravascular space." Once a "pumped" circulation developed in evolution, a rapidly acting, abundant, and nearly fail-safe system to prevent and stop "bugs" from entering, traveling, and dividing in plasma was mandatory.

The second function of the complement system is to promote the inflammatory response. This is primarily accomplished by the anaphylatoxins C3a and C5a. Upon cleavage of C3 to C3b (the major complement opsonin) and C5 to C5b (the trigger of the MAC), the ~10 kilodalton (kDa) C3a and C5a fragments are released, and these can engage their respective receptors to initiate vascular and cellular changes, rapidly leading to a proinflammatory state. These receptors are expressed on many cell types, including endothelial, epithelial, and immune cells. Upon receptor engagement, defensive strategies are initiated and result in increased blood flow and stimulated phagocytes that are now more efficient at binding and ingesting C3b-coated antigens.

Through these same interactions, the complement system instructs the adaptive immune response. Antigens decorated by complement proteins are taken up by monocytes, follicular-dendritic cells (FDCs), B lymphocytes, and other antigen-presenting cells (APCs), resulting in an adaptive immune response

TABLE 21.1 Proteins of the Complement System

Component	Function
Classical Pathway (CP)	
C1q	Part of C1. Binds to immunoglobulin M (IgM), IgG, pentraxins, and ligands on apoptotic cells to initiate CP activation.
C1r	Part of C1. After auto-activation, cleaves C1s.
C1s	Part of C1. After activation by C1r, cleaves C4 and C2.
C4	Cleaved by C1s to form C4b, part of the CP and LP C3 and C5 convertases. An opsonin.[*]
C2	Binds to C4b and then cleaved by C1s to form C2a; enzymatic component of the CP and LP C3 and C5 convertases. C2b is released.[†]Δ
Lectin Pathway (LP)	
MBL	Recognition component for LP activation. Binds to mannose-rich glycans through C-type lectin domains.
MASP-1 and MASP-3	Associated with MBL and ficolins. Cleaves C2, but not C4. Cleaves profactor D.
MASP-2	Associated with MBL and ficolins. Cleaves C2 and C4.
Ficolins 1–3	Recognition components for LP activation. Bind to glycans through fibrinogen-like recognition domains.
Alternative Pathway (AP)	
C3	Cleaved by C3 convertases to form C3b and C3a. C3b is opsonic. A small fraction becomes part of the AP C3 convertase and part of all C5 convertases. C3b is further cleaved to opsonic iC3b and the CR2 ligands C3dg and C3d. C3a is an anaphylatoxin.
Factor B	Binds to C3b and then cleaved by factor D to form Bb, the enzymatic component of the AP C3 and C5 convertases. Ba is released.[‡]○
Factor D	Cleaves factor B bound to C3b to form AP convertases.
Properdin	Stabilizes AP convertases. Binds to microbial ligands to initiate AP activation.
Membrane Attack Complex (MAC)	
C5	Cleaved by C5 convertases to form C5b and C5a. C5b initiates MAC formation. C5a is an anaphylatoxin.
C6	Part of the MAC. Binds membranes.
C7	Part of the MAC. Binds membranes.
C8	Part of the MAC. Initiates pore formation.
C9	Part of the MAC. Polymerizes to form lytic pores.
Soluble Regulatory Proteins	
C1-INH	Serine protease inhibitor of C1r, C1s, MASP-1, MASP-2, kallikrein, factor XII.
C4BP	Binds C4b. Decay accelerating and cofactor activities for C4b-containing convertases.
FH	Binds C3b and polyanions. Has decay-accelerating and cofactor activities for C3b-containing convertases.
FI	Cleaves C3b and C4b bound to a cofactor protein.
Vitronectin	Binds C5b-7, prevents membrane insertion and lysis.
Clusterin	Binds C8 and C9, prevents MAC assembly and lysis.
Membrane Regulatory Proteins	
CD55 (DAF)	Accelerates decay of C3 and C5 convertases.
CD46 (MCP)	Cofactor for FI cleavage of C3b and C4b.
CD59	Binds to C8 and C9, prevents MAC assembly and lysis.
Receptors	
CD35 (CR1)	Opsonic receptor for C3b and C4b. Has decay accelerating and cofactor activity for C4b and C3b and convertases containing these fragments.
CD21 (CR2)	Receptor for C3dg and C3d. Enhances B cell activation.
CD11b/CD18 (CR3)	Opsonic receptor for iC3b. Leukocyte adhesion integrin.
CD11c/CD18 (CR4)	Opsonic receptor for iC3b. Leukocyte adhesion integrin.
CRIg	Opsonic receptor for iC3b and C3c. Inhibits C5 convertases.
C5aR (CD88)	Proinflammatory and chemotactic receptor for C5a.
C5L2	Receptor for C5a. Function not fully defined.
C3aR	Proinflammatory and chemotactic receptor for C3a.

[*] C4a, an anaphylatoxin is released. Function and receptor are not defined.
[†] No defined function upon release.
[‡] Several putative functions reported but requires further study.

(the complement system is often called "nature's adjuvant.") Thus complement activation is required for optimal Ab responses to most foreign antigens. Individuals lacking C3 are predisposed at an early age to bacterial infections, predominantly by encapsulated bacteria.

Complement deficiencies are instructive anomalies of nature. Surprisingly, a complete deficiency in an early component of the classical complement pathway predisposes to autoimmune diseases, particularly systemic lupus erythematosus (SLE) (Chapter 51). Greater than 80% of patients with C1q or C4 deficiency present with SLE. This association indicates that the complement system is required not only for host defense against foreign agents but also to identify and safely clear self-materials (debris or garbage removal), particularly RNA and DNA species.

Much complement-mediated pathology revolves around disturbances of the AP and thus its potent amplification loop. It must be rigorously regulated to prevent activation on normal self and excessive activation on injured self. Even haploinsufficiency of its two major inhibitors predisposes to endothelial damage in atypical hemolytic–uremic syndrome and retinal damage in age-related macular degeneration (ARMD).

In clinical medicine, the complement system participates in three pathological processes: (1) bacterial infections and/or autoimmunity are caused by complete component deficiencies; (2) tissue damage results from complement activation by autoantibodies forming immune complexes (*e.g.*, SLE); and (3) excessive activation at sites of cellular and tissue injury occurs in individuals carrying dysfunctional genetic variants in complement regulators.

Knowledge of how complement is activated and how it can be controlled points to opportunities for the development of therapeutic agents. One such example is anti-C5 monoclonal antibody (mAb) therapy, which has been recently approved to treat several complement-dependent hemolytic disorders. Other new complement therapeutics and diagnostics are on the horizon as biotechnology companies pursue novel complement inhibitors and genetic evaluations are increasingly utilized for helping to define diseases in which the complement system is involved.

COMPLEMENT PATHWAYS

The three pathways of complement activation are the CP, AP, and lectin cascades (Fig. 21.1).[1-4] The CP is initiated by IgM or IgG Ab binding to antigen. The CP can also be activated by innate pattern recognition molecules, such as the pentraxins, cross-reactive protein (CRP) and serum amyloid P (SAP) component,[5] and the membrane-bound lectin, SIGN-R1.[6] It participates with natural IgM in early host defense and provides a mechanism for immune complex and apoptotic cell clearance. The lectin pathway (LP) uses most of the CP components but is activated by mannan-binding lectin (MBL) and the ficolins, which are lectins that recognize repeating carbohydrate patterns on microorganisms.[7] The AP is the most ancient pathway and also has the broadest recognition ability. The AP is engaged by surface components of all types of microorganisms, including bacteria, fungi, parasites, viruses, and virus-infected cells.[8] It is continuously turning over and autoactivates if its inhibitors are lacking. Activation of the AP can also be initiated by properdin (P), a molecule that binds to pathogens and apoptotic cells. This mechanism further promotes its function as an innate and rapid responder to infection.[9] The AP is an important amplification mechanism for CP or LP activation, resulting in greater opsonization and generation of the terminal lytic pathway. For example, the initial trigger on a pathogen surface may be IgM or a lectin, but the majority of the C3b deposited is via AP's amplification or feedback loop that is engaged by just having C3b on a target.

The cleavage of C3 to C3a and C3b is central to all three pathways of complement activation. This enzymatic step exposes a highly reactive thioester bond through which C3b covalently attaches to nearby molecules (Fig. 21.2). Activation of C3 to C3b also exposes sites for interactions with other complement proteins, inhibitors, and receptors. Recent results have shed new light on the structural basis for C3 activation. In 2006, several studies reported the first x-ray structure of C3b, the activated product C3.[10,11] The results revealed a major conformational change in C3 upon cleavage to C3b that exposes the reactive thioester group as well as cryptic binding sites for complement receptors and regulatory proteins. Moreover, the crystal structures of five binding proteins in complex with C3b have now been solved.[12]

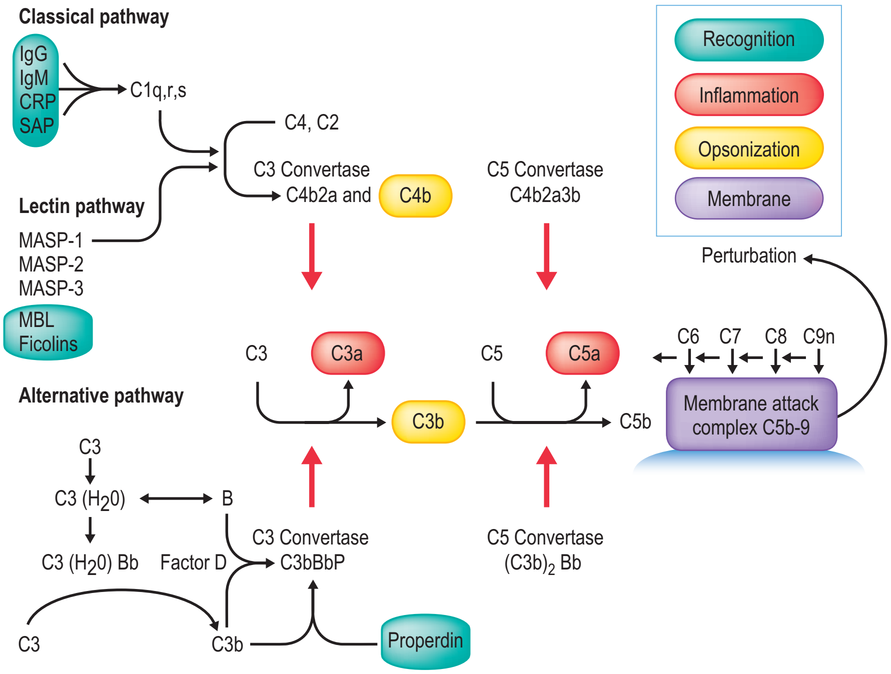

FIG 21.1 Overview of the complement pathways indicating components required for recognition, the enzymatically active fragments and complexes and the major opsonic, inflammatory, and membranolytic products.

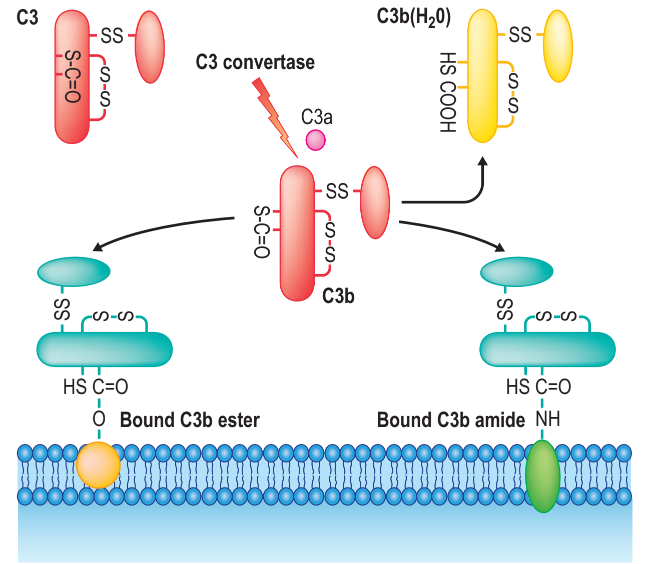

FIG 21.2 Exposure and Reactivity of the C3 Thioester Bond. C3 cleavage by a C3 convertase generates metastable C3b with a reactive thioester. Metastable C3b may be hydrolyzed to form $C3b(H_2O)$ or may react with hydroxyl (ester linkage) or amino (amide linkage) groups to become covalently bound to a surface.

Classical Pathway

KEY CONCEPTS

Structural and Functional Homologies in Complement Pathways

Recognition: C1q, MBL, Ficolins, CRP
Initiating enzymes: C1r, C1s, MASP-1, MASP-2, FD
C3 convertases: C4b2a, C3bBb
C5 convertases: C4b2a3b, $(C3b)_2Bb$
Enzyme subunits of convertases: C2a, Bb
Assembly subunits: C3b, C4b (covalently bound to target)
Anaphylatoxins: C3a, C5a
MAC subunits: C5b, C6, C7, C8, C9
Regulatory proteins: C4BP, FH, CR1, MCP, DAF
Receptor proteins: CR1 and CR2; CR3 and CR4
Major opsonins: C3b and C4b

The CP is focused by Ab binding to a target antigen. In general, the ability of Ab to activate complement is IgM > IgG3 > IgG1 > IgG2 > IgG4. Binding of these Ab exposes sites in the Fc region for attachment of the first subcomponent of complement, C1q.[13,14] C1 is a large calcium-dependent complex composed of C1q and two molecules each of the proenzymes, C1r and C1s. C1q is a 410-kDa protein with six globular heads connected by a collagen-like tail. For IgM, which is pentameric, binding to antigen creates a conformational change that exposes the C1q binding site in the Cμ3 domain. For IgG, at least two closely bound molecules are required to provide multiple attachment points for C1q binding to the Cγ2 domain. Similarly, CCRP or SAP molecules bound to ligand provide multiple C1q binding sites, resulting in CP activation. IgM, IgG, and CRP bind C1q through its globular head groups. Membrane lipids exposed on apoptotic cells or mitochondrial membranes, polyanions, nucleic acids, retroviruses, and endotoxins can also activate the CP.

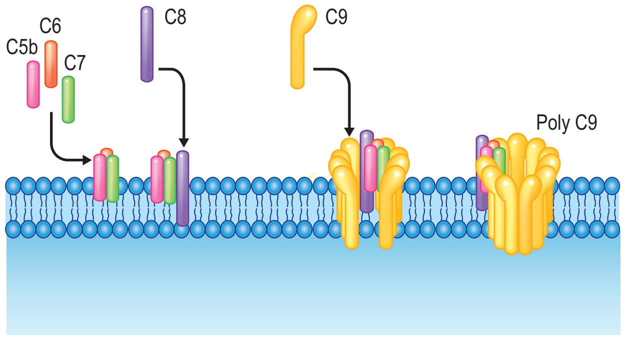

FIG 21.3 Sequence of Protein Interactions in the Assembly of the Membrane Attack Complex (MAC). C5b, generated by a convertase cleaving C5, combines with C6 and C7 to form a hydrophobic complex capable of a membrane interaction. Binding of C8 allows the complex to insert further into the membrane and forms a site for C9 polymerization. C9 polymers (10–15) form a transmembrane pore to mediate cell lysis.

Once C1q binds to an activator through several globular heads, C1r is cleaved by an autocatalytic process. Activated C1r then cleaves and activates C1s, which, in turn, cleaves circulating C4. C4 and C3 are highly homologous proteins that share an unusual posttranslational modification known as an *internal thioester bond* (see Fig. 21.2).[10,15] Cleavage of C4 releases the C4a fragment and exposes the reactive thioester bond in the larger C4b fragment. This allows C4b to attach covalently to nearby target structures, through either amide or ester bonds, to form amino or carboxyl groups on proteins and polysaccharides on cell surfaces, including Abs and a wide array of antigens. The exposed thioester bond is highly but transiently reactive as it is susceptible to rapid hydrolysis. For example, only about 5% of the C4b typically becomes attached to the target. Bound C4b provides an anchor site for C2 attachment, which is then also cleaved by C1s, releasing the smaller fragment C2b.

The complex of C4b2a is termed the *CP C3 convertase* because it has the capacity to cleave C3, releasing C3a. The C2a component of the complex contains the active enzymatic site. C3 cleavage is similar to C4 cleavage in that the larger fragment, C3b, contains a thioester site (see Fig. 21.2) that mediates covalent attachment to nearby surface structures, including the antigen, the Ab, and the attached C4b. C3 is found at a three- to fourfold higher concentration in serum compared with C4, and its cleavage is amplified by the AP. Thus efficient complement activation will result in clusters of multiple bound C3b molecules that can be recognized by cellular receptors. C3b that attaches to C4b within the C3 convertase produces the trimolecular complex C4b2a3b, which is a C5 convertase. Cleavage of C5 produces C5a, which has potent inflammatory activity, and C5b, which initiates the formation of the MAC or, as it is also known, the *terminal complement complex* (TCC) (Fig. 21.3).

Lectin Pathway

The LP is similar to the CP, except that it uses pattern recognition molecules, MBL, and ficolins-1, 2, and 3, instead of Ab to target activation.[7,16] MBL is structurally similar to C1q, with a collagen-like region and globular heads. The globular heads of MBL are C-type lectin domains specific for repeating carbohydrate structures found on microorganisms. Like C1q, MBL and ficolins are in complex with serine proteases, MBL-associated serum proteases (MASPs), which are structurally and functionally similar to C1r and C1s. MASP-1 and -2 are active proteases, but only MASP-2 cleaves both C4 and C2 to generate C4b2a, the same C3 convertase as the CP. MASP-1 can supplement activation by cleaving C2 but not C4. Two nonproteolytic splice products of the *MASP2* and *MASP1/3* genes, sMAP and MAP-1, compete with MASP-1 and MASP-2 for binding to MBL to regulate the LP. Subsequent steps in the LP are identical to those in the CP. Although still controversial, MASP-1 and MASP-3 likely contribute to the AP by cleaving profactor D to active factor D.[7,16,17]

Alternative Pathway

The AP uses proteins that are structurally and functionally homologous to those of the CP, but this pathway has unique features that play three important roles in the complement cascade. The surveillance role of the AP is mediated by a continuous low level of spontaneous activation that results from the hydrolysis of the C3 thioester bond.[8] Hydrolyzed C3, C3(H_2O), assumes a conformation similar to that of C3b and can bind factor B (homologous to C2), which is cleaved by factor D (homologous to C1s) to form a fluid-phase C3 convertase. This convertase cleaves C3 to generate C3b, which can covalently bind to nearby structures and provide the basis for a bound C3 convertase (C3bBb). Because C3b is both a part of this enzyme and a product of the reaction, a positive feedback loop that rapidly deposits more C3b is formed. This low-grade activation process is tightly regulated on host cells and tissues by plasma and membrane-bound complement regulatory proteins. It is the lack of such regulation that usually restricts AP activation to microbial targets. The plasma protein factor H (FH) is particularly important in controlling AP activation, both in the fluid phase and on "nonactivating" surfaces. The latter recruits FH through its binding sites for polyanions, including sialic acid and glycosaminoglycans. "Activating" surfaces, such as microbial polysaccharides, lipopolysaccharides, and foreign glycoproteins, provide C3b attachment sites that are protected from regulatory proteins. Similar to the CP, the AP C5 convertase (C3bBb3b) is formed when a second C3b attaches to the C3 convertase. The AP C3 and C5 convertases are stabilized by P (factor P or P), for which this pathway was originally named.

More recently, an additional role for properdin (P) in initiating AP activation was rediscovered.[8,18,19] P is a pattern-recognition molecule with specificity for microbes and damaged cells. Once bound, P can recruit fluid-phase C3b or C3b (H_2O), independent of covalent binding, and thereby provide a platform for the assembly of the AP convertase. Thus P binding can direct AP activation, similar to MBL in the LP. P binding to certain *Neisseria* species potently activates the AP, and this may account for the susceptibility of P-deficient individuals to infection with *N. meningitidis.*

The third important role of the AP is the amplification of C3b deposition and C5 convertase generation that is initiated by the CP or the LP.[8] This function of the AP is critical in complement-mediated pathology, as it increases the generation of C5a and the MAC, the most inflammatory components of the system. It is this amplification role of the AP that makes it an attractive therapeutic target.

MEMBRANE ATTACK COMPLEX

All three complement pathways merge with the cleavage of C5 into C5a and C5b. Although C5 is structurally homologous to C3 and C4, it lacks an internal thioester bond that allows covalent attachment to surfaces. C3a and C5a are also structurally homologous and, as described below, are the most potent proinflammatory mediators of the complement system. C5b initiates the formation of the MAC (see Fig. 21.3), a complex of C5b, C6, C7, C8, and multiple (5–10) C9 molecules.[20] This complex, as indicated by its name, penetrates membrane bilayers to form pores that disrupt the osmotic barrier, leading to swelling and lysis of susceptible cells. Lysis of Ab-sensitized erythrocytes by the MAC is the basis of the total hemolytic complement (THC) assay or CH_{50}. C5b initiates the formation of the MAC without further proteolytic steps. C5b binds to C6, and this complex binds to C7. The C5b67 complex is lipophilic and associates with cell membranes, if available, or with serum lipoproteins. Once bound to a membrane, C5b67 recruits C8, and the complex penetrates more deeply into the membrane. However, efficient lysis requires C9, a pore-forming molecule with homology to perforin, a protein used by cytotoxic T cells and natural killer (NK) cells for killing virus-infected targets. The complex of C5b678 forms a nidus for C9 binding and polymerization. Although complement-dependent lysis of bacteria can be observed *in vitro*, many pathogens have evolved mechanisms to circumvent this activity of complement.[21] Opsonization by C3b is the most potent mechanism for destruction (adherence followed by ingestion) of bacteria by the complement system. The sublytic MAC is proinflammatory because of its membrane perturbing capabilities for host cells and contributes to the deleterious effects of complement activation in inflammatory diseases.[22]

REGULATION OF COMPLEMENT ACTIVATION

The complement cascade is rapidly activated and highly amplified by the generation of C3 and C5 convertases. There are three main levels of control that limit the potential harm that uncontrolled complement activation might cause: (1) the initiation step in the CP and the LP; (2) the C3 and C5 convertases of all three pathways; and (3) the assembly of the MAC. Both soluble and membrane-bound regulatory proteins serve these functions, which help terminate complement activation and direct it to appropriate targets.[23]

C1 Esterase Inhibitor

C1 esterase inhibitor (C1-INH) is a plasma serine proteinase inhibitor (serpin). C1-INH covalently binds to activated C1r and C1s, irreversibly inhibiting their activity and thereby limiting CP activation. C1-INH inactivation of C1r and C1s also removes them from the C1 complex, exposing sites on the collagen-like region of C1q. Likewise, C1-INH inhibits MASP-1 and MASP-2, kallikrein, factor XIa, factor XIIa, and plasmin of the LP and the contact, coagulation, and fibrinolytic systems. Inherited deficiency of C1-INH is the basis of hereditary angioedema, a disease characterized by recurrent attacks of subcutaneous or submucosal edema (Chapter 42).[24]

Regulators of the C3 and C5 Convertases

The C3 and C5 convertases are central to the generation of the inflammatory and opsonic products of complement activation and are highly regulated by fluid-phase and membrane-bound regulatory proteins. The membrane deposited C4b and C3b may be bound by the regulator to prevent an association with C2 or FB. The convertases themselves are complexes of two or three components, and one mechanism of regulation is the dissociation of these complexes. This type of regulation is termed *decay*

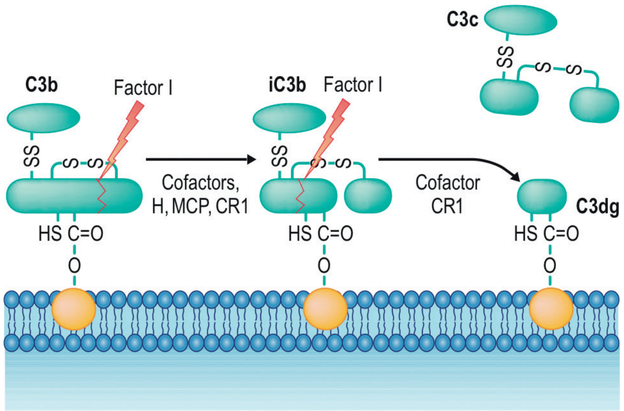

FIG 21.4 FI dependent cleavage of C3 showing the structures of the products and the required cofactors. The cofactor protein binds first and then the serine protease Factor I cleaves the C3b.

acceleration. A second mechanism of regulation is the enzymatic inactivation of the C4b and C3b components of the convertases (Fig. 21.4). This is accomplished by the plasma enzyme factor I (FI), which, however, only acts on C4b or C3b in complex with one of several regulatory proteins. The binding of regulatory proteins to C4b or C3b to enable FI cleavage is termed *cofactor activity.*

Factor I

FI (C3b inactivator, C3bINA) cleaves C4b and C3b into products that are recognized by specific cellular receptors (as discussed below). The sequential cleavages of C3b by FI to iC3b and C3dg are depicted in Fig. 21.4. C4b is cleaved in an analogous manner to C4d. (The iC4b intermediate is found only transiently.) The regulatory proteins that facilitate this cleavage by cofactor activity and those that inactivate C3 and C5 convertases by decay-accelerating activity are members of a family of structurally related proteins encoded within the regulators of complement activation (RCA) genetic locus.[25] This family is characterized by a repeating structure that consists of subunits, termed *complement control protein repeats* (CCP), of about 60 amino acids with a conserved pattern of two disulfide bonds per repeat and are usually encoded by a single exon.

Soluble Regulatory Proteins, C4b-Binding Protein, and FH

C4b-binding protein (C4bp) and FH are fluid-phase regulatory proteins with both decay-accelerating and cofactor activities. C4bp is multimeric, being composed of seven identical subunits, each containing eight CCPs. FH is a single-chain protein composed entirely of 20 CCPs. C4bp is specific for C4b and the C4b-containing convertases of the CP (C4b2b, C4b2b3b), whereas FH regulates C3b and C3b-containing convertases (C3bBb, C3bBb3b, C4b2b3b). FH is essential for regulation of C3 "tickover," and FH deficiency results in an acquired deficiency of C3. Additional binding sites on FH that recognize polyanions, such as sialic acid and glycosaminoglycans, provide targeted regulation of AP activation on surfaces.[23,26-28]

Membrane Regulatory Proteins

The RCA family includes the membrane regulatory proteins decay-accelerating factor (CD55, DAF), membrane cofactor protein (CD46, MCP), and complement receptors CR1 (CD35) and CR2 (CD21).[25,29] CD55 (DAF) and CD46 (MCP), as their names imply, have decay-accelerating and/or cofactor activity, respectively, that inhibits complement activation on cell membranes.[25] Each has an extracellular domain composed exclusively of four CCPs. CD55, a glycophosphatidylinositol (GPI)–anchored protein, and CD46, a transmembrane protein, are widely distributed on cells in contact with blood, with the notable exception of erythrocytes that lack CD46. Soluble CD55 is also found in most biological fluids. Both protect cells from complement-mediated lysis. CD35 (CR1) has decay-accelerating and cofactor activity and is a receptor for bound C3b. The function of CD35 as a complement receptor is discussed later in the chapter.

Complement C2 receptor inhibitor trispanning (CRIT) is a non-RCA membrane regulator of the CP. CRIT was originally identified on *Schistosoma* and *Trypanosoma* parasites and later found to be widely expressed on human tissues and blood cells, except for neutrophils and erythrocytes.[30] CRIT competes with C2 for binding to C4b, blocking the formation of the CP C3 convertase.

Properdin

In contrast to the regulatory proteins discussed above, the plasma protein P (factor P) stabilizes C3 and C5 convertases of the AP, increasing their activity.[8,18,19] This enhancer of AP activation is found as noncovalently linked dimers, trimers, tetramers, and larger species composed of identical 56-kDa chains. The majority of this plasma protein consists of a series of six thrombospondin type 1 modules. P binds to C3b and to Bb, preventing the spontaneous or induced decay of the AP C3 and C5 convertases. Its multimeric structure promotes interaction with clustered C3b. As discussed above, bound P can also recruit C3b to provide a site of assembly for the AP C3 convertase.

Regulators of the Membrane Attack Complex

The MAC is also regulated by both fluid-phase and membrane regulatory proteins.[1,20,23,29]

Soluble MAC Inhibitors: Vitronectin and Clusterin

Soluble hydrophobic proteins block the incorporation of the MAC into membranes. Two well-characterized proteins with this activity are vitronectin (S protein) and clusterin (SP-40,40, apolipoprotein J).[23,29] Vitronectin is in plasma and the extracellular matrix and binds to C5b-7. C8 and C9 can still bind to the complex, but membrane insertion and C9 polymerization are prevented. Soluble complexes of vitronectin and C5b-9 are in plasma during complement activation, and an enzyme-linked immunosorbent assay (ELISA) specific for this complex has been used to monitor activation of the MAC. Clusterin forms a complex with C5b-9, preventing membrane insertion. It is found in plasma, in the male reproductive tract, and on endothelial cells of normal arteries. It is also associated with amyloid deposits, including β amyloid in Alzheimer disease.

Membrane MAC Inhibitor CD59

The primary membrane-bound inhibitor of the MAC is CD59.[23,29] CD59 is a GPI-anchored protein expressed by most cells. CD59 binds to C8 and C9, preventing the incorporation and polymerization of C9.

COMPLEMENT RECEPTORS

Many of the biological effects of complement activation are mediated by cellular receptors for fragments of complement

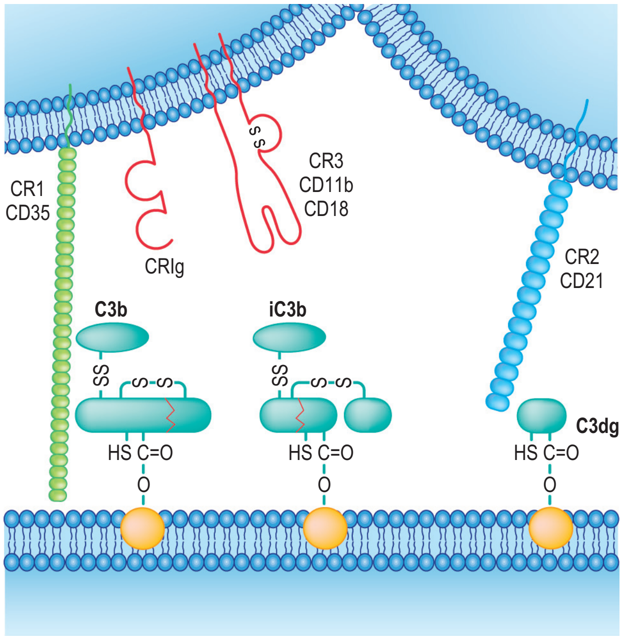

FIG 21.5 **Receptors for Bound C3b and Its Cleavage Products.** Receptors shown are CD35 and CD21 composed of CCP (SCR) subunits; CD11b/CD18 (CR3), a β_2 integrin; and CRIg with one or two immunoglobulin domains. The specificities of the receptors are CD35 for C4b and C3b, (C4b > C3b), CRIg for iC3b > C3b; CD11b/CD18 for iC3b; CD21 for C3dg and C3d. CD11c/CD18 (CR4) is similar to CD11b/CD18 and is not shown. Receptors are not drawn to scale. Their molecular weights are listed in Table 21.1.

proteins. These include receptors for the small soluble complement fragments, C5a and C3a, and receptors for bound complement fragments, C1q and C4b and C3b and their cleaved fragments. Receptors are specific for C3b and for its further breakdown products generated by the enzymatic processing by FI in conjunction with the cofactor proteins mentioned above. The breakdown of C3b and intermediate products are shown in Fig. 21.4 and the receptors for these components in Fig. 21.5.

C1q Receptors

C1q is one of a family of proteins termed *soluble defense collagens*, which includes the "collectins" (MBL, surfactant proteins A and D, conglutinin), and the ficolins. Each of these proteins is composed of a collagen-like linear stem region terminated by multiple globular recognition domains or head groups. The collectins recognize carbohydrates with their C-type lectin head groups, and the ficolins recognize acetyl groups on carbohydrates and other molecules with fibrinogen-like recognition domains. In contrast, the globular head groups of C1q do not recognize carbohydrates but, rather, bind to amino acid motifs on IgG, IgM, and pentraxins. In general, the soluble defense collagens broadly recognize pathogen-associated carbohydrate patterns and damaged or apoptotic cells. Reported direct effects of this group on leukocytes include the enhancement of phagocytosis, triggering of the respiratory burst, and regulation of cytokine responses. Several cell surface proteins have been proposed to facilitate these activities, including CD93 (C1qRp), CD35 (CR1), $\alpha_2\beta_1$ integrin, calreticulin in complex with CD91, gC1q binding protein, and SIPRα. However, none has been definitively established as a receptor in the classic sense.[1,5,16,31]

Complement Receptor 1 (CR1, CD35)

There are five identified receptors for bound fragments of C3 and/or C4. CD35 is a large protein composed of a linear string of CCPs, a transmembrane region, and a short intracytoplasmic domain.[32] Different allelic forms of CD35 are found, the most common being composed of 30 CCPs with a molecular weight of 190 kDa. These CCPs are organized into groups of seven, creating structures termed *long homologous repeats* (LHRs), each of which contains a single binding site. The predominant allele of CD35 contains two binding sites for C3b, three for C4b, and one for C1q. CR1 is expressed on human erythrocytes, monocytes and macrophages, neutrophils, B lymphocytes, a small percentage of T lymphocytes, eosinophils, FDCs, and glomerular podocytes.

CD35 on primate erythrocytes provides a mechanism for clearing soluble immune complexes from the circulation. Although the number of receptors on each erythrocyte is low, the large number of erythrocytes provides the major pool of CR1 in the circulation. Soluble immune complexes that fix complement attach quickly to erythrocytes in the circulation, bypassing monocytes and neutrophils. These erythrocyte-bound complexes are taken to the liver, where they are transferred to Kupffer cells expressing Fc and complement receptors and destroyed. The erythrocytes exit into the circulation to pick up more immune complexes. This clearance pathway is impaired in patients with SLE because of decreased complement in the circulation, decreased CD35 on erythrocytes, and saturated Fc receptors in the liver and spleen.

CD35 on monocytes and neutrophils promotes binding of microbes carrying C3b and C4b on their surface (immune adherence reaction), facilitating their phagocytosis through Fc receptors. CD35 can directly mediate the uptake of microbes when phagocytic cells have been activated by chemokines or integrin interactions with matrix proteins. CD35 is a member of the RCA family and has decay-accelerating and cofactor activity in addition to its function as a receptor. It differs from the membrane regulatory proteins DAF (CD55) and MCP (CD46) in its ability to also bind to C3b and C4b extrinsically (on targets other than the cell expressing it) and in its cofactor activity for iC3b processing. CD35 is the most effective cofactor for FI cleavage of C3b and iC3b to the smallest covalently bound fragment C3dg. C3dg is the major ligand for CR2 on B lymphocytes (described below). The cofactor activity of CD35 on B lymphocytes can process bound C3b to C3dg, facilitating binding to CR2 and lowering the threshold for B-cell activation.[29,33,34]

Complement Receptor 2 (CR2, CD21)

CD21 is also an RCA family protein composed of 15–16 CCPs. CD21 has a limited range of expression that includes B lymphocytes, FDCs, and some epithelial cells. CD21 is specific for the smallest covalently bound C3 fragments, C3dg and C3d, and has weaker binding to iC3b. CD21 is also the Epstein-Barr virus (EBV) receptor on B cells and nasopharyngeal epithelial cells and binds to CD23, a low-affinity IgE receptor.[33,34]

CD21 on B lymphocytes serves a costimulatory role. It is expressed on mature B cells as a complex with CD19 and CD81 (TAPA-1). Coligation of CD21 and the B-cell antigen receptor induces the phosphorylation of CD19, activating several signaling pathways and strongly amplifying B-cell responses to antigen. This role of CD21 is believed to contribute to the strong adjuvant effect produced by attaching C3d to antigen.[33,34]

Complement Receptors 3 and 4

CR3 and CR4 are the β_2 integrins commonly known as *CD11b/CD18 (Mac-1)* and *CD11c/CD18.*[34,35] β_2 integrins are large heterodimers found on neutrophils and monocytes with multiple roles in adhesion to endothelium and matrix molecules as well as direct recognition of microbial pathogens. The binding activities of β_2 integrins are regulated by cellular activation often through chemokine receptors. Both CD11b/CD18 and CD11c/CD18 are expressed primarily on neutrophils, monocytes, and NK cells and bind to iC3b and, to a lesser extent, C3b. CD11b/CD18 has been studied more extensively than CD11c/CD18. CD11b/CD18 expression, clustering, and conformation are all rapidly upregulated by chemokine activation of neutrophils, leading to increased responses to ligand. CR3 plays an essential role in neutrophil attachment to and migration through activated endothelium to sites in inflammation and in the regulation of neutrophil apoptosis. Deficiency of the β_2 chain (CD18) results in leukocyte adhesion deficiency, characterized by recurrent pyogenic infections, and defects in inflammatory and phagocytic responses. Complement receptors CD11b/CD18 and CD11c/CD18 provide an essential function for the removal of microbial pathogens following complement activation, since C3b processing to iC3b often occurs rapidly after deposition.

Complement Receptor of the Immunoglobulin Superfamily (CRIg)

CRIg is a receptor for iC3b and C3b present on Kupffer cells in the liver as well as other tissue macrophages but is absent from splenic macrophages, peripheral blood cells, bone marrow–derived macrophages, and monocyte/macrophage cell lines.[35,36] Two alternative-spliced forms of human CRIg were identified with one and two Ig domains. The mouse receptor has a single Ig domain. CRIg removes C3b or iC3b-opsonized particles from the circulation by the liver.

C5a and C3a Receptors

During complement activation, the homologous proteins C3 and C5 are each cleaved near the amino-terminus of the α chains to release a soluble peptide fragment of approximately 8 kDa. These fragments are designated C3a and C5a. C5a may also be generated locally by direct cleavage of C5 by thrombin or leukocyte proteases.[37] C3a and C5a are termed *anaphylatoxins* because of their ability to increase vascular permeability, contract smooth muscle, and trigger the release of vasoactive amines from mast cells and basophils.[38-41] C5a is 10- to 100-fold more active than C3a. These peptides are also chemotactic: C5a is specific for neutrophils, monocytes, and macrophages, whereas C3a is specific for mast cells and eosinophils. Other biological activities of complement anaphylatoxins are summarized in Table 21.2.

Structurally, anaphylatoxins are compact structures consisting of multiple helices cross-linked by disulfide bonds with more flexible carboxy-terminal regions. The C-terminal peptide of C3a interacts with the C3aR and can reproduce C3a agonist activity. In contrast, C5a interacts with the C5aR at multiple sites. Plasma carboxypeptidases cleave the C-terminal arginine from C3a and C5a producing the des-Arg forms. This inactivates C3a; however, $C5a_{desarg}$ retains much of its biological activity. The C5aR (CD88 and C5L2) and the C3aR are rhodopsin-type receptors with seven transmembrane-spanning domains coupled to G-protein signaling pathways. C5aR is expressed at high levels on neutrophils and is also found by macrophages, mast cells, basophils, smooth muscle cells, and endothelial cells. If C5a is generated locally, for example, in an extravascular site of infection, it helps induce an acute local inflammatory response, including vasodilation, edema, neutrophil chemotaxis, and activation of neutrophils and macrophages for enhanced phagocytosis and killing. The inflammatory activities of C5a can also contribute to complement-mediated pathology in some conditions, such as sepsis, acute respiratory distress syndrome, and ischemia/reperfusion (I/R) injury, making the C5a–C5aR interaction an attractive therapeutic target.

TABLE 21.2 Cellular Targets and Effects of Complement Anaphylatoxins

	Targets Bearing Receptors	Effects
C3a, C5a	Mast cells, basophils	Degranulation, release of vasoactive amines: contraction of smooth muscle, increased vascular permeability
C3a	Eosinophils	Chemotaxis, degranulation
C5a	Endothelium	Increased adhesion of leukocytes; augmented chemokinesis and cytokine synthesis
C5a	Neutrophils, monocytes/macrophages, eosinophils, basophils, astrocytes	Chemotaxis
C5a	Neutrophils, monocytes/macrophages	Priming: activation of receptors, assembly of nicotinamide adenine dinucleotide phosphate (NADPH) oxidase; activation: degranulation, respiratory burst
C5a	Resident macrophages	Regulation of FcγR expression (↑activating, ↓inhibitory)
C5a	Hepatocytes	Acute phase protein synthesis
C3a, C5a	Lymphocytes (antigen-presenting cells)	Regulation of T-cell responses to antigen

The C5L2 receptor binds to both C5a and $C5a_{desarg}$. C5L2 was initially believed to be a default or decoy receptor for C5a because it is uncoupled from G proteins. Genetic deletion of C5L2 ($Gpr77^{-/-}$) in mice resulted in enhanced neutrophil infiltration and cytokine production in the pulmonary Arthus reaction, supporting an antiinflammatory role for C5L2 in immune complex disease, where genetic deletion of C5aR is fully protective.[40] However, studies in a cecal ligation and puncture (CLP) model of sepsis found increased survival in mice lacking either C5aR or C5L2.[41] The results suggest an active proinflammatory role for C5L2 that requires C5a and results in the release of the inflammatory signal, high-mobility group box-1 protein (HMGB1) from phagocytic cells. Thus both C5aR and C5L2 may contribute synergistically to harmful inflammatory events during sepsis.

COMPLEMENT IN HOST DEFENSE AND IMMUNITY

Complement in Host Defense

Complement activation provides a coordinated response to infection that results in the opsonization of microbial pathogens and the attraction and activation of phagocytic cells to kill them.

Complement-dependent opsonization is of greatest importance in infections with encapsulated extracellular bacteria, and individuals with deficiencies in Ab production, neutrophil function, or C3 share increased susceptibility to these organisms, including *Streptococcus pneumoniae* and *Haemophilus influenzae.* MBL deficiency is also associated with recurrent pyogenic infections in young children. In general, activation of complement by natural Ab or MBL results in C3b and iC3b deposition on these pathogens, overcoming the antiphagocytic effects of the capsule. Phagocytic cells ingest and kill the organisms using CD35, CD11b/CD18, and CD11c/CD18 receptors in conjunction with other innate and Fc receptors. C5aR signaling activates these receptors, leading to increased phagocytosis. Gram-negative bacteria are susceptible to complement-dependent lysis. This is evident in the increased incidence of disseminated neisserial infection in individuals deficient in C3, any of the MAC components, or P, as discussed below.

Complement in Inflammation

An essential function of complement in host defense is the coordination of the local inflammatory response. C5a is the most potent complement product in this activity.[39] Sublytic deposition of the MAC on endothelial cells and platelets and C3a interaction with the C3aR also contribute to the proinflammatory effects of complement activation. As discussed below, these potent inflammatory fragments of complement, when generated in high amounts or targeted inappropriately, result in many of the disease-related deleterious effects of complement. Local production of C5a at a site of infection occurs either through local complement activation or through direct cleavage of C5 by tissue macrophages or thrombin.[37,38] This C5a is released and sets up a chemotactic gradient for neutrophils and macrophages. In addition, C5a activates endothelial cells to express P-selectin and synthesize chemokines, including interleukin-8 (IL-8). Interaction of C5a with mast cells releases vasoactive amines, increasing endothelial permeability. Neutrophils and macrophages are "primed" by interaction of C5a with its receptor. Priming includes enhancement of chemotaxis, activation of complement receptors for phagocytosis increased expression of activating FcγR, and assembly of the nicotinamide adenine dinucleotide phosphate (NADPH)–oxidase that is required for effective killing of microbes after phagocytosis. C5a also prevents neutrophil apoptosis, prolonging survival and contributing to local accumulation. Together, these actions result in the attraction and activation of potent antimicrobial cells and resolution of infection (Fig. 21.6).

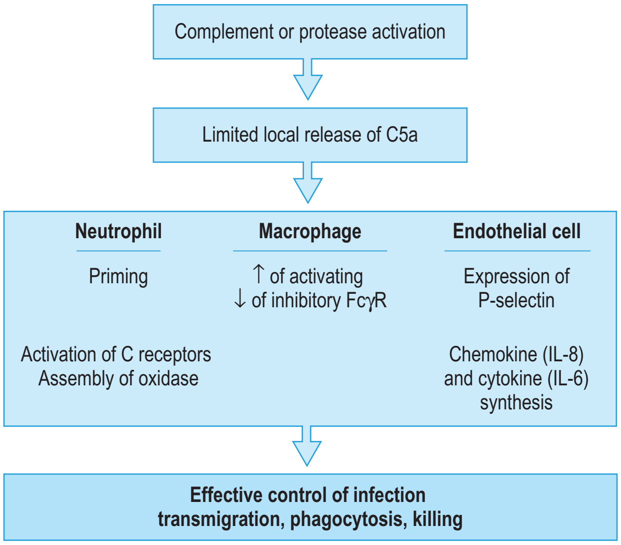

FIG 21.6 C5a in Local Host Defense. Note that C5a can also be released by a direct protease event, such as by thrombin. IL-8, Interleukin 8.

Pathogen Evasion of Complement

Further evidence of the host defense function of complement is the association of complement evasion strategies with virulence. Pathogenic gram-negative bacteria, such as *Salmonella,* have lipopolysaccharides with long O-polysaccharide side chains that promote rapid shedding of the MAC and prevent its insertion into the cell membrane. *Neisseria* species have several FH-binding components that help restrict AP activation and protect against lysis. Group A and B streptococci and *S. pneumoniae* have cell surface components (M protein, Bac or beta, PspC, Hic) that bind to FH and/or C4bp, restricting complement activation. Other organisms, including type 3 group B streptococci, elaborate sialic acid–containing capsules or cell walls to limit AP activation.

Although complement deficiencies are not generally associated with viral infections, the importance of complement in host defense against viruses is suggested by the multiple strategies used by viruses to evade complement.[21,42] Several viruses produce complement regulatory proteins, including vaccinia virus complement control protein and herpes virus glycoprotein C, which facilitate breakdown of C3b and C4b. Some viruses, such as human immunodeficiency virus (HIV), incorporate complement regulatory proteins into the viral envelope, a strategy that is also used by other pathogens, such as *Schistosoma.*[21,42,43]

There are also many examples of complement receptors and membrane regulatory proteins being exploited as receptors for pathogens to invade cells. Examples of these include strategies of direct pathogen binding to receptors as well as deposition of C3 fragments followed by invasion through host C3 receptors.[21]

Role of Complement in Adaptive Immunity

Over the past 10 years there has been renewed interest in the role of the innate immune system in adaptive immune responses.[1,8] The importance of complement in humoral immunity has been recognized since the observation that complement depletion of mice before immunization decreased Ab responses to thymus-dependent antigens. Further studies have shown that complement receptors CR1 (CD35) and CR2 (CD21) are also required.[33,34] In humans, these receptors are found together on B cells and FDCs. CD35 is also expressed on a number of other cell types (described above), including erythrocytes and phagocytic cells.

Effects of Complement on the Humoral Immune Response

Results obtained by experimental manipulation of C3, C4, and their receptors in mouse models indicate roles for these complement components at multiple levels in the humoral immune response.[33,34] One caveat regarding these studies is that in the mouse CD35 and CD21 are alternative splice products of the same gene, and genetically deficient animals lack both receptors.[34,44] In humans, CD35 and CD21 are encoded by separate genes. The first role of CD35/CD21 is in B-cell development, indicated by a pronounced defect in B-1-cell development in CD35/CD21–deficient mice. B-1 cells are generally found outside lymphoid follicles, have a restricted repertoire, and are essential in the production of natural Ab to pathogens, such as *S.*

KEY CONCEPTS

Abuse by and Evasion Strategies of Complement by Pathogens: Some Examples

1. Bacteria

Block C1, C3b deposition
    Streptococcus pneumoniae
Block MAC access to plasma membrane
    Salmonella
Limit access of C3b, iC3b to C receptors by capsule
    Streptococcus pneumoniae
    Haemophilus influenzae
Block AP activation by sialylation
    Streptococcus agalactiae (GBS) type III,
    Neisseria
Bind FH, C4BP to inhibit complement activation
    Streptococcus pneumoniae (Hic)
    Streptococcus pyogenes (GAS)(M protein)
    Neisseria
Use CD55 (DAF), CD46 (MCP) for attachment to cells
    Streptococcus pyogenes (GAS)(M protein)
    Neisseria
    Escherichia coli
Use complement receptors for entry
    Mycobacterium tuberculosis (CR3)
    Bacillus anthracis spores (CR3)

2. Viruses

Express complement regulatory proteins homologous to those synthesized by the host
    Herpes simplex virus (glycoprotein C)
    Poxviruses (SPICE/VICE)
Express unique complement regulatory proteins
    Flaviviruses (Dengue, West Nile)
Use CD55 (DAF), CD46 (MCP) for attachment to cells
    Measles virus, adenovirus, herpes virus 6 (CD46)
    Picornaviruses, hantavirus (CD55)
Use complement receptors for entry
    Epstein-Barr virus (CD21)
    Human immunodeficiency virus (CD35, CR3)

3. Parasites

Express complement regulatory proteins
    Schistosoma (CRIT)
Acquire complement regulatory proteins from host
    Schistosoma (CD55)
Use complement receptors for entry
    Leishmania (CR1, CR3)

pneumoniae, and to self antigens exposed on damaged cells, such as phosphatidylcholine and DNA. Although the mechanism of this defect in CD35/CD21–deficient mice is not fully understood, these mice have an altered repertoire of natural Ab and B-1 cells.[33,34,44] Decreased natural Ab may contribute to susceptibility to infection and autoimmune disease in hereditary complement deficiency (discussed below).

A second role for complement in the Ab response is the well-described function of CD21 as a coreceptor for the mature B-cell response to antigen.[33,34,44,45] As described above, CD21 is associated with the signaling complex of CD19 and CD81 (TAPA-1) in the B-cell membrane. Coligation of CD21 with the B-cell antigen receptor occurs naturally when the antigen activates complement and covalently binds C3dg. This coligation of the B-cell receptor with CD21 greatly decreases the threshold for B-cell activation and blocks Fas-initiated apoptosis of B cells. B cells activated by complement-opsonized antigen have increased ability to present antigen as well as survival and proliferation during encounters with T-dependent antigens.

The expression of CD35 and CD21 on FDCs is also important in the Ab response. FDCs trap antigen in the germinal centers and provide selection of somatically mutated high-affinity B-cell clones. Antigen trapped on FDCs also provides a source of long-term stimulation for maintenance of memory B cells. FDCs use complement receptors (CD35 and CD21) and FcγR to trap and retain antigen for these functions. Expression of CD21 on both FDC and B cells is required for effective affinity maturation of the Ab response and for the development and maintenance of memory B cells.

Complement and T-Cell Activation

Studies in primary pulmonary infection with influenza indicate that C3-deficient mice have a defect in influenza-specific CD4 and CD8 T-cell priming.[45] CR1/2 deficiency had no effect. The mechanism is unknown but may be more efficient uptake and presentation of C3-opsonized virus by APC through CR3 and CR4 or stimulation of T-cell responses through the C3aR.

Costimulation of human T cells *in vitro* through CD3 and CD46 leads to the development of T cells with a regulatory phenotype characterized by synthesis of IL-10 in the absence of other Th2 cytokines (IL-2, IL-4) (Chapter 9).[46] The induction of regulatory T cells (Tregs) was seen in response to both anti-CD46 cross-linking and natural ligands (C3b dimers, streptococcal M protein).

CD55-deficient mice showed enhanced T-cell responses to immunization and increased T cell–dependent autoimmune disease. These effects were complement dependent and apparently involve the loss of CD55 regulation of local complement synthesis by APCs during cognate interactions with T cells. One postulated mechanism is that CD55 inhibits the generation of C3a and C5a by APCs, preventing their interactions with C3aR and C5aR on T cells.[47] Complement anaphylatoxins, C3a and C5a, have many important effects in inflammatory diseases that include attraction and activation of inflammatory cells, as well as regulation of APC and T-cell responses. Examples of these will be discussed in the sections below.

Role of Complement in Clearance of Apoptotic Cells

Damaged tissue and dead and dying cells activate complement through several pathways. This can increase local inflammation and injury, as in I/R injury and hemolytic–uremic syndrome (HUS) (discussed below). Complement activation by apoptotic cells contributes to their opsonization and clearance and may prevent the development of autoimmunity. The deleterious consequences of complement activation following tissue damage are mainly attributable to AP-dependent generation of C5a and the MAC, whereas the beneficial effects are dependent on early CP components and innate recognition molecules.[48,49]

Necrosis, as occurs following ischemic tissue injury, exposes phospholipids and mitochondrial proteins that activate complement directly or indirectly. The pathways are different depending on the tissue involved.[48] For example, renal reperfusion injury appears to be initiated by the AP, possibly secondary to the loss of regulatory proteins on tubular epithelial cells. Intestinal (I/R) injury is initiated by natural IgM Ab and requires both the CP for initiation and the AP for injury. MBL and CRP-initiated complement activation have been proposed to contribute to myocardial reperfusion injury after coronary artery ligation.

Apoptotic cells are recognized by multiple receptors and opsonins.[49,50] The association between early CP deficiencies and

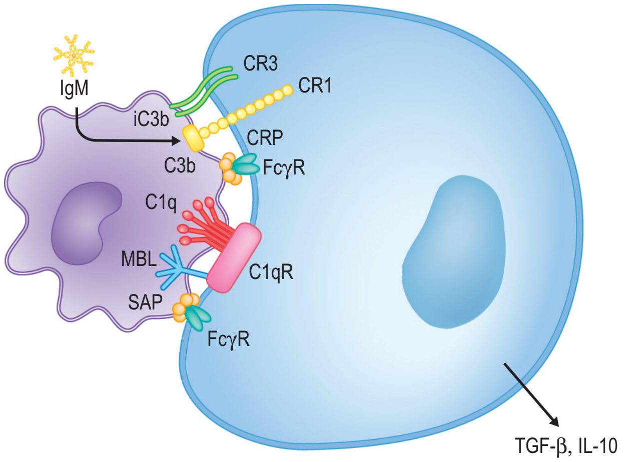

FIG 21.7 Pathways of Opsonization of Apoptotic Cells by Complement. Innate recognition of apoptotic cells by natural immunoglobulin M (IgM), cross-reactive protein (CRP), serum amyloid P (SAP), C1q, and mannose-binding lectin (MBL) is shown. Each reaction activates complement leading to opsonization by C3b and iC3b. In addition, C1q and MBL bind to collectin receptors, and CRP and SAP bind to FcγR on macrophages. Cytokine responses to apoptotic cells opsonized by complement include the antiinflammatory cytokines, transforming growth factor-β (TGF-β), and interleukin-10 (IL-10).

SLE (see below and Chapter 51) has been attributed to a failure of complement-dependent opsonization, resulting in accumulation of apoptotic cells and released autoantigens. Support for this hypothesis is provided by studies of mice deficient in C1q, IgM, or SAP, all of which develop autoantibodies against phospholipid and nuclear antigens characteristic of SLE, and by the therapeutic effect of CRP in mouse models of SLE.[5] The role of complement in apoptotic cell recognition and uptake by macrophages is depicted in Fig. 21.7. MBL, C1q, and surfactant protein-D (SP-D) bind to apoptotic cells and facilitate clearance through direct binding to cellular receptors as well as complement activation.[50] Natural IgM Ab, CRP, and SAP bind to phospholipids exposed on late apoptotic cells. All three proteins can also activate the CP generating C1q, C4b, C3b, and iC3b ligands for complement receptors. CRP and SAP also directly opsonize apoptotic cells for uptake through Fcγ receptors.[51] Phagocytosis of apoptotic cells generally induces antiinflammatory cytokines transforming growth factor-β (TGF-β) and IL-10.[52,53]

Targeted Activation of Complement for Opsonization

Interestingly, CRP and SAP also bind complement regulatory proteins, FH and C4bp, which helps limit complement activation to the deposition of opsonic components with little or no lysis or generation of C5a.[53,54] This type of complement activation was also observed on acrosome-activated spermatozoa. In this case, the CP was activated by CRP from follicular fluid, resulting in bound C3b and iC3b, which are proposed to bind complement receptors on the egg and facilitate fertilization. Riley-Vargas et al. have proposed the acronym TRACS (targeted and restricted activation of the complement system) for this type of limited complement activation that occurs as part of normal processes, such as the acrosome reaction, and the recognition and removal of ischemic tissue and apoptotic cells.[55]

COMPLEMENT DEFICIENCIES

Genetics and Incidence

Complete genetic deficiencies of complement proteins are rare, with an estimated combined prevalence of 0.03% for any inherited complete deficiency (excluding MBL deficiency) in the general population.[2-4,56-58] For most components, inheritance is autosomal and expression is codominant, so complete deficiency is homozygous recessive and heterozygotes express half levels. There are two C4 genes (*C4A* and *C4B*), so a range of partial deficiencies can be observed. All cases of C1-INH deficiency have been heterozygous, and P deficiency is X-linked. MBL is found in multiple allelic forms with different levels of expression ranging from 5 nanograms per milliliter (ng/mL) to more than 5 micrograms per milliliter (μg/mL) in plasma. Deficiencies specific to the LP are not detected by the screening assays described below but can be determined by specific assays.[7] A 10% incidence of MBL deficiency and a single case of MASP-2 deficiency have been described.

The most common clinical presentations of patients with complement deficiencies are recurrent infections with encapsulated bacteria, recurrent neisserial infections, and systemic autoimmune disease (Table 21.3). Populations with these disease manifestations have a much higher incidence of complement deficiency. For example, in Caucasian patients with SLE, the incidence of C2 deficiency is nearly 1%, 100-fold higher than in the general population. Screening of patients with autoimmune disease for complement deficiencies is useful, as these individuals are at higher risk for certain disease manifestations and may be at greater risk for infectious complications. Complement deficiency is found in as many as 20% of patients with recurrent disseminated neisserial infections. Evaluation of complement function is highly recommended in patients with recurrent or disseminated neisserial infections so that appropriate immunization and antibiotic prophylaxis can be initiated.

Complement deficiencies are most readily detected by hemolytic screening assays (the CH_{50} and AH_{50}), which determine the dilution of patient's serum needed to lyse 50% of erythrocytes sensitive to the CP (CH_{50}) or the AP (AH_{50}).[59] Deficiency of any C1 subcomponent, or any of the other CP components (C2–C8), will result in little or no lysis in the CH_{50} (CH_{50} values <5%). C9-deficient patients may have residual activity in this assay (CH_{50} values <30%). Little or no lysis is observed in the AH_{50} assay if factor D, P, or any of the components C3–C9 are deficient. Deficiency of factor B has recently been described.[60] By comparing the results of the two assays, it is possible to narrow down the search for the deficient component (Fig. 21.8). Hemolytic and antigenic assays may be done for each individual component to confirm the deficiency.

CP Deficiencies

Patients with deficiencies of early CP components (C1, C4, C2) are most commonly identified as having systemic autoimmune disease but are also at increased risk of infection.[3,4,56-58] The primary infectious agents in these patients are encapsulated bacteria, *S. pneumoniae, H. influenzae, N. meningitidis,* and *Streptococcus agalactiae,* which rely on Ab and CP opsonization for clearance.

C1 Deficiency

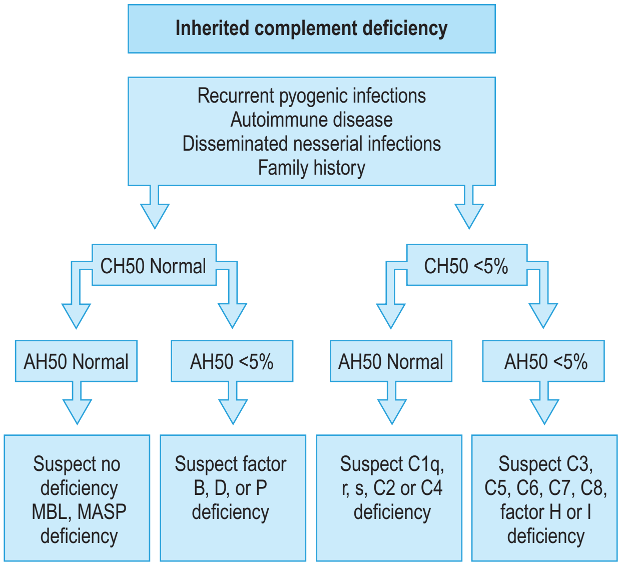
C1-deficient patients most commonly lack C1q, but C1r or C1s deficiency also results in nonfunctional C1 and no CP activity.

TABLE 21.3 Clinical Effects of Genetic Complement Deficiency

Deficient Component	Resulting Defect	Clinical Associations
C1q, C1r, C1s, C4 or C2	Inability to activate the CP	Systemic lupus erythematosus
Factor D, P	Inability to activate the AP	Infections, *Neisseria meningitidis*
MBL, MASP-2	Decreased or absent ability to activate the LP	Recurrent childhood infections, pyogenic bacteria
C3	Opsonization. No MAC. No activation of AP. Decreased inflammation (no C3a).	Recurrent childhood infections, *N. meningitidis, Streptococcus pneumoniae,* other encapsulated bacteria; autoimmune disease (uncommon)
FH, FI, C4 and C3NeFs	Lack of regulation of fluid-phase C3 convertases, severe acquired C3 deficiency	Infections, membranoproliferative glomerulonephritis
C5, C6, C7, C8, C9	Inability to form the MAC	Infection—recurrent, disseminated Neisserial
Serum carboxypeptidase-N	Failure to control C3a, C5a, bradykinin	Recurrent angioedema
C1-INH	Loss of regulation of C1 and bradykinin	Recurrent angioedema (HAE)
FH, FI, CD46 (haploinsufficiency)	Decreased regulation of C3 convertases	Atypical hemolytic–uremic syndrome, age-related macular degeneration*
DAF, CD59	Failure to regulate complement activation on autologous cells (especially red blood cells)	Paroxysmal nocturnal hemoglobinuria (PNH)

C1 INH, C1 esterase inhibitor; DAF, decay-accelerating factor; MAC, membrane attack complex; MASP, MBL-associated serine protease; MBL, mannan-binding lectin; NeF, nephritic factor (stabilizing autoAb to convertase); HAE, hereditary angioedema.

*Heterozygous C3 variants that lead to a gain of function cause atypical hemolytic–uremic syndrome (aHUS), age-related macular degeneration (ARMD), and C3G.



Inherited complement deficiency
Recurrent pyogenic infections
Autoimmune disease
Disseminated nesserial infections
Family history
CH50 Normal
CH50 <5%
AH50 Normal
AH50 <5%
AH50 Normal
AH50 <5%
Suspect no deficiency MBL, MASP deficiency
Suspect factor B, D, or P deficiency
Suspect C1q, r, s, C2 or C4 deficiency
Suspect C3, C5, C6, C7, C8, factor H or I deficiency

C9 deficiency may have up to 30% normal CH50 with low AH50

FIG 21.8 Flow Chart for the Evaluation of Inherited Complement Deficiencies Using Hemolytic Screening Assays for the Classical Pathway (CH_{50}) and the Alternative Pathway (AH_{50}). For each assay, the entire activation pathway including the membrane attack complex (MAC) is required for lysis.

CLINICAL PEARLS

Value of Screening for Complement Deficiencies

1. Patients with recurrent bacterial infections and normal white blood cells and immunoglobulins should be analyzed for a complement deficiency (obtain CH_{50} and AP_{50}).
2. Patients with recurrent or disseminated neisserial infection should be evaluated for deficiency of C3–C9 by CH_{50} and for properdin by AP_{50}.
3. Prophylactic antibiotics and immunization should be considered in complement-deficient individuals, especially for pneumococcus and neisserial species.
4. Patients with systemic lupus erythematosus (SLE) (especially young children and those with familial lupus, and recurrent bacterial infections) should be screened with a CH_{50}.

Absence of C1q is highly associated with the development of SLE, with an incidence of 90%.[56-59] It has been proposed that this association is related to defective clearance of apoptotic cells.[61] Apoptotic cells may be opsonized by IgM, or pentraxins, leading to activation of the CP, which may be initiated by IgM or pentraxin (CRP and SAP). Cells can also be cleared by direct C1q binding, leading to attachment and uptake through other phagocytic receptors (*e.g.*, phosphatidylserine receptor).[52] Other proposed mechanisms to account for the strong association between C1 and C4 deficiency (see below) and SLE include defective immune complex clearance and defective development and maintenance of B-cell tolerance.

C4 Deficiency

There are two C4 genes, C4A and C4B, located within the major histocompatibility complex (MHC) on chromosome 6.[58] The two forms of C4 have similar function, but different substrate preferences for the covalent binding reaction that occurs on activation to C4b. C4A is more efficient in attaching to amino groups on proteins, such as immune complexes, whereas C4B is more efficient in attaching to carbohydrates. Complete C4 deficiency requires four null alleles and is rarely found but is highly associated with SLE (75% incidence). Partial C4 deficiencies with one to three null alleles, however, are relatively common, found in up to 25% of individuals. Complete C4A deficiency is greatly overrepresented in the SLE population. C4A deficiencies are found in about 1% of the general population and 10–15% of patients with SLE. Complete C4B deficiencies are more commonly associated with bacterial infections, suggesting that the functionally different C4 genes contribute differently to host defense and autoimmunity.

C2 Deficiency

The gene for C2 is also located within the MHC. C2 deficiency is the most common complete complement deficiency, with about a 0.01% incidence in the population.[56-58] About half of C2-deficient individuals are clinically normal. The remaining individuals have recurrent pyogenic infections and/or rheumatological diseases. The most common infectious agents are *S. pneumoniae, H. influenzae, N. meningitidis,* and *S. agalactiae.* Infections are invasive and mainly occur in childhood, suggesting that the immune defect may be overcome by development of acquired immune defenses. Rheumatological diseases include SLE (15%), vasculitis, polymyositis, and Henoch-Schönlein purpura. SLE associated with C2 deficiency has some features that distinguish it from other types of SLE; these features include equal expression in males and females, early onset, increased photosensitivity, decreased renal disease, lower frequency of antidsDNA Ab, and higher frequency of anti-SSA/Ro and anti-C1q Ab.[56-58]

LP Deficiencies

MBL deficiency was originally found as a serum defect in the opsonization of yeast in pediatric patients with recurrent infections. There are multiple MBL polymorphisms in the population, in both the promoter and coding regions, and MBL deficiency is common (estimated to be 14% in the normal Swedish population).[56] In addition to the association of MBL deficiency in children with recurrent infections, there is a two- to threefold increased frequency of MBL deficiency in SLE, and these individuals have more frequent and more severe infections during the course of their disease. Serious infectious complications are also more frequent in the subgroups of patients with cystic fibrosis and RA with MBL deficiency.

A single homozygous MASP-2 deficiency has been reported.[7] The patient was asymptomatic until the age of 13 years when he was diagnosed with ulcerative colitis. Additional autoimmune manifestations developed along with recurrent severe infections with *S. pneumoniae.*

AP DEFICIENCIES

Individuals with complete deficiencies of factor D or P have been reported. Patients with factor D deficiency have presented with recurrent infections by *Neisseria* and other organisms. Properdin deficiency is X-linked, and patients most commonly have severe childhood infections with *N. meningitidis.*[18,56,59]

C3 Deficiencies

C3 is central to all three complement activation pathways. Nineteen families with primary inherited deficiency of C3 have been reported.[62] The most common presentation is recurrent life-threatening infections in early childhood (before the age of 2 years), sometimes followed by immune complex disease. The infections observed are primarily respiratory tract infections (48%) and meningitis (34%) with a variety of pathogens, especially encapsulated bacteria. The organisms most often involved are *N. meningitidis* and *S. pneumoniae,* but other encapsulated gram-negative and gram-positive bacteria have also been observed. Recurrent infections are seen in more than 50% of patients with C3 deficiency. This clinical presentation is similar to that seen in hypogammaglobulinemia. Individuals with C3 deficiency may develop renal disease (26%), including membranoproliferative glomerulonephritis (MPGN) and mesangiocapillary glomerulonephritis (MCGN) and autoimmune disease (26%), most commonly SLE.

Acquired C3 Deficiency: Genetic Deficiencies of FH and FI and C3 and C4 Nephritic Factors

Factors H and I are required to control C3 convertase in the fluid phase of the AP. Complete deficiency of either protein results in C3 cleavage and depletion to very low levels. C5, factor B, and P levels may also be reduced. The clinical presentation of patients with FH or FI deficiency resembles that of patients with primary C3 deficiency.[62] The highest disease association is recurrent infection with *N. meningitidis* and *S. pneumoniae,* and there is also an increased incidence of SLE. FH deficiency is more commonly associated with renal disease compared with C3 or FI deficiency (73% of individuals with FH deficiency compared with 13% of individuals with FI deficiency and 26% of those with C3 deficiency).

Nephritic factors (NeFs) are autoantibodies specific to the CP or the AP C3 convertase (C4b2a or C3bBb) or the AP C5 convertase that stabilizes these enzyme complexes and prevents normal regulatory control. The AP C3Nef induces unregulated complement activation, resulting in acquired C3 deficiency. NeFs are often associated with MPGN type II. C3NeF is also associated with partial lipodystrophy, a condition in which fat is lost from the waist upward.

Deficiencies of Complement Receptors

Deficiencies of CR1 (CD35) and CR2 (CD21)

The complete genetic deficiencies of CR1 or CR2 have not been reported. However, partial deficiencies of CR1 on erythrocytes, B lymphocytes, and polymorphonuclear leukocytes and of CR2 on B lymphocytes have been reported in patients with SLE. Decreased CR1 on erythrocytes may be acquired as a result of immune complex clearance.[3,4,56,59]

Leukocyte Adhesion Deficiency: CR3 and CR4 Deficiency

Leukocyte adhesion deficiency (LAD; Chapter 22) is a syndrome caused by mutations of the common β_2-integrin chain, CD18, found in LFA-1, CR3, and CR4. Defects are related to adhesion and activation of phagocytic cells, and the clinical presentation includes childhood infections with pyogenic bacteria.

Deficiencies of Regulatory Proteins

Hereditary Angioedema: C1-INH Deficiency

Hereditary angioedema (HAE) is found in individuals with heterozygous (autosomal dominant pattern of inheritance) deficiency of C1-INH.[24] C1-INH is a serine protease inhibitor (serpin) with regulatory activity for C1r, C1s, MASP-1, and MASP-2 of the complement system; factor XII (Hageman factor) and kallikrein of the contact system; factor XI and thrombin of the coagulation system; and plasmin and tissue plasminogen activator (tPA) of the fibrinolytic system. Although previous studies implicated a C2 product (C2 kinin) as a mediator, more recent data, including studies in a C1-INH deficient mouse model, indicate that bradykinin is the primary biological mediator of angioedema in HAE.[24] In the more common form of HAE (type I, 85% of patients), reduced synthesis of C1-INH is found (5–30% of normal), along with decreased serum C4 and C2. In type II HAE, an abnormal C1-INH is synthesized, making antigenic levels normal or elevated with reduced functional activity and decreased C4 and C2. Clinically, type I and type II HAE are indistinguishable.

HAE presents in childhood or adolescence as recurrent episodes of swelling that are subcutaneous and/or submucosal, nonpainful, nonpruritic, and nonpitting. Urticaria is not present. Episodes are self-limiting, usually peaking at 24 hours and resolving over 2–5 days. Attacks are variable in frequency, severity, duration and location, and initiating factors are poorly understood. The most common areas involved are the extremities, face, genitals, and respiratory and gastrointestinal tracts. Intestinal attacks are often associated with vomiting and diarrhea and are extremely painful (partial obstruction from the bowel wall edema). Laryngeal attacks may result in life-threatening respiratory tract narrowing.

Recurrent attacks continue throughout the life of the patient and may involve multiple sites or progress from one site to another. Diagnosis of HAE is suggested by family history and clinical findings. Confirmation is based on decreased C1-INH functional activity (<10–35% of normal). It is important to note that although C1-INH protein is decreased in type I HAE, it can be normal or even elevated in type II HAE. C4 levels are below normal in 95% of patients with HAE. Acquired forms of C1-INH deficiency have been described, usually in older patients with lymphoproliferative diseases. These are usually caused by autoantibodies to C1-INH and are distinguished from HAE by a lack of family history and decreased C1q as well as C4. The management and treatment of HAE are discussed in Chapter 42.

Paroxysmal Nocturnal Hemoglobinuria: DAF and CD59 Deficiency

Paroxysmal nocturnal hemoglobinuria (PNH) is a rare acquired disorder in which a somatic mutation in the *Pig-A* gene in a clone of bone marrow stem cell results in defective synthesis of GPI-anchored proteins. PNH is characterized clinically by intravascular hemolysis and venous thrombosis. DAF and CD59 are GPI-anchored complement regulatory proteins expressed on erythrocytes, and PNH erythrocytes are highly susceptible to lysis. Studies of individuals with isolated DAF and CD59 deficiencies indicate that hemolysis is more highly associated with CD59 deficiency. The basis for thrombosis in PNH is poorly understood. A mAb to C5 has been approved by the U.S. Food and Drug Administration (FDA) to treat PNH.

Control of Localized Complement Activation: Atypical Hemolytic–Uremic Syndrome, Age-Related Macular Degeneration

HUS is a rare disease characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. “Typical” HUS is found in children and is caused by *E. coli,* mainly O157:H7, producing a shiga-like toxin. Atypical HUS affects older children and adults and is not associated with an enteropathic infection. Recently, mutations in the complement regulatory proteins FH, FI, or CD46 have been identified in approximately 50% of patients with atypical HUS. FH mutations associated with HUS are clustered in the C-terminal end of the molecule in CCP20, a region that is required for FH binding to polyanions and endothelial cells. The ability of FH to regulate fluid-phase AP activation is not affected, and C3 levels are normal. These findings have led to the hypothesis that local complement regulation is essential for preventing renal disease following endothelial cell injury and that FH acts locally after binding to exposed matrix or damaged endothelium. FH and the membrane protein CD46 are both cofactors for FI-mediated cleavage of C3b.

An additional FH polymorphism (Tyr/His402) identified by genetic screening has been shown to be associated with the development of ARMD, a major cause of blindness in older adults.[63] This polymorphism is located in CCP7 in a region of FH that binds heparin and CRP.[28,64,65] As is the case for the mutations associated with atypical HUS (aHUS), this region of FH is not required for regulation of the fluid-phase AP convertase. ARMD develops when abnormal deposits of protein, termed *drusen,* form in the retina. Recent findings support the view that the local inflammatory response, including complement activation with MAC deposition, damages the retina, leading to vision loss. Additional genetic analyses identified protective FH and FI variants, as well as protective and high-risk polymorphisms, in the *FI* and *FB* genes. Although complement factors are not the only genes linked to ARMD, they are estimated to account for more than 50% of cases. Up to 10% of cases of advanced ARMD may carry a rare variation in FH or FI. These variants commonly lead to haploinsufficiency. These findings are driving the development of new complement-based therapeutics that could provide protection from a very common form of age-related visual loss.

COMPLEMENT IN DISEASE

Measurement of Complement in a Clinical Setting

Laboratory tests for complement include functional assays for the CP (CH_{50}), the AP (AH_{50}), and the LP (LP_{50}). Functional and antigenic assays for each of the individual components are available in specialty laboratories. The CH_{50} is a hemolytic assay, in which sheep erythrocytes sensitized with rabbit Ab are incubated with serial dilutions of the patient’s serum. The titer is the dilution at which 50% of the sheep erythrocytes are lysed. The CH_{50} requires all of the CP and terminal components (C1–C9). A comparable assay for the AP uses a buffer that blocks CP activation and employs rabbit erythrocytes in place of sensitized sheep erythrocytes. Rabbit erythrocytes spontaneously activate the human AP and are lysed in the assay. The AH_{50} requires all of the AP and terminal components (factor B, D and P and C3–C9). The combined use of the CH_{50} and AH_{50} is the most effective screening method for genetic deficiencies of complement components. Complete deficiency will generally result in titers of <5% in one or both assays. Because C3–C9 are common to both pathways, the combined results of the two assays can rapidly determine whether the deficiency is one of these shared components, one of the CP components (C1, C2, C4) or one of the AP components (factors B, D, P) (Fig. 21.8). Properdin deficiency results in low, but not absent, lysis in the AH_{50}, and patients with C9 deficiency may have values up to 30% of normal in the CH_{50}. Deficiencies of FH and FI and nephritic factors often result in very low C3 levels, leading to reduced titers in both assays.

LP function (and MBL deficiency) is determined by using a specific ELISA, in which the patient’s serum is placed into wells coated with mannan. Binding MBL and activation of the LP results in the deposition of C4b and C4d that are detected with mAbs. MBL levels may also be determined antigenically.

Heterozygous C1-INH deficiency, as described above, is associated with the clinical syndrome of HAE.[24] The diagnosis can be made on the basis of clinical findings and family history. C1-INH activity is reduced in these patients, and C4 protein is also low in 95% of patients, especially during attacks of edema. In type I HAE (85% of cases), C1-INH protein levels are low, but in type II HAE (15% of cases), an abnormal C1-INH protein is made, and antigenic levels are normal or elevated. There is an acquired form of C1-INH deficiency associated with lymphoma, in which low C1-INH is accompanied by decreased C1q as well as C4 and C2.

Complement levels may also be decreased in diseases or conditions in which complement is activated, leading to consumption. In contrast to genetic deficiencies, complement consumption characteristically results in low, but not absent, functional activity. In addition, multiple components of one or more pathways are expected to be low, and these decreased levels of complement are often correlated with disease activity. The most commonly used and most readily available complement tests are C3 and C4 protein and the CH_{50}. Diseases accompanied by CP activation

TABLE 21.4 Complement Test Interpretation

Pathway	CH_{50}	C4	C3	Related diseases
Classical pathway (CP)	↓	↓	↓	SLE, serum sickness, vasculitis, Subacute Bacterial Endocarditis, MPGN (type I)
Alternative pathway (AP)	↓	N	↓	Poststreptococcal glomerulonephritis, MPGN (type II)
Fluid-phase activation of the CP	↓	↓	N	C4NeF, HAE, cryoglobulinemia
Fluid-phase activation of the AP	↓	N	↓	FH or FI deficiency, C3NeF, MPGN (type II)
Acute-phase response	↑	↑	↑	Acute and chronic inflammation
Decreased CH_{50} (sample collection problems)	↓	N	N	Cryoglobulins, cold activation, sample mishandling; coagulation-associated activation
Decreased CH_{50} (biosynthetic)	↓	N	↓	Severe liver disease; decreased C3, C6, C9

N, normal; SLE, systemic lupus erythematosus; MPGN, membranoproliferative glomerulonephritis; HAE, hereditary angioedema; NeF, nephritic factor.

result in decreased CH_{50}, C4, and C3 levels. The AP is usually spared. These are primarily immune complex–associated diseases, both autoimmune and infectious, and are listed in Table 21.4. In addition, 20% of cases of acute renal allograft rejection are associated with decreased CH_{50} and C2. Another cause of selective CP activation is essentially a laboratory artifact, in which clotting of the blood sample in the cold is associated with consumption of the early CP. Plasma CH_{50} is normal, but the serum CH_{50} value is markedly decreased. C3 and C4 antigenic tests are normal, but their functional activity is lost.

The AP is activated in gram-negative sepsis, poststreptococcal glomerulonephritis, MPGN, IgA nephropathy, FH or FI deficiency, and PNH. Laboratory values may show decreased C3 with decreased or normal CH_{50}, and normal C4 levels (see Table 21.4). AP activation is not always reflected in decreased C3 because C3 is found at the highest concentration of all complement components and is an acute-phase reactant with elevated synthesis during disease states.

In clinical practice, evaluation of complement levels may be useful in a variety of circumstances. Initial consideration of complement deficiency may be appropriate in patients presenting with autoimmune conditions or repetitive pyogenic infections in the setting of a normal white blood cell (WBC) count and immunoglobulinemia (see Table 21.3). The complement profile can also be helpful in differential diagnoses of SLE and its look-alikes (see Table 21.4). Monitoring complement levels is frequently used to follow disease activity in patients with SLE. Complement levels may predict renal disease activity and may reflect a response to therapy in SLE. However, complement levels are rarely useful in isolation and should be taken in the context of clinical assessment and other laboratory values as reflected in disease activity index scores (*e.g.*, the Systemic Lupus Erythematosus Disease Activity Index 2000).

Role of Complement in Specific Immunological Diseases

Complement activation is involved in the pathogenesis of many immunological diseases. A general concept emerging from current research in this area is that most of the pathogenic effects of complement depend on the generation of C5a and the MAC. Further, it is becoming recognized that regardless of the initial activation mechanism, AP amplification is often needed to produce sufficient quantities of these mediators to cause disease. Finally, systems biology approaches are increasingly revealing that members of the complement cascade interact with other inflammatory mediators, resulting in diseases that are a product of complex gene–environment interactions, such as asthma and Alzheimer disease.

Systemic Lupus Erythematosus (Chapter 51)

CLINICAL PEARLS

Complement Tests for Diagnosis and Monitoring of Systemic Lupus Erythematosus (SLE)

A low C4 and C3 assist in the diagnosis of SLE.

Decreased C3 and C4 are associated with increased severity of disease, and especially with lupus nephritis.

On serial observations, decreasing C3 and C4 levels predict and help to establish an SLE flare-up.

Note: Decreases in C4 may precede decreases in C3.

Remission after treatment of lupus often shows return toward normal levels of C4, followed by increases in C3.

Note: Patients with SLE who have partial C4 deficiency may have persistently low C4 levels.

Complete absence of CH_{50} implies the existence of a hereditary deficiency of one of the classical complement pathway components, usually C1q, C4, or C2.

Complement plays a dual role in SLE.[56,57,66,67] There is a strong association of genetic deficiencies of C1q, C1r, C1s, C4, C2, and, to a lesser degree, C3 with SLE, indicating a protective role. Three main complement-dependent mechanisms have been proposed: (1) complement-dependent clearance of immune complexes; (2) modulating the adaptive immune system, particularly through the development and maintenance of self-tolerance in B lymphocytes; and (3) a requirement for complement in the clearance of apoptotic cells and potential autoantigens released from damaged cells. The pathogenesis of SLE results, in large part, from inflammatory response to immune complexes formed by autoantibodies (*e.g.*, Ab to double-stranded DNA [antidsDNA]) binding to antigens from dead and dying cells. However, complement activation is believed to play a pathogenic role in tissue damage induced by autoantibodies in SLE. There is evidence for complement activation in skin and renal lesions of patients with SLE, as well as in autoantibody-mediated hemolytic anemia and thrombocytopenia.

Antiphospholipid Syndrome (Chapter 61)

Antiphospholipid syndrome is characterized by antiphospholipid Ab, recurrent fetal loss, vascular thrombosis, and thrombocytopenia. Antiphospholipid Abs are found in 50% of patients with SLE, and thrombotic events occur in about 50% of them. Antiphospholipid Abs identified in patients without SLE have similar clinical consequences. Disease pathogenesis has been attributed to the procoagulant effects of antiphospholipid Abs. A mouse model of antiphospholipid Ab syndrome has been used to demonstrate that injection of pregnant mice with human IgG antiphospholipid Ab results in fetal loss and wasting. In this model, complement is required for pathogenesis, and treatment with complement inhibitors is protective. Studies in the mouse model are consistent with initial complement activation by antiphospholipid Ab bound to the decidua, followed by C5a generation and recruitment of neutrophils. The AP as well as the CP was required for pathology. Interestingly, C3 deposition in the decidua was decreased if neutrophils were depleted, suggesting an amplification pathway mediated either by tissue damage or by neutrophil release of complement components.

Rheumatoid Arthritis (Chapter 52)

Patients with RA generally have normal or elevated complement values systemically.[67,68] There is, however, evidence for local complement activation in joint fluid, in synovia, and in rheumatoid nodules. In addition to being elevated in the joints of patients with RA, complement activation products are also found in patients with osteoarthritis, SLE, Reiter syndrome, and gout. Concentrations of C3a and C5a in joint fluid are higher in RA than in other types of arthritis. An important role for complement activation in the pathogenesis of RA is suggested by studies in two animal models—collagen-induced arthritis and the K/BxN-derived Ab transfer model. In the first model, inflammatory joint disease was ameliorated by treatment with an Ab to C5 that blocks its cleavage, preventing generation of C5a and the MAC. In the second model, disease was prevented by genetic deficiency of factor B, but not C4, indicating an essential involvement of the AP.

Vasculitis (Chapters 58, 59)

Human vasculitides encompass a spectrum of disease mechanisms and clinical manifestations. Some, such as giant-cell arteritis and the antineutrophil cytoplasmic Ab (ANCA)–associated vasculitides, Wegener granulomatosis, microscopic polyangiitis, and Churg-Strauss syndrome, are not associated with local complement deposition or evidence of systemic complement depletion. Despite that, a "self-fueling inflammatory amplification loop," as a result of the generation of C5a by activated neutrophils and neutrophil priming by C5a, appears to drive necrotizing vascular injury. Additionally, in vasculitides associated with circulating immune complexes, C3b, MAC, and/or AP components are deposited in lesions, and complement profiles consistent with activation are found (see Table 21.4).

Immunological Renal Diseases (Chapter 68)

Complement activation is evident in most types of glomerulonephritis, with the site and pathway of activation dependent on the site of immune complex or autoantibody deposition. AP activation has been identified in IgA nephropathy, poststreptococcal glomerulonephritis, and MPGN type II. More recent results have implicated activation of the LP in IgA nephropathy. Glomerular deposition of MBL has been associated with greater histological damage and higher proteinuria.

MPGN is a chronic progressive form of glomerulonephritis characterized by production of enlarged glomerular tufts by endocapillary proliferation and thickening of glomerular capillaries. MPGN has been historically divided into three histological groups, designated type I, II, and III based on electron microscopy of the glomerular lesions. Complement activation has been detected in all forms of MPGN, with decreases in circulating complement component levels and the presence of C3 on biopsy, in addition to being seen with other glomerulonephritides (*e.g.*, SLE). Given that the historical classification of MPGN did not help delineate disease pathogenesis, MPGN is now increasingly been viewed as immunoglobulin-mediated (associated with CP activation) and non–immunoglobulin-mediated (associated with AP activation). Additionally, the term *C3 glomerulopathy* is being used to describe those cases of glomerular involvement secondary to the AP activation.

In glomerulonephritis secondary to immune complex disease (immunoglobulin-mediated, such as SLE and MPGN type I), complement activation is primarily by the CP, and C4 is detected along with C3 and IgG in glomerular deposits. Complement activation contributes to renal disease by attracting and activating inflammatory cells through the anaphylatoxin C5a and by direct damage to cells through the MAC. Pathology caused by inflammatory cell infiltration is predominant when subendothelial immune complex deposition and complement activation occur.

In contrast, in non–immunoglobulin-mediated glomerulonephritis (*e.g.*, MPGN type II), defects in the tightly regulated AP are believed to result in excessive activity of the C3 convertase. This can occur either in the presence of the C3 nephritic factor (C3Nef), a stabilizing autoantibody, or in the setting of deficient functional FH activity, either through mutations or acquired defects. C3NeF is a pathogenic autoantibody that binds to the AP C3 convertase (C3bBb), preventing its decay and regulation by FH and FI. Absence of functional FH results in unregulated C3 convertase activity, resulting in uncontrolled glomerular inflammation and renal disease. Understandably, such reclassification has helped target treatment, for example, by using plasma infusion or exchange and even the anti-C5 mAb eculizumab in certain cases.

Asthma (Chapter 41)

Asthma is a chronic inflammatory disease of the lung, in which Th2 responses to environmental allergens frequently play a critical role. The development of mice deficient in receptors for C3a and C5a has led to a new understanding of the roles of the complement anaphylatoxins in asthma. Several studies have demonstrated a correlation between C3a and C5a release in asthmatic lungs and the influx of eosinophils and neutrophils. C3-deficient and C3aR-deficient mice were protected from development of acute bronchoconstriction, airway inflammation, and airway hyperresponsiveness. C5a inhibition had similar effects on the response to challenge in an established allergic environment. However, in contradiction to these findings, C5 deficiency was genetically linked to susceptibility to experimental allergic asthma. Further studies found that C5a signaling (most likely through the C5aR on pulmonary DCs) during initial pulmonary exposure to allergen decreased Th2 cytokine and IgE production, thereby preventing the initiation of the allergic response. Thus it appears that both the C3a-C3aR and C5a-C5aR axes contribute to asthma pathogenesis. However, how disruption of their homeostatic roles on different immune cells versus the bronchial epithelium contributes to asthma pathogenesis remains to be understood.

Neurological Disease

Proteins from the complement system are normally found in the central nervous system (CNS) and the peripheral nervous systems. Low levels of hemolytic complement (0.25% of serum levels) can be measured in the cerebrospinal fluid if care is taken to stabilize it with gelatin during storage. Levels of anaphylatoxins are increased in the CNS when the blood–brain barrier is impaired. Complement proteins and regulatory proteins are synthesized by glial cells and astrocytes, and their synthesis is enhanced by inflammatory cytokines, such as IL-6. There is evidence both from human multiple sclerosis (MS) (Chapter 66) and the animal model, experimental allergic encephalitis (EAE), that complement activation with the generation of the MAC contributes to the demyelination in these diseases. Generation of the MAC can lead to oligodendrocyte death, generation of inflammatory mediators, or a repair process in which myelin synthesis is decreased. Complement activation on myelin and oligodendrocytes is initiated by antimyelin Ab or directly by myelin through the CP. There is evidence of MAC formation in the cerebrospinal fluid of patients with MS, and complement depletion, inhibition, and genetic deficiency are protective in rat and mouse models of EAE.

There is also evidence of complement activation in degenerative neurological conditions, such as Alzheimer disease. In Alzheimer disease, neurofibrillary tangles and senile plaques composed of β-amyloid and other proteins develop, resulting in neuronal loss and dementia with progressive loss of cognitive function. Complement activation products C1q, C4, C3, and MAC components, as well as clusterin (ApoJ) and vitronectin (S40), are found deposited in areas of β-amyloid, suggesting CP activation. Peptides derived from β-amyloid were shown to activate C1 directly by binding to the collagen-like domain. SAP, a component of all types of amyloid, including β-amyloid, activates the CP as well. There are limited data on the role of complement in the pathogenesis of Alzheimer disease, with some studies reporting enhanced disease following complement inhibition and another finding decreased inflammatory changes and neuronal degeneration in C1q deficiency. Finally, excessive complement activity, notably C4, has been implicated in the development of schizophrenia and has been associated with reduced numbers of synapses. This suggests that the role of complement proteins in neuropsychiatric illness extends beyond inflammation-mediated tissue damage.[69,70]

Ischemia/Reperfusion Injury

I/R injury refers to injury induced by inflammatory mediators, such as reactive oxygen intermediates produced by activated neutrophils, following the reperfusion of hypoxic tissue. Different pathways of complement activation may be important in different sites of injury, probably because of differences in expression of complement regulatory proteins and the nature of the tissue damage and the antigens exposed to the innate immune system. The primary complement mediators of tissue injury are C5a and the MAC acting locally and, in some cases, C5a acting systemically. In experimental renal I/R injury and in human tubular necrosis, the AP appears to be directly activated and neither Ab nor the CP is required. However, in intestinal I/R injury, the CP as well as the AP are required, and a natural IgM Ab to a newly exposed antigen on damaged endothelium initiates complement activation. In coronary artery ligation/reperfusion models, innate recognition of epitopes of ischemic tissue by MBL and CRP leads to lectin and CP activation, respectively.

COMPLEMENT-BASED THERAPEUTICS

The multiple roles of complement in inflammatory and autoimmune diseases make it an attractive target for therapeutic intervention. Recombinant complement inhibitors, inhibitory mAb, and peptide-based receptor inhibitors have been developed to block the detrimental effects of the complement activation fragments.[70] As described above, products of the complement cascade have many beneficial effects in host defense and the adaptive immune response. The detrimental effects of complement activation are, for the most part, associated with C5a and the MAC. Thus targeting either the generation of C5a or its association with C5aR might be expected to control inflammation while maintaining other important functions, such as opsonization. An anti-C5 mAb that prevents C5 cleavage (eculizumab) has been approved for human use in the treatment of PNH[70] and atypical HUS. It is also being evaluated for treatment of refractory glomerulonephritides with C3 deposition and severe Ab-mediated rejection after organ transplantation. Other drugs targeting the C5 pathway, as well as mAb directed to components of the AP (*e.g.*, factor D), are under investigation for ARMD. Peptides and mAb directed at the C5aR, as well as upstream of C3 convertase production, have shown promise in a number of inflammatory models in animals and are being evaluated for the treatment of sepsis, reperfusion injury, and asthma. Other approaches that are being developed will target complement regulatory proteins to specific cell or tissue targets. As the importance of this system is clarified in a variety of inflammatory diseases, it is likely that further research will establish new complement-based therapeutic agents for additional applications.

ON THE HORIZON

Future Directions in Complement Research

Functional analysis of polymorphisms and rare variants in complement proteins identified in genome-wide association studies (GWAS) and by next generation sequencing of inflammatory and autoimmune diseases will be functionally characterized to provide insight into pathogenesis and treatment.

Genetic sequencing of entire complement activation pathways and their regulators and receptors in patients with inflammatory and autoimmune diseases will reveal novel pathogenic mechanisms and approaches to diagnosis and therapy.

RNA sequence analysis will identify "up and down" regulation of complement proteins in human disease.

Structural analysis of complement protein complexes will lead to targeted small molecules to inhibit or enhance complement activation.

Therapeutic trials of existing agents and those in development will dramatically refine therapy of complement-mediated diseases.

Proteome studies in patients with infectious, inflammatory, and autoimmune diseases will reveal patterns of complement activation and biomarkers for diagnosis, disease activity, and monitoring responses to therapy.

MULTIPLE-CHOICE QUESTIONS

1. All of the following are features of the complement system EXCEPT for:
   A. It works in a few minutes and features a feedback loop.
   B. It can interact (bind to) almost any foreign material or self-debris.
   C. It is abundant in plasma but also is secreted locally by many cells.
   D. It has a specific memory system for prior interactions with microbes.

2. All of the following are true about a complete deficiency of a complement component in the activating cascade EXCEPT:
   A. A deficiency of C5, C6, C7, C8, or C9 usually presents with a neisserial infection.
   B. A deficiency of properdin whose gene is on the X chromosome also presents in males with a neisserial infection.
   C. A complete deficiency of C3 commonly presents with early age onset of recurrent viral, fungal, and/or protozoan infections.
   D. In the classical pathway (CP), up to C3 (C1q, C4, C2), recurrent bacterial infections and, particularly, autoimmunity (systemic lupus erythematosus [SLE]) are the two most common clinical scenarios.

3. Which of the following is FALSE relative to measuring C4 and C3 antigenic levels in patients with SLE?
   A. A low factor B antigenic level is commonly observed and is indicative of alternative pathway (AP) activation.
   B. Low C4 and C3 point to activation of the CP by immune complexes.
   C. Reduced C4 and C3 correlate with renal disease, DNA antibodies, and, overall, more severe disease.
   D. A rise in C4 and C3 to normal levels with immunosuppressive therapy is associated with a patient having better short-term and long-term clinical outcomes.

4. Which statement is FALSE about complement regulators/inhibitors?
   A. Abundant in plasma.
   B. Expressed ubiquitously on cell membranes.
   C. Haploinsufficiency of factor H or factor I is well tolerated and does not lead to human disease.
   D. A complete deficiency of plasma protein factor H (FH) or plasma enzyme factor I (FI) leads to overactivation of the alternative pathway (AP) and consumption of C3 (clinical presentation like that of C3 deficiency).

5. Which statement is FALSE about complement receptors:
   A. Complement receptors are abundant on neutrophils, monocytes, and B lymphocytes.
   B. Complement system does not participate in adaptive immunity other than by serving as a “complement” to immunoglobulin M (IgM)– and IgG-mediated events.
   C. Complement receptor one (CR1, CD35) is present on red blood cells, where it carries out immune adherence for C4b/C3b–coated materials and then takes them to the spleen and/or the liver for transfer to macrophages.
   D. Complement receptors and Fcγ receptors work together to mediate opsonization and ingestion of infectious bacteria and viruses.

Phagocyte Deficiencies

Steven M. Holland, Gülbü Uzel

We have learned a great deal about phagocytes since their discovery by Metchnikoff in 1905: Neutrophils, monocytes, macrophages, and eosinophils traffic to sites of infection or inflammation and engulf microorganisms and apoptotic cells as the lead players in the innate immune response.

NEUTROPHILS

Neutrophils, also known as *granulocytes* because of their numerous cytoplasmic granules, are crucial for the host defense against bacteria and fungi. They are bone marrow–derived, terminally differentiated cells incapable of further cellular division. They have a short life span in the circulation ($t_{1/2} \approx 7$ hours), but survive an additional 1–2 days in tissue. In peripheral blood, they are normally maintained at 3000–6000 cells/mm^3 and represent 30–50% of the circulating leukocytes. There are four pools of neutrophils *in vivo: (i)* the bone marrow pool (≈90% of the total); *(ii)* the circulating pool (≈3% of the total); *(iii)* the marginated pool (adherent to the endothelium, ≈4% of the total); and *(iv)* those located in the tissues as extravasated or exudative neutrophils. About 55–60% of bone marrow is dedicated to the production of neutrophils, producing around 10^{11} cells daily, but this is upregulatable in times of stress.

Myeloid cell differentiation is a complex stepwise process that typically extends over 2 weeks in bone marrow. The pluripotent stem cell, the precursor for all hematopoiesis, develops into lineage-committed progenitors proceeding to terminally differentiated distinct cells, all the while preserving and regenerating more pluripotent stem cells.[1]

PRODUCTION OF MACROPHAGES AND GRANULOCYTES

The pluripotent stem cell gives rise to the myeloid stem cell from which the colony-forming unit granulocyte/erythrocyte/macrophage/megakaryocyte (CFU-GEMM) is derived. Among the growth factors that are influential at this step are stem cell factor (SCF), interleukin-3 (IL-3), and granulocyte macrophage–colony-stimulating factor (GM-CSF).[2] CFU-GEMM further differentiates into the colony-forming unit–granulocyte macrophage (CFU-GM) under the continuing influence of these growth factors. The colony-forming unit–granulocyte (CFU-G), a neutrophil lineage committed precursor, is derived from CFU-GM under the control of IL-3, GM-CSF, and granulocyte–colony-stimulating factor (G-CSF). The myeloblast is formed from the CFU-G under the influence of GM-CSF and G-CSF and is the first morphologically distinct cell of the neutrophil lineage. Promyelocyte, myelocyte, metamyelocyte, band form, and mature neutrophil formation follow consecutively under the ongoing control of G-CSF and GM-CSF. The maturation process from stem cell to the myelocyte stage takes 4–6 days and an additional 5–7 days for the myelocyte to form the mature neutrophil, all in bone marrow.

Macrophage differentiation is similar to granulocyte differentiation in many respects. CFU-GM differentiates into the colony-forming unit–macrophage (CFU-M) followed by the formation of the monoblast, promonocyte, and monocyte under the influence of macrophage colony-stimulating factor (M-CSF).[3] After monocytes are released into blood, they circulate for 1–4 days before entering tissues, where they further differentiate into macrophages.

EVOLUTION OF NEUTROPHIL GRANULES

During myelopoiesis in bone marrow, the first granules form at about the promyelocyte stage, stain blue with the Wright or Romanowsky stain, and are called *primary granules* or *azurophilic granules*. Their formation ceases at the myelocyte stage, and they are distributed among the daughter cells. These primary granules contain microbicidal enzymes, including defensins, hydrolases, and proteases (Table 22.1). As the granulocyte precursors mature and divide, the number of primary granules per cell decreases. After the promyelocyte stage, secondary or specific granules form. In the mature neutrophil, they comprise about two-thirds of the granules. The secondary granules are less dense and contain cytochrome b_{558}, lysozyme, lactoferrin, and collagenase. The gelatinase-containing tertiary granule probably forms after the metamyelocyte stage and can be detected in the band form and the mature granulocyte.

DISORDERS OF NEUTROPHIL PRODUCTION

Chronic neutropenia refers to conditions with absolute neutrophil counts (ANCs) of less than 500 cells/μL lasting more than 6 months. Chronic neutropenia can have many etiologies, as listed in Table 22.2.

Severe Congenital Neutropenia and Cyclic Neutropenia

Kostmann originally described extensive northern Swedish kindred with both recessive and dominant neutropenia, but subsequently sporadic cases were added, making this a confusing melange of neutropenia syndromes.[4] Severe congenital neutropenia (SCN) is now known to be a heterogeneous group of disorders that present similarly. The genes recognized as mendelian causes of

TABLE 22.1 Neutrophil Granule Components

Granule	Contents	Properties
Primary (azurophilic) granules	*Lysosomal hydrolases* Myeloperoxidase Defensins Lysozyme Elastase Cathepsin G Azurocidin Proteinase 3 Bacterial—permeability increasing protein (BPI) *Acid hydrolases* Cathepsin B Cathepsin D β-Glycerophosphatase granulocyte β-Glucuronidase *N*-acetyl-β-glucosaminidase α-Mannosidase Other Collagenase	• First formed during myelopoiesis at promyelocyte stage • Appear blue when stained with Wright stain • Least mobilizable granule • Measure ≈ 0.8 µm • Defensins constitute 30–50% of granule contents • Augment the microbial damage initiated by reactive oxidants • Help digest dead microbes and host cells • BPI neutralizes gram-negative bacteria
Secondary (specific) granules	*Lysosomal hydrolases* Lysozyme *Other* Collagenase Gelatinase Lactoferrin Vitamin B_{12}–binding proteins Cytochrome b_{558} Histaminidase FMLF receptors C3bi receptors	• Synthesis begins at the myelocyte stage • These granules are specific to phagocytes • Measure ≈0.5 µm • Binding proteins deprive microorganisms of nutrients • Most are positively charged, enhancing cell surface
Tertiary (smaller) granules	*Acid hydrolases* Cathepsin B Cathepsin D β-Glycerophosphatase granulocyte β-Glucuronidase *N*-acetyl-β-glucosaminidase α-Mannosidase *Other* Gelatinase	• Heterogeneous population of organelles, including C-particles and secretory vesicles • Detected in the band form and mature neutrophils

TABLE 22.2 Causes of Neutropenia

Classification	Etiology
Hematological	Kostmann syndrome Severe congenital neutropenia Cyclic neutropenia Myelodysplastic syndrome Aplastic anemia Leukemia
Immunological/inflammatory disorders	Severe combined immunodeficiency (SCID) Hyper-IgM syndrome (CD40L) Chediak-Higashi syndrome Cartilage–hair hypoplasia Reticular dysgenesis Dyskeratosis congenita Autoimmune neutropenia Isoimmune neutropenia
Infections	Human immunodeficiency virus (HIV) Parvovirus Epstein-Barr virus Malaria Cytomegalovirus
Inborn errors of metabolism/ nutritional disorders	Gaucher disease Glycogen storage disease, type Ib Transcobalamin deficiency Vitamin B_{12}, folate deficiency
Other	Schwachman-Bodian-Diamond syndrome Idiopathic neutropenia Chemotherapy Radiation therapy Drugs (*e.g.,* vancomycin, chloramphenicol, sulfamethoxazole, clozapine) Toxins (*e.g.,* benzene) Dialysis Reticuloendothelial sequestration

neutropenia are the neutrophil elastase (*ELANE* or *ELA2*), *HAX1*, *G6PC3*, *GFI1*, *GATA2*, *JAGN1*, *VPS45* genes, and activating mutations in the Wiskott–Aldrich syndrome (*WAS*) gene.

SCN is usually diagnosed in the neonatal period or early infancy because of the occurrence of life-threatening pyogenic infections, cellulitis, stomatitis, peritonitis, perirectal abscess, or meningitis. The most common bacteria isolated are *Staphylococcus aureus*, *Escherichia coli*, and *Pseudomonas aeruginosa.* Patients usually have an ANC below 200 cells/µL, mild anemia, and hypergammaglobulinemia, sometimes with eosinophilia and monocytosis. SCN represents an impairment of myeloid differentiation because of maturational arrest of neutrophil precursors at the level of promyelocytes or myelocytes in bone marrow. A subset of patients with SCN (7.5–10%) subsequently develops a myelodysplastic syndrome (MDS) or acute myeloid leukemia (AML), which has been associated with acquired truncation mutations of the G-CSF receptor (G-CSFR).

The majority of patients with SCN have heterozygous mutations in the neutrophil elastase (*ELANE*, formerly *ELA2*).[4] The clinically fascinating cyclic form of this disorder has oscillating neutrophil counts with 21-day cycles, hence the name cyclic neutropenia (CN). These mutations are transmitted as autosomal dominant mutations but also occur spontaneously. There is no clear genotype–phenotype correlation between specific *ELANE* mutations that lead to CN as opposed to SCN. These typically missense mutations lead to intracellular accumulation of mutant proteins that are inappropriately trafficked into azurophilic granules.[5] This mutated, aberrantly folded protein is thought to contribute to neutrophil precursor apoptosis and the clinical phenotype of neutropenia, but the mechanisms by which this occurs are still somewhat obscure. Treatment with subcutaneous G-CSF can typically increase the ANC above 1000 cells/µL, with a decrease in the frequency of infections and significant clinical improvement overall.[6] Patients with SCN who have received long-term G-CSF therapy are at an increased risk of developing AML or MDS, which correlates with overall G-CSF responsiveness.

Homozygous loss-of-function mutations in *HAX1* account for the majority of recessive cases of SCN,[7] some of which were in original pedigree described by Kostmann. Patients may have isolated SCN or associated neurological problems (cognitive impairment, developmental delay, or epilepsy), depending on which isoform of *HAX1* is mutated. Patients with mutations affecting isoform A have only SCN, as opposed to patients with mutations affecting both isoforms (A and B), who develop neurological problems in addition to SCN.[8]

Dominant zinc finger mutations disabling transcriptional repressor activity of the *growth factor independent 1* (*GFI1*) gene have been described in a few patients with SCN.[4] *GFI1* is a transcriptional repressor prooncogene controlling normal hematopoietic cell differentiation and also regulates *ELANE* as well as several of the CAAT enhancer binding proteins (C/EBP). Mutations in *GFI1* are also associated with aberrations in lymphoid and myeloid cells, leading to a circulating population of immature myeloid cells. *Gfi1* knock-out mice have impaired T-helper type 2 (Th2) regulation and B-cell, Th17, and dendritic-cell (DC) differentiation.

Mutations in the *glucose-6-phosphatase catalytic subunit 3 (G6PC3)* gene complex cause another form of SCN along with developmental and somatic problems.[9] *G6PC3* encodes glucose-6-phosphatase-β, which hydrolyzes glucose-6-phosphate (G6P) in the final step of gluconeogenesis and glycogenolysis. It is coupled to a glucose transporter (G6PT) that facilitates G6P transport from the cytoplasm to the endoplasmic reticulum. Mutations in the *G6PT* gene lead to glycogen storage disease type Ib, which has variable neutropenia and infections and other complications, such as liver adenomas, growth retardation, osteoporosis, polycystic ovaries, and inflammatory bowel disease (IBD). Children with these complications have increased susceptibility to bacterial infections and cardiovascular abnormalities, including prominent ectatic superficial veins.

Shwachman-Bodian-Diamond Syndrome

Shwachman-Bodian-Diamond syndrome (SBDS) was first described in 1964 as a disorder with pancreatic exocrine insufficiency and bone marrow dysfunction. Currently, it is recognized as the second most common cause of inherited exocrine pancreatic insufficiency after cystic fibrosis. It is autosomal recessive (located at 7q11) with an estimated incidence of 0.5–1/100 000.[10] The SDBS protein belongs to a highly conserved protein family involved in RNA metabolism. Mutations cause defects in the development of the exocrine pancreas, hematopoiesis, and chondrogenesis. Recurring mutations result from gene conversion caused by recombination with a pseudogene in 89% of unrelated patients; 60% carry two converted alleles. (Pseudogene conversion is also the cause of the majority of cases of $p47^{phox}$-deficient chronic granulomatous disease [CGD].)

Patients present with recurrent infections, failure to thrive, hematopoietic dysfunction, metaphyseal dysostosis, growth retardation, and fatty replacement of the pancreas. Most patients have mild neutropenia, and a few have neutrophil counts below 500 cells/μL, which can be intermittent or chronic.[11] Anemia and thrombocytopenia are associated with neutropenia. Congenital aplastic anemia is an unusual presentation. Upper and lower respiratory tract pyogenic infections are common and related to neutropenia. Short ribs with broadened anterior ends are common radiological findings, along with metaphyseal dyschondroplasia of the femoral head. The diagnosis is suggested by neutropenia, radiological findings, and abnormal pancreatic exocrine function. It is confirmed by gene sequencing.

Autoimmune Neutropenia

Autoimmune neutropenia (AIN) is caused by peripheral destruction of neutrophils as a result of granulocyte-specific autoantibodies.[12]

Primary Autoimmune Neutropenia

Primary AIN is seen in infancy unassociated with other systemic immune-mediated disorders and is the most common form of neutropenia, equally affecting boys and girls at around 1/100 000.[12] The average age at diagnosis is 8 months. The majority present with mild skin and upper respiratory tract infections; some patients remain asymptomatic despite low neutrophil counts. The majority of patients have a neutrophil count greater than 500 cells/μL at the time of diagnosis, but the ANCs may transiently increase two- to threefold during severe infection. Bone marrow shows normal to increased cellularity. Myeloid precursors typically reach the myelocyte/metamyelocyte stage. Phagocytosed granulocytes in bone marrow may indicate removal of sensitized granulocytes there. Granulocyte-specific antibodies are detected by direct granulocyte immunofluorescence testing (D-GIFT), the vast majority of which are immunoglobulin G (IgG) against glycoproteins of the granulocyte membrane designated neutrophil antigens (NAs). NAs are located on IgG receptor IIA or IIIB (FcγRIIa and FcγRIIIb).

AIN is generally self-limiting. Disappearance of the antibodies from the circulation precedes normalization of neutrophil counts. Prophylactic antibiotic treatment should be reserved for those with recurrent infections. Alternative treatment strategies for severe infections and in the setting of emergency surgical interventions include high-dose intravenous immunoglobulin (IVIG), corticosteroids, and G-CSF, with the latter being the most effective at increasing the ANC.

Secondary Autoimmune Neutropenia

Secondary AIN can be seen at any age and has a more variable clinical course. Hepatitis, systemic lupus erythematosus (SLE), or Hodgkin disease may underlie it and cause other autoimmune problems as well. These antineutrophil antibodies (ANAs) have pan-FcγRIII specificity. CD18/CD11b antibodies have been detected in a subset of patients with secondary AIN. This neutropenia responds poorly to most therapies.

Alloimmune Neonatal Neutropenia

First described by Lalezari in 1966, alloimmune neonatal neutropenia (ANN) is caused by the transplacental transfer of maternal antibodies against the fetal neutrophil antigens NA1, NA2, and NB1, leading to immune destruction of neonatal neutrophils.[13] These complement-activating antineutrophil IgG antibodies can be detected in about 1/500 live births. Antibody coated neutrophils in ANN are phagocytosed by the reticuloendothelial system and removed from circulation, leaving the neutropenic neonate at risk for infections. Omphalitis, cellulitis, and pneumonia typically occur within the first 2 weeks of life in association with neutropenia. Diagnosis can be made by detection of neutrophil-specific alloantibodies in the maternal serum. ANN responds to G-CSF or high-dose IVIG, but most patients improve without specific treatment in a few weeks to 6 months with waning of maternal antibody.

DEFECTS OF LEUKOCYTE ADHESION

Migration of circulating leukocytes from the bloodstream into tissues depends on complex bidirectional interactions between leukocytes and endothelial cells (Chapter 11). The initial steps involve the activation of circulating leukocytes by signal molecules released from inflamed tissues or from the bacteria themselves.

After activation by chemotactic factors, such as the complement fragment C5a, IL-8, leukotriene B4 (LTB4), or the bacterial product formyl-methionyl-leucyl-phenylalanine (fMLF), leukocytes rapidly become adhesive to the endothelium, other leukocytes, or laboratory surfaces. The activation process involves translocation of subcellular granules containing adhesion molecules (CD18/CD11b) to the polymorphonuclear leukocyte (PMN) surface and qualitative alterations in the adhesion molecules constitutively expressed on the plasma membrane. Adhesion and transmigration of leukocytes occur as a result of interactions between three groups of molecules: leukocyte integrins, endothelial intercellular adhesion molecules (ICAMs, members of the immunoglobulin supergene family), and glycosaminoglycans or selectins (Fig. 22.1). The first step in targeting PMNs to inflamed tissues is the rolling or tethering of PMNs on the endothelium of postcapillary venules.[14] This is attributed to the interactions between CD15s (sialyl Lewis^{X} or SLe^{X}) expressed on the leukocyte surface and P-selectin or E-selectin—members of the selectin family of adhesion molecules—expressed on the vascular endothelium. In addition, L-selectin on the leukocyte surface interacts with its counterligands P-selectin, CD34, glyCAM-1, and other glycoproteins located on the endothelial surface. *Rolling*, a relatively low affinity interaction mediated by selectins, is followed by *firm adhesion*, which is a high affinity interaction between integrins on the neutrophil and ICAMs on the endothelium. Adhesion is followed by the transmigration of neutrophils between endothelial cells out to the extracellular matrix (ECM).

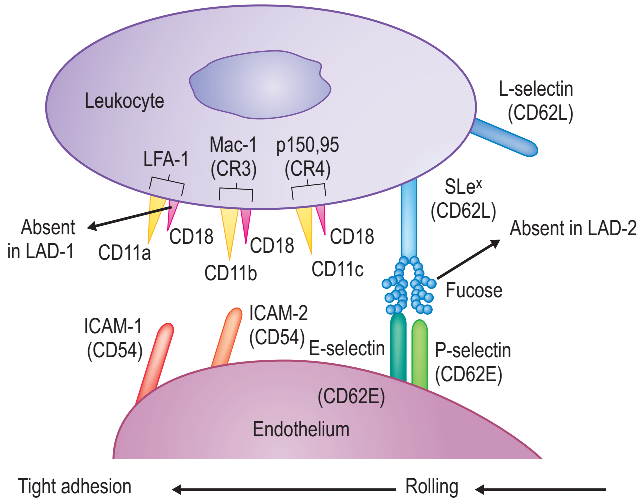

FIG 22.1 Leukocyte Adhesion to Nonlymphoid Endothelium. Selectins (L-selectin/CD62L, P-selectin/CD62P, and E-selectin/CD62E), integrins (CD18/CD11a or LFA-1, CD18/CD11b or Mac-1, and CD18/CD11c or p150,95), and intercellular adhesion molecules (ICAMs) are involved in leukocyte adhesion to the nonlymphoid endothelium. Rolling, the initial step of leukocyte adhesion, is mediated by the interactions of E-selectin and P-selectin on endothelial surfaces with the sialyl Lewis^{x} (SLe^{x} or CD15s) of leukocytes as well as L-selectin on the leukocyte surfaces with its counterligands CD34 or glyCAM-1. This low-affinity tethering or rolling facilitates tight adhesion as a result of the interactions of leukocyte function–associated antigen-1 (LFA-1) with ICAM-1 or ICAM-2 and Mac-1 with ICAM-2. CD18 is the molecule that is missing or dysfunctional in leukocyte adhesion defect-1 (LAD-1); SLe^{x} is the missing molecule in LAD-2.

Leukocyte Adhesion Defect-1

In the 1970s, infants and children were recognized with severe, recurrent life-threatening bacterial infections affecting the skin, gingiva, and lungs. A common clinical feature was delayed separation of the umbilical stump with severe omphalitis. These patients were shown to have defects in membrane expression of the leukocyte adhesion glycoproteins of the integrin superfamily.[15,16]

Integrins are noncovalently associated, heterodimeric cell surface receptors, comprising one α subunit (CD11a, CD11b, or CD11c) and a common β chain (CD18), which is required for surface expression of the CD11 chains. These proteins mediate leukocyte adhesion to the endothelium and other leukocytes. Leukocyte adhesion defect-1 (LAD-1) results from mutations in the CD18 gene (*ITGB2*), located on chromosome 21q22. Patients with LAD-1 have defective polymorphonuclear cell adherence, leading to defective chemotaxis and trafficking, as well as low natural killer (NK) and cytotoxic T-lymphocyte (CTL) activity. The absence of CR3 leads to loss of complement-mediated phagocytosis and bacterial killing. LAD-1 is often manifested by delayed umbilical cord separation, omphalitis, persistent leukocytosis, destructive periodontitis, and recurrent infections with *S. aureus*, *Pseudomonas aeruginosa*, and *Klebsiella* spp. Patients with some residual CD18 expression and function (*i.e.*, hypomorphic mutations) live beyond childhood with less frequent or severe infections and do not typically have delayed umbilical cord separation. Persistent neutrophil leukocytosis (usually >15 000 cells/μL) in the absence of infection is common in all patients, driven by both low-level ongoing infection and impaired exit of neutrophils from the circulation. Oral ulcers, severe periodontitis, gingivitis with apical bone loss (Fig. 22.2), and eventual loss of permanent teeth are major problems in LAD-1 and reflect excessive IL-17 expression by CD4 T cells as a result of uninhibited IL-23 production by tissue macrophages.[17] Necrotizing cutaneous ulcers with delayed wound healing and lingering eschar formation are common (Fig. 22.3). Defective chemotaxis and adhesion mean that leukocytes fail to migrate to sites of infection, accounting for the inability to form pus and erythema at the site of infection. Biopsies of the ulcers

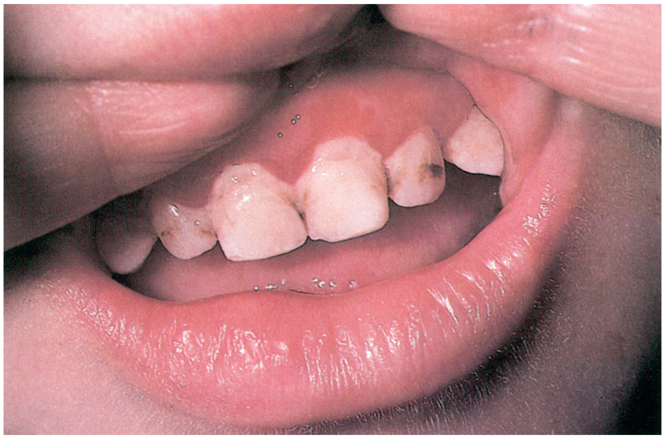

FIG 22.2 Oral Pathology in a Patient With Leukocyte Adhesion Defect-1 (LAD-1). Gingivitis and severe periodontitis are hallmarks of LAD-1.

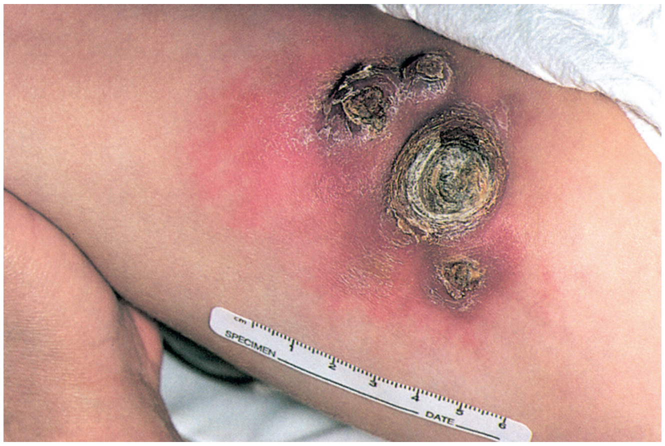

FIG 22.3 **Skin Infection of a Patient With Leukocyte Adhesion Defect-1 (LAD-1).** Failure to form pus, inability to demarcate the fibrotic skin debris, and limited inflammation.

characteristically show poorly formed granulation tissue and scant fibrinous exudate without neutrophils. Ulcerative gastrointestinal (GI) disorders resembling idiopathic IBD are also recognized in LAD-1, especially as patients grow older.

Although most cases of CD18 deficiency are homozygous, compound heterozygotes also occur.[18] The diagnosis is usually made by flow cytometric analysis of neutrophils showing decreased or absent CD18 and its associated heterodimers: CD11a, CD11b, and CD11c, and confirmed by mutational analysis of *ITGB2*. More subtle phenotypes can be detected by testing for mobilization of CD18 complexes, such as CD18/CD11b from neutrophils upon cellular stimulation. Definitive therapy of LAD-1 is bone marrow transplantation. Infections must be managed aggressively, since inflammatory responses and clinical signs are unreliable in these patients with profoundly impaired innate immune responses. Surgery is often essential for debridement of nonhealing ulcers, which frequently need tissue grafts, but immunomodulation of the affected cytokine pathways may also be helpful. Although not correcting the underlying gene defect, but reflecting the excessive production of IL-23 and IL-17 at sites of inflammation that is associated with severe oral ulcers, periodontitis and bone loss, a patient with moderate LAD-1 (34% of control CD18 activity) was treated with ustekinumab, which blocks IL-23-dependent production of IL-17. After one year of treatment the patient's severe chronic periodontitis and a deep sacral ulcer had resolved without serious infections or adverse reaction. This approach to therapy offers additional insight into the complex pathophysiology of LAD-1 inflammation and suggests the possibility of novel therapeutic approaches to symptomatic management.[18a]

KEY CONCEPTS

Leukocyte Adhesion Defect (LAD)

- Three types of adhesion defect are known: LAD-1, -2, and -3. There are two phenotypes for LAD-1: moderate and severe.
- LAD-1 results from mutations in CD18; LAD-2 is caused by mutations in sialyl Lewis^X (CD15s); LAD-3 results from mutations in *FERMT3*.
- High white blood cell count, delayed umbilical cord separation, recurrent bacterial infections, skin ulcers, defective wound healing, gingivitis, and periodontitis are the hallmarks of LAD-1.

Leukocyte Adhesion Defect-2

A distinct defect of leukocyte adhesion with susceptibility to infection was described by Etzioni et al. in 1992 and named LAD-2.[15,19] It is characterized by growth retardation and mental retardation, hypotonia, seizures, dysmorphic features, strabismus, and persistent periodontitis. In contrast to LAD-1, wound healing is not impaired, nor is the susceptibility to bacterial infections as severe. Hypofucosylation of the protein CD15s (sialyl Lewis^X, SLe^X) on neutrophils impairs the rolling step of neutrophil adhesion. The underlying defect is in guanosine diphosphate (GDP)–fucose biosynthesis, resulting from mutations in the GDP–fucose transporter-1 (*FUCT1* or *SLC35C1*), hence the designation of this disease as a congenital disorder of glycosylation IIc (CDGIIc). In addition to severe impairment in neutrophil migration as in LAD-1, lymphocyte homing to skin is also defective. Patients with LAD-2 have had relatively mild courses of infections with several pneumonias and superinfection of varicella lesions,[19] and some have reportedly improved with fucose supplementation. In addition to SLe^X, fucosylated blood group antigens are also affected, leading to the Bombay blood group phenotype (lack of the H antigen) and Lewis a^-b^- in these patients. Absence of CD15 on patient neutrophils can be detected by flow cytometry. Effective and prompt treatment of infections is central to the management of LAD-2.

Leukocyte Adhesion Defect-3

Following the elucidation of LAD-1 and LAD-2, another leukocyte adhesion deficiency was recognized, initially named LAD-1/variant (LAD-1v), now LAD-3. It had a distinct infantile bleeding diathesis similar to Glanzmann-type thrombasthenia along with defective leukocyte adhesion.[20] Although CD18/CD11a (lymphocyte function–associated antigen-1 [LFA-1] or $\alpha_1\beta_2$) is the main integrin on leukocytes, $\alpha_{IIb}\beta_3$ (also called *GPIIb-IIIa*) allows platelets to bind fibrinogen to promote clotting. This was initially described in Turkish patients and ascribed to *FERMT3*, which encodes KINDLIN3, an adaptor protein expressed in hematopoietic cells that regulates integrin activation.[21,22] KINDLIN3 activates integrins through binding to distinct motifs on the short tails of the integrin β subunits. Phenotypically, leukocytes and platelets in LAD-3 have defective β_3, β_2, and β_1 integrin activation as a result of loss of "inside out" or chemokine-mediated LFA-1 activation and intrinsic LFA-1/$\alpha_1\beta_2$ adhesiveness. In addition, these cells have decreased adherence to endothelial cells and reduced expression of the Rap-1 guanine nucleotide exchange factor, CalDAG-GEFI (CDGI). Based on the location and severity of mutation, LAD-3 leukocytes may also display loss of adhesion to vascular cell adhesion molecule-1 (VCAM-1). LAD-3 platelets have decreased binding to soluble fibrinogen, do not respond properly to thrombin via thrombin receptors (PARs), and therefore have poor platelet granule secretion through integrin activation. Bone marrow transplantation is necessary and curative.

CHRONIC GRANULOMATOUS DISEASE

CGD characterized by recurrent infections and hypergammaglobulinemia was first described in 1954. CGD results from defective phagocyte superoxide production leading to impaired microbial killing. It comprises five genotypes with a common phenotype (Table 22.3), characterized by recurrent severe bacterial and fungal infections and tissue granuloma formation.[23] CGD occurs at around 0.5–1/100 000 births. It is inherited in X-linked

TABLE 22.3 Genotype–Phenotype Correlations in X-Linked Chronic Granulomatous Disease (CGD)

	X91^0	X91$^-$	X91$^+$

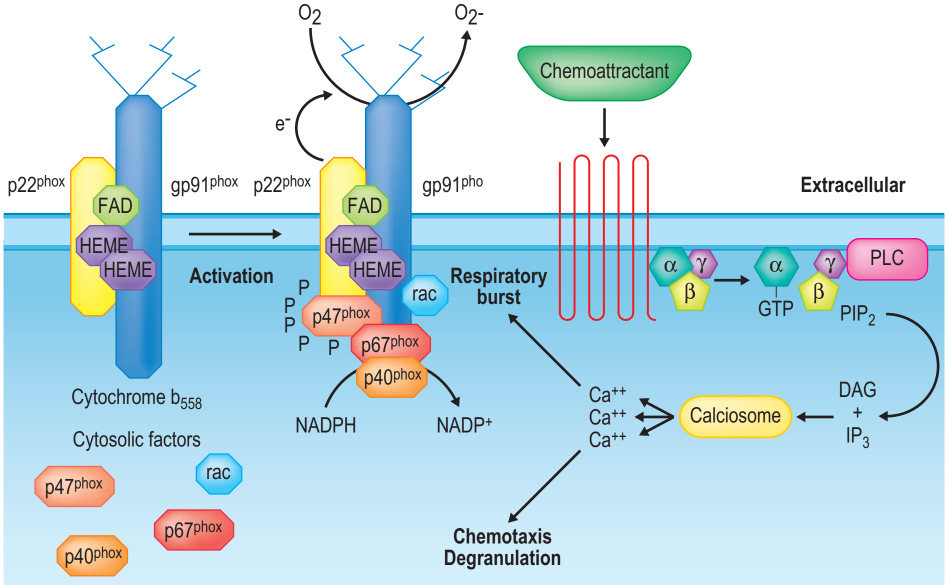

FIG 22.4 **Schematic Representation of the Nicotinamide Adenine Dinucleotide Phosphate (NADPH) Oxidase System.** Chemoattractants interact with their receptors on the neutrophil surface, leading to an increase in intracellular calcium concentration. This activation results in the assembly of the NADPH oxidase complex following phosphorylation of cytosolic factors. This, in turn, leads to superoxide production. DAG, diacylglycerol; PIP$_2$, phosphatidylinositol bisphosphate; IP$_3$, inositol triphosphate; α, β, γ, subunits of the guanosine triphosphate (GTP)–coupled receptors.

and autosomal recessive patterns, with the relative frequencies of recessive disease depending on the rates of local consanguinity. In the United States, the X-linked form accounts for about 65% of cases and the autosomal recessive p47^{phox} (phagocyte oxidase) deficiency for about 25%.

Patients with CGD often present with pneumonia, liver abscess, skin infections, lymphadenitis, or osteomyelitis; bacteremia is relatively uncommon. Initial presentation with IBD is not unusual. Exuberant tissue granuloma formation at the sites of infection, at surgical wounds, and in hollow viscera is a frequent problem seen more often in patients with the X-linked form of CGD.

The NADPH Oxidase and Its Activity

The nicotinamide adenine dinucleotide phosphate (NADPH) oxidase is a multicomponent system that transfers an electron to molecular oxygen by way of FAD and heme to form superoxide (O_2^-) (Fig. 22.4). Cytochrome b$_{558}$ is a membrane-bound heterodimer lodged in the wall of the secondary granules; the large glycosylated β subunit is gp91^{phox} and the small nonglycosylated α subunit is p22^{phox}. The cytoplasmic tail of gp91^{phox} binds FAD, heme, and NADPH, which are required for electron transfer to oxygen (O_2). Neutrophil stimulation leads to aggregation and phosphorylation of p47^{phox}, p67^{phox}, p40^{phox}, and the small guanosine triphosphate (GTP)–binding proteins RAC1/RAC2, which dock with the cytochrome at the membrane through binding of p47^{phox} and p22^{phox}.

Segal et al. showed that much of the killing effect of neutrophils is, in fact, carried out by proteases, enhanced by NADPH oxidase activity.[24] Charge created by electron flux across the membrane is compensated mostly by K^+ flux, which enhances microbial killing. Papayannopoulos and Zychlinksy identified neutrophil extracellular traps (NETs; extruded DNA with attached antimicrobial peptides), which depend on superoxide generation and are deficient in CGD.[25]

Mutations Leading to CGD

X-Linked CGD

The most common form of CGD is caused by mutations in *CYBB*, which encodes gp91^{phox} (located at Xp21.1) (see Table 22.3). Mutations include deletions (22.2%), insertions (7%), deletion/insertions (1.5%), nonsense (29.8%), missense (19.4%), splice sites (19.5%), and promoters (0.6%).[26] The spontaneous mutation rate is approximately 11%. With large interstitial deletions adjacent genes may be deleted as well, leading to complex phenotypes. Telomeric deletions cause McLeod syndrome (*KX*, or Kell antigen deletion), Duchenne muscular dystrophy (*DMD*), and X-linked retinitis pigmentosa (*RPGR*) along with CGD.[27] McLeod syndrome includes absent erythrocyte Kx protein and diminished levels of Kell blood group antigens. Patients may eventually develop progressive neurodegenerative symptoms, such as areflexia, dystonia, and choreiform movements. In patients with McLeod syndrome, anti-Kx and anti-Km antibodies are formed when transfusions are given, making future transfusions extremely difficult. Deletions centromeric from *CYBB* may cause ornithine decarboxylase deficiency along with CGD.[28]

Autosomal Recessive CGD

Mutations in p47*phox* (*NCF1*, located at 7q11.23) cause the majority of the recessive cases of CGD, around 25%, usually caused by homozygous deletions of the canonical GT splice site at the start of exon 2.[29] p22*phox* (*CYBA*, located at 16q24) and p67*phox* (*NCF2*, located at 1q25) are responsible for less than 5% of CGD cases each. p40*phox* (*NCF4*, located at 22q13.1) deficiency has been reported in a boy with early-onset severe granulomatous fistulizing colitis without a significant infectious phenotype.[30] No autosomal dominant cases of CGD have been identified.

Clinical Manifestations of CGD

The first severe infection usually occurs in infancy or childhood but can also occur in adulthood. Later diagnoses usually are seen in patients with residual superoxide production, either hypomorphic gp91*phox* or p47*phox* deficiency.[23,31] The constellation of signs and symptoms that suggest CGD range from failure to thrive, to IBD, to visceral abscesses, to recurrent sinopulmonary infections, to characteristic infections. Infections are most commonly pneumonia, lymphadenitis, liver abscess, skin abscess, perianal abscess, and osteomyelitis. As in other neutrophil defects, the most common pathogen is *S. aureus.* Characteristic infections are caused by catalase-positive organisms such as *S. aureus*, *Burkholderia cepacia* complex, *Serratia marcescens*, *Nocardia* spp., and *Aspergillus* spp. (Fig. 22.5).

Staphylococcal liver abscesses in CGD are dense and necrotic and cause significant morbidity. Their fibrocaseous consistency means that percutaneous drainage was rarely successful, and open surgery was required. However, combined steroid and antibiotic therapy of CGD liver abscess has now become the preferred approach in many centers.[32] Liver involvement leading to portal hypertension is the likely cause of the splenomegaly commonly seen in CGD and is also closely tied to mortality.[33]

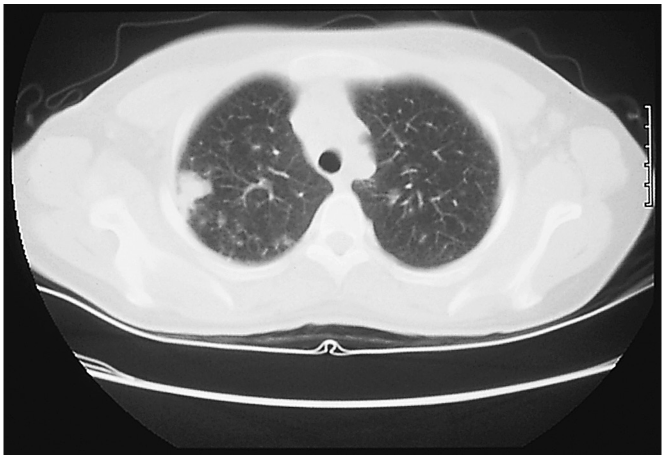

FIG 22.5 **Computed Tomography (CT) Scan of the Lungs of a Patient With Chronic Granulomatous Disease (CGD) and *Aspergillus* Pneumonia.** *Aspergillus* pneumonia is often a peripheral consolidation in the lung parenchyma.

Pulmonary aspergillosis remains a major cause of death in CGD.[23] *Aspergillus fumigatus* is the most commonly isolated fungus, but it is now easily and successfully treated with azole antifungals. In contrast, *A. nidulans* and *A. viridinutans*, species with low pathogenicity in the normal host, cause severe disease in CGD.[34,35] Surgical resection of these infections is often required. *Aspergillus* infections in CGD are often unaccompanied by fever and leukocytosis.[34] Acute diffuse pulmonary fungal infection in CGD is referred to as "mulch pneumonitis," characterized by fever, hypoxia, and diffuse pulmonary infiltrates caused by inhalation of fungi, typically during mulching, leaf raking, or gardening.[36] This syndrome can be the initial presentation of CGD in older children and adults and is important to recognize, since it best responds to a combination of antifungals and steroids.

Septicemia is relatively uncommon but may occur with *B. cepacia* complex and *Chromobacterium violaceum*. *Granulibacter bethesdensis* is a pathognomonic gram-negative rod that causes chronic necrotic lymph node and spleen involvement in CGD.[37]

Inflammatory granuloma formation is one of the hallmarks of CGD. Pyloric outlet obstruction, bladder outlet obstruction, and ureteral obstruction are common. Crohn-like IBD affects between 30–50% of patients, predominantly X-linked, and may involve the esophagus (Fig. 22.6), jejunum, ileum, cecum, rectum, and perirectal area.[38] GI manifestations can include diarrhea,

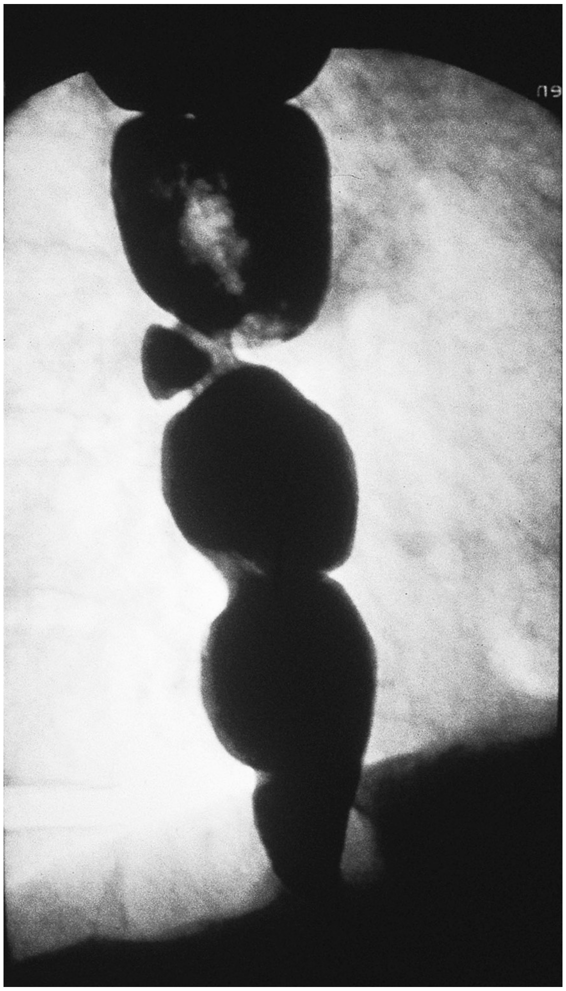

FIG 22.6 **Esophageal Involvement in Chronic Granulomatous Disease (CGD).** Esophageal strictures caused by granuloma formation as shown by barium swallow.

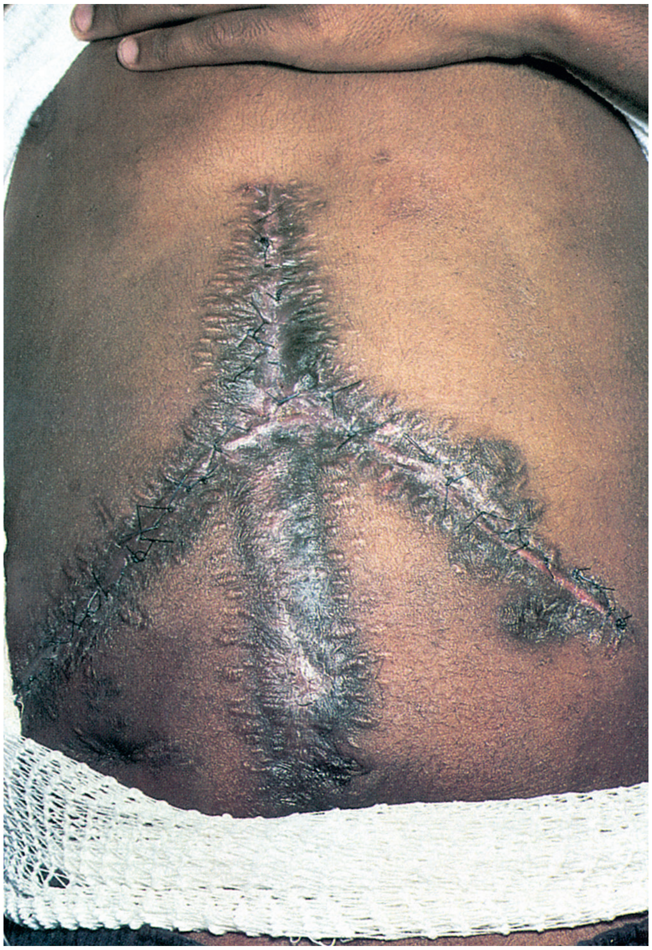

FIG 22.7 **Exuberant Granuloma Formation in Chronic Granulomatous Disease (CGD).** Wound dehiscence and impaired wound healing at surgical incision sites as a result of dysregulated inflammatory responses in a patient with X-linked CGD.

malabsorption, abdominal pain, growth delay, and hypoalbuminemia. The median age of initial GI manifestations is 5 years, and abdominal pain is common. Interestingly, GI involvement has no effect on mortality, is not associated with liver disease, and is unaffected by the use of interferon-γ (IFN-γ).[31,33,38]

Granulomata respond very well to steroids and often require a slow taper over several weeks to months. Exuberant formation of granulation tissue and dysregulated cutaneous inflammatory responses lead to wound dehiscence and impaired wound healing (Fig. 22.7). Autoimmune and rheumatological problems have been reported at higher than normal levels in patients with CGD.[39]

A comprehensive study of 287 patients with CGD from 244 kindred correlated the production of reactive oxygen intermediates with survival.[31] Patients with residual superoxide production had significantly better long-term survival compared with patients without residual superoxide production. Confirming the importance of this association, there was a direct correlation between the degree of superoxide and survival. Consistent with their previously recognized milder disease and better survival, patients with mutations in p47^{phox} had significant residual superoxide production. For those with gp91^{phox} mutations, the findings were more surprising. Patients with X-linked CGD with residual superoxide production were those with missense or splice mutations in the first 309 amino acids of gp91^{phox}. Those with missense mutations involving amino acids 310–587 had no residual superoxide production, regardless of protein levels. Therefore identification of the specific molecular subtype of CGD and specific mutation has important implications for severity and survival. Interestingly, mortality curves did not diverge until after age 20 years, suggesting that residual superoxide production determines later toxicities, such as liver dysfunction, not early childhood mortality from infection. It is critical to keep in mind that this comprehensive study included data from patients followed for up to 30 years—that is, a significant number of patients were born before the advent of modern antimicrobials. Therefore survival of a child born in the current age and who receives ideal management may well exceed that in the reported population.

CLINICAL PEARLS

Chronic Granulomatous Disease (CGD)

- CGD comprises a group of five inherited disorders with a common phenotype.
- Infections with catalase-positive bacteria and fungi and granuloma formation in the gastrointestinal and urinary tract are major problems in CGD.
- Oral prophylactic antibiotics and subcutaneous interferon (IFN)-γ injections three times a week are currently recommended for CGD.
- Diagnosis can be made via nitroblue tetrazolium (NBT) test or dihydrorhodamine (DHR) assay, the latter being a more sensitive diagnostic tool.
- Bone marrow transplantation is highly effective and curative.

Diagnosis of CGD

The diagnosis of CGD is most easily established by the dihydrorhodamine (DHR) assay, which measures the hydrogen peroxide–dependent conversion of DHR 123 to rhodamine 123, which is accompanied by fluorescence. This test is relatively reproducible and can be quantized on a flow cytometer allowing the determination of a DHR index, which correlates with residual superoxide production capacity. Other assays include NBTR and dichlorofluorescein (DCF), but these are somewhat more complicated or more prone to reader effects (Fig. 22.8). One important false positive to keep in mind in DHR testing is myeloperoxidase (MPO) deficiency. MPO deficiency gives a DHR result consistent with CGD, but when superoxide production is measured by NBTR or the more specific ferricytochrome c reduction, it is normal to increased.

Treatment of CGD

Prophylactic trimethoprim–sulfamethoxazole (TMP-SMX) significantly reduces the frequency of bacterial infections in CGD, especially those caused by *S. aureus*. TMP-SMX prophylaxis is ineffective against fungal infections but does not encourage them. Prophylactic itraconazole prevents fungal infections. IFN-γ is beneficial as a prophylactic treatment in CGD. In a multicenter, placebo-controlled trial of IFN-γ, the number and severity of infections were significantly reduced by IFN-γ. The exact mechanism of action of IFN-γ is not known, but it has multiple effects, including stimulation of components of NADPH oxidase in partial deficiencies, increased bactericidal activity through neutrophil granule components, and Fc receptor expression. Subcutaneous administration of recombinant IFN-γ three times

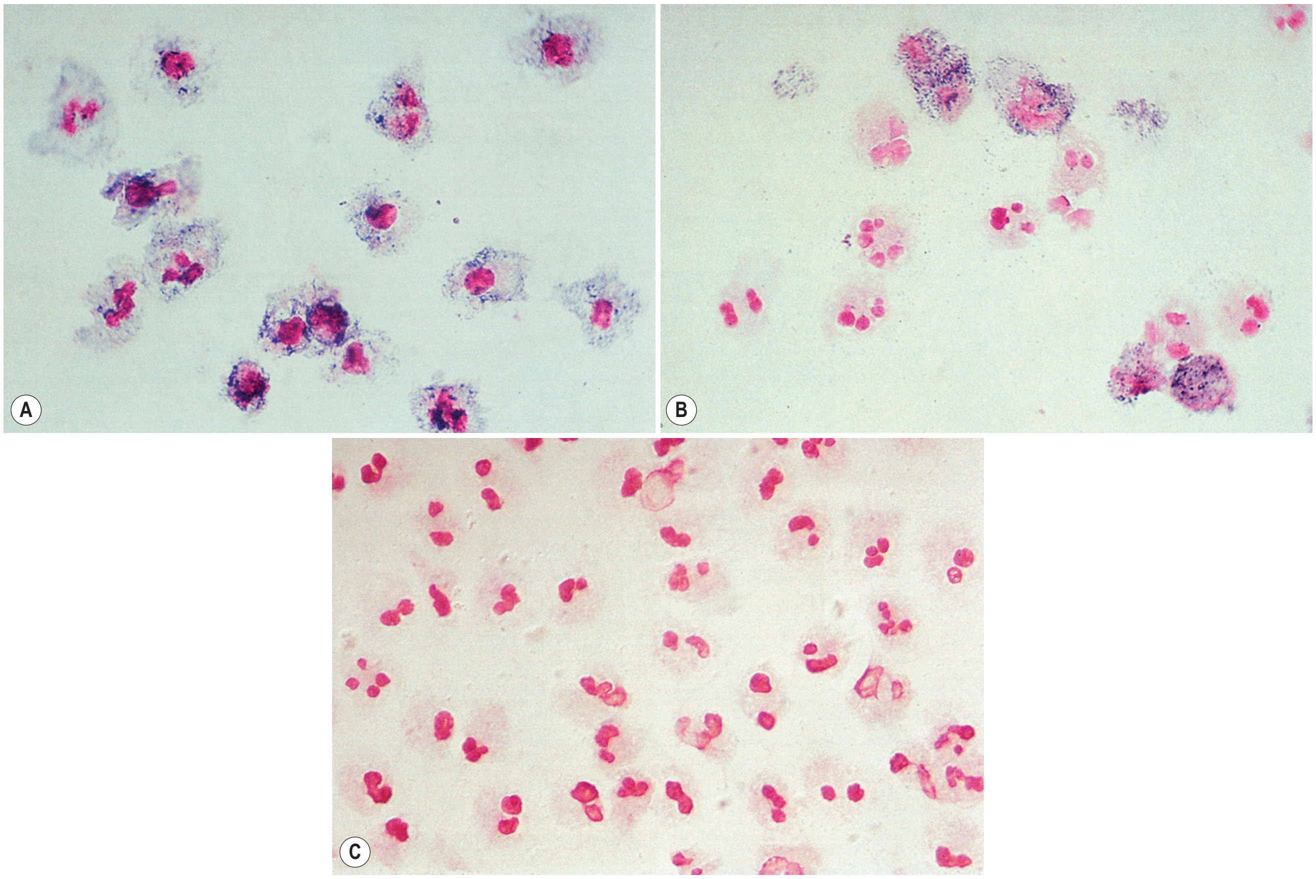

FIG 22.8 **Laboratory Diagnosis of Chronic Granulomatous Disease (CGD) with the Nitroblue Tetrazolium (NBT) Test.** (A) Nitroblue tetrazolium reduction (NBTR) reduction by purified normal neutrophils following stimulation with phorbol esters and calcium ionophore. NBT is reduced by all neutrophils, showing a blue/purple deposit. (B) NBTR by purified neutrophils from an X-linked CGD carrier; two different populations of cells are seen. Normal (unaffected cells) reduce the NBT dye and stain blue/purple, whereas affected cells fail to reduce the NBT dye and appear clear. (C) Neutrophils from a patient with CGD fail to reduce the NBT dye and appear clear. (Courtesy of Dr. Douglas B. Kuhns, Leidos, Frederick, MD.)

a week at a dose of 50 μg/m^2 (for those with body surface area >0.5 m^2) is recommended. The adverse effects of recombinant IFN-γ in patients with CGD have been limited to fever, chills, headache, flu-like illness, and diarrhea. During severe infections, leukocyte transfusions are sometimes used in addition to antibiotics, but this approach may lead to alloimmunization, compromising future bone marrow transplantation opportunities.

Because CGD is predominantly a hematopoietic disorder, bone marrow transplantation can cure CGD, even in the setting of active infection.[40] The type of transplant that is used in patients with CGD varies among centers, but both fully myeloablative and partially myeloablative transplants (reduced intensity conditioning) have been effective. Although active infection is a relative contraindication for bone marrow transplantation overall, there are certain infections in CGD, especially those caused by atypical *Aspergillus* spp. infections, that are not curable with standard antifungal therapy. Bone marrow transplantation prevents not only recurrent life-threatening infections, but also GI disease and growth retardation and is currently successful in about 90% of cases.

MYELOPEROXIDASE DEFICIENCY

MPO is a heme-containing enzyme necessary for the conversion of hydrogen peroxide (H_2O_2) to hypochlorous acid (HOCl). MPO is expressed early in myeloid differentiation and resides in the azurophilic granules of neutrophils and the lysosomes of monocytes.[41] Mature MPO is a symmetrical molecule of four peptides, with each half consisting of a heavy–light chain heterodimer. Neutrophils of individuals with MPO deficiency fail to produce HOCl upon stimulation, whereas the NADPH oxidase system remains unaffected. Prolonged supranormal levels of superoxide and H_2O_2 production follow stimulation in MPO-deficient neutrophils. This may result from lack of negative feedback regulation of HOCl on the NADPH oxidase, although the exact mechanism is unknown. MPO deficiency can be primary (congenital) or secondary (acquired).

Primary MPO Deficiency

Primary MPO deficiency is the most common phagocyte defect with a frequency of 1/4000. Both total and partial MPO deficiencies have been described. Patients with primary MPO deficiency do not usually have increased infections, probably because MPO-independent mechanisms compensate for the lack of MPO-dependent microbicidal activity. Visceral candidiasis occurring with concurrent diabetes has been reported in some patients. However, the frequency of such cases is very low. Affected individuals may develop nonfungal infections, malignancies, and certain skin disorders. In several cohorts of patients with complete MPO deficiency, an increased incidence of solid or hematological tumors has been observed.[40] MPO-deficient neutrophils have no apparent defect in the phagocytosis of bacteria or fungi, but microbicidal activity is slower than normal. MPO-deficient neutrophils are severely impaired in killing *Candida* spp. or *Aspergillus* spp. *in vitro* despite the fact that most patients with MPO deficiency do not develop significant fungal infections. This suggests that the mucosal barrier to fungal infection is independent of MPO activity and is able to prevent invasive infection.

The most common mutation is a missense replacement of arginine 569 with tryptophan (R569W), causing maturational arrest of the MPO precursor and preventing heme incorporation. Most patients are compound heterozygotes. The diagnosis of MPO deficiency is made by using anti-MPO monoclonal antibodies (mAbs) in flow cytometric analysis of neutrophils. No MPO expression is seen in congenital deficiency, whereas near-normal antigenic reactivity may be seen with the acquired form.[41] Maintenance antibiotic or antifungal therapy is not routinely recommended. Prompt and prolonged therapy is advised in patients with diabetes mellitus and congenital MPO deficiency, as they may develop localized or systemic infections.

Secondary or Acquired MPO Deficiency

In the majority of patients, MPO deficiency is partial and transient. Secondary MPO deficiency occurs under certain clinical conditions, such as some hematological malignancies or disseminated cancers, exposure to cytotoxic agents or antiinflammatory medications, iron deficiency, lead intoxication, thrombotic diseases, renal transplantation, and pregnancy. MPO activity in bone marrow myeloid precursors as well as peripheral blood cells may vary from cell to cell. Treatment of the underlying condition typically corrects the defect. This deficiency is most likely linked to somatic mutations in the case of malignancy or toxic–metabolic effects on MPO activity.[41]

Specific Granule Deficiency

Neutrophil-specific granule deficiency (SGD) is a rare disorder of leukocyte maturation in which neutrophil secondary granules and some primary granule proteins are absent as a result of mutations in CCAAT/enhancer binding protein epsilon (*C/EBPε*, located at 14q11.2), a member of the leucine zipper family of transcription factors.[42] SGD is characterized by frequent, severe pyogenic infections, a paucity or absence of neutrophil-specific granule proteins and defensins, and atypical neutrophil nuclear structure with mostly bilobed nuclei. *In vitro*, these patients' cells show diminished neutrophil migration, reduced staphylococcal killing, reduced phagocytosis, and increased cell surface-to-volume ratio. Eosinophils and platelets are also affected in SGD. Platelets lack high-molecular-weight (HMW) von Willebrand factor multimers and have reduced platelet fibrinogen and fibronectin due to diminished platelet α granules. Bleeding diatheses and neutrophil phagocytosis of platelets are seen in SGD. In addition, SGD eosinophils are deficient in the eosinophil-specific granule proteins eosinophil cationic protein (ECP), eosinophil-derived neurotoxin (EDN), and major basic protein (MBP) despite the presence of messenger RNA (mRNA) transcripts for these proteins. Few patients have been reported to have survived beyond adolescence except for those with a milder dominant form. Bone marrow transplantation should be considered early in the course of the disease.

KEY CONCEPTS

Specific Granule Deficiency (SGD)

- SGD is caused by promyelocyte–myelocyte transition block as a result of a mutation in the *C/EBPε* gene.
- Absence of secondary granule proteins, and a selective loss of the primary granule defensins are the pathological findings in SGD granulocytes.
- The prognosis is very poor in recessive forms of SGD.

CHEDIAK-HIGASHI SYNDROME

Chediak-Higashi syndrome (CHS) is a rare, autosomal recessive disorder characterized by partial oculocutaneous albinism, increased susceptibility to infections, deficient NK-cell activity, and abnormal giant primary granules in neutrophils.[43] This immunodeficiency was first reported by Beguez-Cesar in 1943 and then further elaborated by Chediak and Higashi a decade later. The hallmark of CHS is giant abnormal granules in all granule-containing cells, including melanocytes (melanosomes are members of the lysosomal lineage of organelles), neutrophils, central and peripheral nerve tissues, fibroblasts, and hair. The problem is the inability to form appropriate lysosomes and cytoplasmic granules. CHS granulocytes lack cathepsin G and elastase, but the defensin content is normal. The giant granules of CHS are derived predominantly from azurophilic granules. CHS is classically described as a biphasic immunodeficiency, in which susceptibility to infection marks the first phase, and an accelerated lymphoproliferative syndrome with histiocytic infiltration of various tissues marks the second. Rarely, the accelerated phase may be the initial presentation. The giant organelles are derived from the late compartments of the endocytic pathway, affecting specifically late endosomes and lysosomes with minimal or no effect on early endosomes. *CHS1* encodes a 3801 amino acid peptide (lysosomal transporter [LYST]) that has a vital role in lysosomal trafficking. Lysosomal exocytosis triggered by membrane wounding is impaired in Chediak-Higashi fibroblasts. The reduced survival of fibroblasts after wounding indicates that impaired lysosomal exocytosis inhibits membrane resealing. Inability of cells to repair plasma membrane lesions may contribute to the pathology of CHS. The degree of albinism can vary from a slightly diluted skin pigment to hypopigmented skin and hair, photophobia, nystagmus, strabismus, macular hypoplasia, and reduced visual acuity. Skin biopsy shows large irregular melanin granules in melanocytes. Microscopic analysis of hair also shows poor distribution of melanin. Pancytopenia, neutropenia, and lack of NK-cell activity result in frequent pyogenic infections, usually caused by staphylococci or streptococci. Hepatosplenomegaly and lymphadenopathy are common. A mild bleeding diathesis results from platelet storage pool deficiency. Neurological dysfunction, including mental retardation, seizures, cranial nerve palsies, and progressive peripheral neuropathy, has been noted in CHS.

The lymphoma-like lymphohistiocytic accelerated phase is characterized by increased hepatosplenomegaly, lymphadenopathy, and worsened pancytopenia, which may resemble the virus-associated hemophagocytic syndromes or familial hemophagocytic lymphohistiocytosis. Although chemotherapy can induce transient remissions, relapses are common. Bone marrow transplantation prevents the accelerated phase and restores NK-cell function, but it does not resolve the central or peripheral nervous system abnormalities. Demonstration of giant azurophilic cytoplasmic inclusions on peripheral blood smear is very suggestive of the diagnosis of CHS; mutation analysis confirms the diagnosis.

HYPER-IGE RECURRENT INFECTION, OR JOB'S SYNDROME

Davis et al. first described hypoinflammatory recurrent infections with severe eczema in 1966. This was further refined and expanded by Buckley et al. in 1972, who recognized the characteristic IgE elevation. We now consider this to be a multisystem autosomal dominant disorder caused by heterozygous mutations in signal transducer and activator of transcription 3 (*STAT3*, located at 17q21).[44] Mutations in *STAT3* are mostly missense and clustered in either the DNA-binding domain or Src homology 2 (SH2) domains. Hyper-IgE recurrent infection (HIES, or Job's syndrome) is characterized by recurrent infections of the lower respiratory system and skin, chronic eczema, arterial anomalies, including coronary arterial tortuosity and aneurysms, extremely elevated IgE levels, and eosinophilia (Table 22.4). HIES occurs in all racial and ethnic groups.

Facial, Skeletal, and Dental Abnormalities

Facial abnormalities seen in the majority of the patients are a protruding, prominent mandible and forehead, apparent ocular hypertelorism, a broad nasal bridge, and a wide, fleshy nasal tip with increased interalar distance (Fig. 22.9). Midline anomalies common in this disorder are high-arched palate.

Skeletal abnormalities are common. Grimbacher et al. noted pathological fractures in 57% and scoliosis in 76% (Fig. 22.10). Low bone density and cortical bone loss are also common but not clearly correlated with the fracture rate. Other infrequent skeletal abnormalities reported in HIES are craniosynostosis, spina bifida, bifid rib, wedge-shaped lumbar vertebra, hemivertebra, and pseudoarthritis of the hip. Hyperextensibility of joints is common. A unique dental abnormality seen in this syndrome is retained primary teeth causing delayed eruption of permanent teeth.

TABLE 22.4 Clinical and Laboratory Findings in Patients With the Hyper-IgE Syndrome

Findings	Incidence (%)
Eczema	100
High IgE levels (>2000 IU/mL)	97
Eosinophilia (>2 SD above the mean for normals)	93
Boils	87
Pneumonia	87
Mucocutaneous candidiasis	83
Characteristic facies (in those ≥16 years)	83
Lung cysts	77
Scoliosis (for those ≥16 years)	76
Hyperextensible joints	68
Delayed shedding of primary teeth	72
Bone fractures	57

Adapted from Grimbacher B, Holland SM, Gallin JI, et al. Hyper-IgE syndrome disorder. N Engl J Med 1999; 340: 692.

KEY CONCEPTS

Hyper-IgE Recurrent Infection Syndrome (HIES) or Job's Syndrome

- Recurrent infections of the lower respiratory system and skin, chronic eczema, extremely elevated immunoglobulin E (IgE) levels, and eosinophilia are the hallmarks of the syndrome.
- Facial, skeletal, and dental abnormalities are very common.
- Lung abscesses and pneumatoceles following pneumonias caused by *Staphylococcus aureus* and *Haemophilus influenzae* are the major factors for morbidity.

Infections and Immunological Characteristics

Moderate to severe eczema presenting within the first hours to weeks of life is almost universal in HIES. Mucocutaneous candidiasis involving finger and toenails, mouth, vagina, and intertriginous areas is seen in most patients. Primary pulmonary infections are caused by *S. aureus*, *Haemophilus influenzae*, and *Streptococcus pneumoniae*. These pneumonias are often associated with abscess formation and usually lead to the development of pneumatoceles (see Fig. 22.10). Once lung cavities are formed, they provide an attractive environment for superinfection with *Pseudomonas* or *Aspergillus* spp. The clinical morphotype suggests abnormal tissue remodeling. *Pneumocystis jiroveci* pneumonia, cryptococcosis, histoplasmosis, and coccidioidomycosis have been reported. IgE levels are usually above 2000 IU/mL, but substantial fluctuations in IgE levels have been recorded over time, and the IgE levels do not correlate with disease activity or eosinophilia. Total serum IgG levels are usually within the normal range. Eosinophilia is common; the white blood cell (WBC) count is usually normal to low.

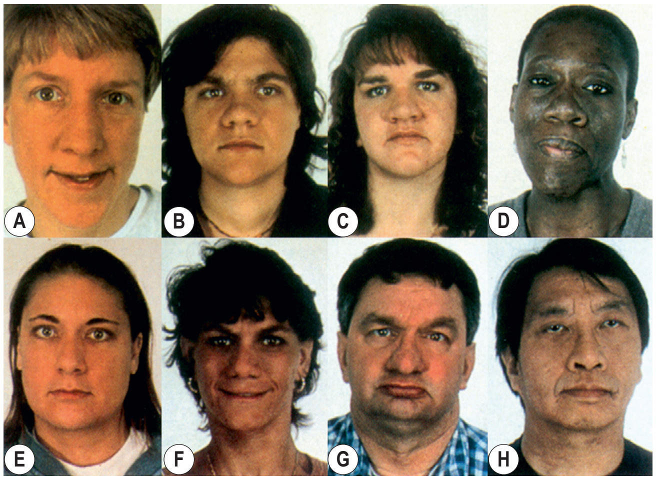

FIG 22.9 Facial Abnormalities Seen in Patients With Hyper-IgE Recurrent Infection Syndrome (HIES). Prominent mandible and forehead, apparent hypertelorism, broad nasal bridge with a wide nasal tip, and increased interalar distance are commonly seen facial features of HIES. (With permission from Grimbacher B, Holland SM, Gallin JI, et al. Hyper-IgE syndrome with recurrent infections—an autosomal dominant multisystem disorder. N Engl J Med 1999; 340: 692.)

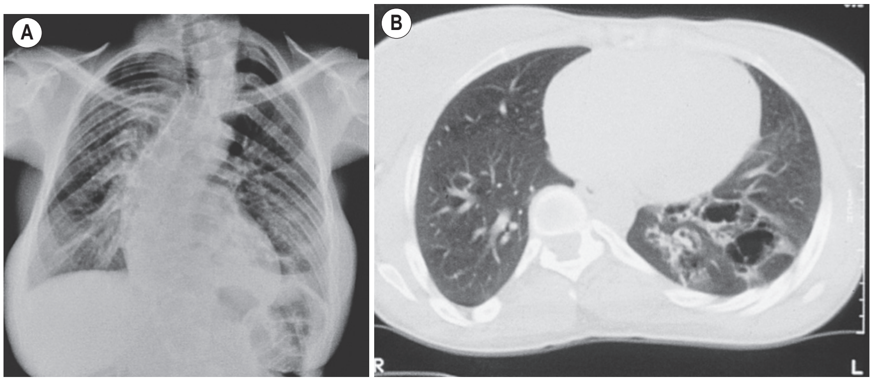

FIG 22.10 **Thoracic Pathology in Hyper-IgE Recurrent Infection Syndrome (HIES).** (A) Chest X-ray of a patient with scoliosis. (B) Computed tomography (CT) scan of the lungs in the same patient demonstrates multiple pneumatoceles caused by prior infections.

Mutations in *STAT3* lead to disruption of cytokine signaling, including IL-6, IL-10, IL-11, and IL-17. Signal transducer and activator of transcription 3 (STAT3) deficiency leads to elevated tumor necrosis factor-α (TNF-α) and IFN-γ, but reduced IL-17 producing T cells (Th17 cells). This latter defect may explain the predisposition to mucocutaneous candidiasis.[45] Memory B and T cells are low. Shingles vesicles are increased in Job's syndrome despite the fact that primary varicella-zoster virus (VZV) infections are normally eliminated. Lymphomas, but not epithelial malignancies, are increased in STAT3 deficiency.

Recently gain-of-function mutations in STAT3 associated with high IL-6 response have been identified in children characterized by failure to thrive, arthritis, livedo, and lung disease.

DOCK8 Deficiency (Autosomal Recessive Hyper-IgE Syndrome)

Several distinct diseases have elevated IgE, eczema, and eosinophilia. Dedicator of cytokinesis 8 (*DOCK8*, located at 9p24) deficiency includes food allergies, asthma, herpesvirus infections, human papilloma virus (HPV), and molluscum contagiosum infections, which are not part of dominant negative STAT3 deficiency. In addition to the infection susceptibility, patients with DOCK8 deficiency are predisposed to cutaneous and lymphoid malignancies.[46] Although Th17 cells are markedly diminished in patients with STAT3 deficiency, they are less severely reduced in those with DOCK8 deficiency (patients with HIES-like disease[45]). The specific contributions of these relatively IL-17–deficient states are areas of active investigation.

GATA2 Deficiency (Monomac Syndrome)

GATA2 (located at 3q21.3) is an early hematopoietic transcription factor most active in myeloid development.[47] The syndrome of monocytopenia and mycobacterial disease (monoMAC) is characterized by late childhood or adult-onset disseminated nontuberculous mycobacterial disease or disseminated fungal disease. Patients have absolute circulating monocytopenia, NK-cell cytopenia, and B-cell lymphopenia. Despite these circulating cytopenias, there are tissue macrophages and plasma cells, and Ig levels are normal to elevated. Neutrophils are variably affected. Other infections in this syndrome include HPV infection, molluscum contagiosum, histoplasmosis, and aspergillosis. Progressive pulmonary alveolar proteinosis is common, as are cytogenetic abnormalities of bone marrow, such as trisomy 8 and monosomy 7. Diagnosis is suspected on the basis of the infections and the abnormal results on hemography. Since most routine hematological laboratory studies allow quite low ranges of normal monocyte percentages, it is necessary to look at absolute monocyte numbers. Other presentations of this syndrome include aplastic anemia, acute myelogenous leukemia, lymphedema, and chronic myelomonocytic leukemia. Sequencing of *GATA2* is required for diagnosis.

ASSESSMENT OF NEUTROPHIL FUNCTION

Discrete abnormalities in neutrophil function lead to recurrent bacterial or fungal infections. Assays have been developed to interrogate those functions. However, since neutrophils cannot be viably stored or frozen, samples are usually examined fresh with simultaneous normal volunteer controls. The techniques discussed here are reviewed in detail by Elloumi et al.[48] and in Chapter 94.

Isolation of Neutrophils

Most assays require neutrophils to be purified away from other leukocytes and blood components. Blood is usually anticoagulated using either citrate or heparin (10 units/mL) tubes and maintained at 20–25°C (room temperature) in polypropylene containers. Most protocols use differences in the cell density as the basis for the separation by sedimentation or centrifugation, or both. Typically, $1–2 \times 10^6$ neutrophils can be isolated per milliliter of whole blood.

Neutrophil Adherence

The adhesive function of phagocytes is commonly assessed by passage of 1 mL of whole blood through a column filled with nylon wool. Adherence is measured as the difference in the absolute neutrophil count of the precolumn sample and of the sample after passage through the nylon wool column. Alternatively, isolated neutrophils can be induced to bind to plastic using a 96-well plate either uncoated or coated with fetal bovine serum, a ligand like ICAM-1, or a specific ECM protein, such as fibrinogen or fibronectin. Endothelial cell monolayers harvested from human umbilical veins can serve as a more physiological substrate for the measurement of cell adhesion. Isolated neutrophils are preloaded with the cell permeant, acetoxymethyl ester derivative of the fluorescent dye, calcein (calcein-AM). Nonspecific esterases in the cytosol cleave the ester linkage, trapping the fluorescent probe in the cytosol. The labeled neutrophils are added to each well and incubated in the absence or presence of phorbol myristate acetate (PMA) to promote adherence through activated integrins. At the end of the incubation, the wells are washed to remove nonadherent cells. The fluorescence of each well is determined with a fluorescent microplate reader and compared with the fluorescence of a control well with a fixed number of fluorescent cells. Under control conditions, fewer than 10% of the neutrophils adhere to plastic or to plastic coated with fetal bovine serum. Slightly more neutrophil adherence is observed on wells coated with fibrinogen. Treatment of normal neutrophils with PMA for 30 minutes results in the adherence of 100% of the neutrophils under all conditions. This adherence is abnormal in patients with LAD. Neutrophils isolated from patients with typical LAD-1 generally exhibit markedly reduced adherence under both unstimulated and PMA conditions.

Neutrophil Chemotaxis

Neutrophil chemotaxis *in vivo* can be evaluated by using skin windows. Skin blisters are gently raised on the volar surface of the forearm using a vacuum pump and a blister device, with little hemorrhage or vascular damage. The roof of the blister is removed, and the exposed dermis is bathed with autologous serum with the use of a skin window chamber. In 24 hours, exudative neutrophils accumulate in the autologous serum bathing the skin lesion. The skin chamber provides a mechanism for characterizing the immune cells as well as the soluble immune mediators that accumulate in the autologous serum during the evolution of the inflammatory response. Chemotaxis *in vitro* is generally measured by using a Boyden chamber. The Boyden chamber includes three components: a lower (chemoattractant) chamber, a nitrocellulose or polycarbonate filter layer, and an upper cell chamber. The lower compartments of the Boyden chamber are filled with a chemoattractant, such as fMLF; 10^{-8} M) or IL-8 (10 ng/mL). Recently an improved rapid fluorescence-based measure of neutrophil chemotaxis, which uses a new 96-well disposable chemotaxis chamber that can be read in a fluorescence microplate reader, has been developed.

Expression of Surface Antigens

The expression of cell surface antigens on neutrophils relies on labeled mAbs analyzed by flow cytometry. The panel may include the β_2 integrins (CD11a, CD11b, CD11c, and CD18), selectins (CD62L), Fcγ receptors I, II, and III (CD64, CD32 and CD16), leukosialin (CD43), the common leukocyte antigen (CD45), and markers for the specific granules (CD67), and azurophilic granules (CD63). The expression of surface antigens can be used to assess the responsiveness of neutrophils to particular ligands, such as fMLF and lipopolysaccharide (LPS).

Neutrophil Degranulation

The proteases, acid hydrolases, and inflammatory mediators released from storage granules in neutrophils can mediate bacterial killing, tissue damage, healing, and immune regulation. Lactoferrin from specific granules can chelate iron, resulting in a bactericidal or bacteriostatic effect. Stimulation of neutrophils with various secretagogues can release granular enzymes into the extracellular fluid. Treatment of the neutrophils with cytochalasin b (5 μg/mL) disrupts microfilament assembly and facilitates the release of both specific and azurophilic enzymes. To differentiate degranulation from cell lysis, release of the cytosolic enzyme lactate dehydrogenase should be monitored simultaneously. The release of azurophilic granules can be assessed by determination of β-glucuronidase activity. Supernatant fluids or cell extracts obtained from stimulated neutrophils are incubated with 4-methylumbelliferyl-β-ᴅ-glucuronide. Alternatively, myeloperoxidase can be determined by using commercially available enzyme-linked immunoassays. CD63 is also found in the membrane of azurophilic granules and migrates to the neutrophil surface after stimulation with fMLF in the presence of cytochalasin b. The release of specific granules can be assessed by determination of lactoferrin levels using an enzyme-linked immunoassay. The carcinoembryonic antigen CD66b (formerly CD67) is found on the neutrophil surface and in the specific granules, and its expression on the surface of the neutrophils is increased after stimulation with fMLF or LPS. Detection of the constituents of secretory granules can be assessed by flow cytometric analysis of the change in expression of surface proteins, such as adhesion molecules, and cytochrome b_{558} of the NADPH oxidase.

Generation of Reactive Oxygen Species

The release of reactive oxygen intermediates, such as O_2^- and H_2O_2, is an important component of the neutrophil bactericidal machinery. Neutrophils isolated from patients with CGD are unable to generate superoxide, leading to their oxygen-dependent bactericidal defect. The production of O_2^- can be detected by using the reduction of cytochrome c. Because O_2^- causes a one-to-one stoichiometric reduction of ferricytochrome c to ferrocytochrome c, the resultant increase in the absorption spectrum at 550 nM can be used to quantitate the production of O_2^-. Superoxide dismutase is added to an identical tube to control for the nonspecific reduction of cytochrome c. However, since cytochrome is not permeable to the cells, the detection of O_2^- is limited to that released into the extracellular milieu. Neutrophils isolated from patients with CGD produce little O_2^- in response to PMA in 10 minutes. However, some patients with forms of CGD associated with residual superoxide production have low, but detectable, O_2^- production in 60 minutes. Neutrophils isolated from X-linked heterozygous carriers of CGD can yield a full spectrum of O_2^- production, whereas neutrophils from autosomal recessive carriers of CGD generally yield a normal response. Although the detection of O_2^- by reduction of cytochrome c is useful in the diagnosis of patients with CGD, it cannot be used in the diagnosis of carriers because of the wide spectrum of responses that result from the degree of X-chromosome lyonization.

The extracellular release of H_2O_2 can be measured by using horseradish peroxidase–induced oxidation of either phenol red or Amplex red. PMN suspensions in the presence of horseradish peroxidase and one of the chromophores are exposed to either PMA or buffer alone. Changes in optical density of phenol red at 600 nm can be determined with a standard microplate reader. Amplex red is a much more sensitive fluorescent chromophore, and H_2O_2-dependent changes in fluorescence can be determined with a fluorescence microplate reader.

The NBT test is a qualitative assay of O_2^- production. Either whole blood or isolated neutrophils are mixed with NBT in a chamber slide and stimulated with PMA for 15–30 minutes at 37°C. The slide is counterstained with 0.1% safranin and examined under a microscope. The NBT test yields a visual record of the reduction of the NBT dye to the insoluble, blue-black deposits of formazan. Normal neutrophils, but not neutrophils from patients with CGD, reduce the yellow dye to black-brown-blue aggregates in the cells. The NBT test can be used to diagnose

X-linked carriers of CGD but cannot differentiate autosomal carriers from normal subjects.

An alternative to the NBT test is a flow cytometric assay, in which the dye, dihydrorhodamine-1,2,3 is used. Neutrophils are loaded with the nonfluorescent dye and then stimulated with PMA for 15 minutes at 37°C. The H_2O_2 produced oxidizes the dye and results in increased fluorescence, detectable with a flow cytometer. Catalase is added to prevent cell-to-cell diffusion of H_2O_2. Since dye is localized to the cytoplasm, and catalase is present in the extracellular fluid, the dihydrorhodamine-1,2,3 assay detects the intracellular production of reactive oxygen metabolites. Stimulation of normal neutrophils with PMA results in a two-log shift in the fluorescence intensity. Neutrophils from an X-linked carrier of CGD exhibit mosaicism with a negatively stained (abnormal) population and a brightly stained positive population. Neutrophils from a patient with X-linked CGD that lack $gp91^{phox}$ express little increase in fluorescence, whereas neutrophils from a patient with a deficiency in $p47^{phox}$ exhibit a slight increase in fluorescence. The major advantages of the dihydrorhodamine-1,2,3 assay are the sensitivity, the signal-to-noise ratio, and the ease of counting a large number of cells.

Western Blot for Determination of NADPH Oxidase Defect

Determination of the specific protein defect in CGD by Western blot analysis provides direction for the genetic defect. A validated normal control and a typical $gp91^{phox}$ CGD are included on each blot to ensure adequate development of $p22^{phox}$. Patients with $p47^{phox}$ CGD are Western blot negative. Patients with $p67^{phox}$ CGD are generally Western blot negative. Because $p22^{phox}$ and $gp91^{phox}$ exist as a membrane complex, patients with a defect are $p22^{phox}$, in general, are Western blot negative for both $p22^{phox}$ and $gp91^{phox}$. In contrast, defects in $gp91^{phox}$ yield more variable results. In general, patients with nonsense defects in $gp91^{phox}$ exhibit low but detectable levels of $p22^{phox}$. Patients with missense mutations in $gp91^{phox}$ that yield detectable $gp91^{phox}$ protein exhibit proportionately higher levels of $p22^{phox}$.

TRANSLATIONAL RESEARCH

The progress made over the past 60 years in understanding and managing phagocyte defects has been remarkable, spanning initial identification, phenotyping, and molecular characterization. The last 20 years have seen the advent of oral antifungals, potent oral antibiotics, oral antivirals, reduced intensity conditioning for bone marrow transplantation, and gene therapy. These advances have transformed the quality of life and longevity of all patients with immune deficiencies. We now need further in-depth study of the mechanisms that drive disease pathophysiology to gain novel insights. The advent of therapeutic cytokines, small molecule inhibitors and agonists, RNA inhibitors, and effective means of gene transfer should make directed approaches to disease modification a reality. However, we must be sure we know exactly what functions need addressing. The downstream effects of genetic defects are surprisingly complex and not always as straightforward as has been anticipated. More detailed clinical and functional phenotyping, careful examination of developmental and gene expression effects, and continued longitudinal studies of large cohorts will convert these severe diseases punctuated by acute, life-threatening infections into chronic conditions that are successfully treated medically or successfully managed until successful bone marrow transplantation becomes available.

ON THE HORIZON

- Early recognition and molecular diagnosis of all phagocyte defects, leading to prophylactic antimicrobial treatment, where indicated
- Improvement in bone marrow transplantation technology to allow for early, safe, successful, fertility-preserving transplantation in all cases
- Understanding the mechanisms of the hepatic complications of chronic granulomatous disease (CGD) that correlate with mortality
- Characterizing the pathways that converge on signal transducer and activator of transcription 3 (STAT3) signaling causing the complex somatic and immune disorder, hyper-IgE recurrent infection syndrome (HIES).

MULTIPLE-CHOICE QUESTIONS

1. A 12-year-old boy with X-linked chronic granulomatous disease (CGD) presents to your office with progressive fever, dyspnea, and hypoxia a week after a Halloween hayride at a local farm. His chest X-ray shows extensive bilateral military infiltrates. The MOST likely diagnosis and management:
   - **A.** *Burkholderia cepacia* complex pneumonia; initiate antibacterials
   - **B.** *Nocardia spp.* pneumonia; initiate antibacterials
   - **C.** *Serratia marcescens* pneumonia; initiate antibacterials
   - **D.** Mulch pneumonitis; initiate antifungals and corticosteroids
   - **E.** *Staphylococcus aureus* bacteremia; initiate antibacterials and obtain echocardiogram

2. Leukocyte adhesion defect-1 (LAD-1) leads to low numbers of neutrophils in the tissues (tissue neutropenia) and recurrent severe infections. Progressive severe periodontitis is characteristic, with most patients losing all their teeth by late adolescence. The immunological mechanism behind the periodontal disease is:
   - **A.** Tissue neutropenia leading to severe bacterial infection
   - **B.** Excessive interferon (IFN)-γ production
   - **C.** Poor root maintenance by defective macrophages
   - **D.** Excessive interleukin (IL)-17 production
   - **E.** Severe tooth decay caused by impaired neutrophil trafficking

3. GATA2 deficiency is a complex disease with manifestations involving hematopoietic and lymphatic development. It is often identified in adolescence or adulthood with cytopenias and/or infections. Signs and symptoms that should lead to early consideration of GATA2 deficiency include:
   - **A.** Human papilloma virus (HPV) infection, mycobacterial infection, monocytopenia
   - **B.** Respiratory syncytial virus (RSV) infection, staphylococcal pneumonia, monocytosis
   - **C.** Influenza infection, *Aspergillus* infection, thrombocytopenia
   - **D.** Adenovirus infection, *Bordetella* infection, anemia
   - **E.** Cytomegalovirus (CMV) infection, streptococcal infection, lymphocytosis

Mast Cells, Basophils, and Mastocytosis

Joshua Boyce, Laura Fanning

Mast cells and basophils are functionally related effector cells of hematopoietic origin that are implicated in allergy, type 2 immune responses to parasites, and innate immunity. Both cell types derive from bone marrow progenitors and express high-affinity immunoglobulin E (IgE) Fc receptors (FcεRI) on their surface. Both release histamine and generate a variety of other inflammatory mediators in response to both IgE- and non–IgE-mediated activation. However, there are important differences between mast cells and basophils in terms of their developmental origins, morphology, distribution, and mechanisms and responses to stimulation[1] (Table 23.1, Fig. 23.1). This chapter will deal with the functional characteristics of both cell types in host defense and disease.

KEY CONCEPTS

Origins of Basophils and Mast Cells

- Mast cells and basophils represent distinct hematopoietic lineages.
- Basophils are granulocytes that mature in the bone marrow, circulate in blood, and can be recruited into peripheral tissues at sites of inflammatory responses.
- Mast cell progenitors arise in bone marrow, but mast cells mature in peripheral tissues.
- Mast cells are present throughout connective tissues and mucosal surfaces and are particularly abundant near epithelial surfaces exposed to the environment.
- CD117 and its ligand stem cell factor (SCF) are critical for mast cell development and survival.
- Basophil development is promoted in the context of T_H2 inflammatory responses and regulated by cytokines, including interleukin-3 (IL-3) and thymic stromal lymphopoietin (TSLP).

DEVELOPMENT AND DISTRIBUTION OF MAST CELLS

Mast Cell Development and Survival

Mast cells are evolutionarily ancient, predating the emergence of adaptive immunity. A mast cell–like cell containing histamine and heparin has been identified in *Styela plicata*, a urochordate species that first appeared around 500 million years ago.[1] Studies in rodents indicate that mast cells derive from hematopoietic stem cell (HSC)–derived granulocyte–monocyte progenitor cells (GMPs) in bone marrow, which can give rise to basophils and other lineages.[2] In mice, the transcription factors C/EBPα and MITF interact antagonistically and specify basophil versus mast cell fate, respectively, in GMPs. Basophils undergo full differentiation in bone marrow, whereas mast cells differentiate from committed precursors that migrate to their ultimate tissue destinations before acquiring the morphological and biochemical characteristics of mature mast cells.[3] Moreover, circulating basophils are short-lived and terminally differentiated, whereas mast cells can survive for long periods, and retain the capacity for proliferation and substantial inducible gene expression. This likely explains the high degree of heterogeneity among mast cell subpopulations.

In mice, committed mast cell progenitors (MCPs) can be identified cytofluorographically as a Kit (CD117)^{hi,} FcεRI$^+$, β7 integrin$^+$ mononuclear cell population. A similar cell population was recently identified in human blood.[4] In *ex vivo* colony forming assays, both mouse and human CD117$^+$, FcεRI$^+$, β7 integrin$^+$ cells give rise preferentially to mast cells. In studies of cells sorted from various organs BALB/c mice, committed basophil precursors (BaPs) were found exclusively in bone marrow, whereas committed mast cell progenitors were most abundant in the small intestine.[2] This study identified a splenic population of cells capable of giving rise to both mast cells and basophils with *ex vivo* culture (bipotent basophil–mast cell precursor [BMCP]). However, neither mature mast cells nor mast cell progenitors show significant overlap in gene expression profiles with basophils in either mice or humans.[4,5] Thus despite some functional similarities, the bulk of evidence suggests that the developmental pathways of mast cells and basophils diverge early in hematopoiesis and that the two cell types likely serve correspondingly very different functions.

CD117 and its ligand, stem cell factor (SCF), are absolutely required for mast cell development. SCF exists as both a membrane-bound protein expressed by fibroblasts and other stromal cells, as well as a soluble form. Mice with mutations in the loci for CD117 (W/W^v or W^{sh}/W^{sh} mice) or SCF (Sl/Sl^d mice) lack mast cells, among other hematopoietic and nonhematopoietic defects.[1] Although loss-of-function mutations in CD117 or SCF have not been identified in humans, gain-of-function mutations in CD117 are associated with systemic mastocytosis,[6] suggesting that the SCF-KIT axis is important for human mast cell development as well. Although SCF can stimulate mast cell development from either mouse or human progenitor cells *in vitro,* mouse mast cells can be derived *in vitro* from unfractionated bone marrow cells by using interleukin-3 (IL-3) or thymic stromal lymphopoietin (TSLP) as the sole exogenous growth factors.[7] Mice lacking IL-3 have wild-type levels of mast cells under steady-state conditions but show diminished capacity to develop a reactive mast cell hyperplasia in the intestine in response to helminth infections.[8] TSLP knock-out mice display modest steady-state reductions in mast cell numbers in all organs studied.[7] Additionally, transgenic overexpression of IL-9 results in marked

TABLE 23.1 **Natural History, Major Mediators, and Surface Membrane Structures of Human Mast Cells and Basophils**

Characteristic	Basophils	Mast Cells
Natural History		
Origin of precursor cells	Bone marrow	Bone marrow
Site of maturation	Bone marrow	Peripheral tissues (a few in bone marrow)
Mature cells in the circulation	Yes (usually <1% of blood leukocytes)	No
Mature cells recruited into tissues from circulation	Yes (during immunological, inflammatory responses)	No
Mature cells normally residing in connective tissues	No (not detectable by microscopy)	Yes
Proliferative ability of morphologically mature cells	None reported	Yes (in certain circumstances)
Life span	Days (like other granulocytes)	Weeks to months (based on studies in rodents)
Mediators		
Major mediators stored preformed in cytoplasm	Histamine, chondroitin sulfates-glucuronidase, elastase, cathepsin G-like enzyme, eosinophil cationic protein, major basic protein, Charcot-Leyden crystal protein, eosinophil peroxidase, some positive for tryptase, chymase, carboxypeptidase A	Histamine, heparin and/or chondroitin sulfates, chymase and/or tryptase, many acid hydrolases, cathepsin G, carboxypeptidase A
Major lipid mediators produced upon appropriate activation	LTC$_4$, PAF	PGD$_2$, LTC$_4$, LTB$_4$, PAF, TXA$_2$
Cytokines and growth factors released upon appropriate activation	IL-2, IL-3, IL-4, IL-5, IL-6, IL-9, IL-13, IL-15, TSLP	IL-1β, IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-9, IL-10, IL-11, IL-13, IL-15, IL-16, IL-17A, IL-18, IL-22, IL-24, IL-25, IL-33, TNF-α, SCF, NGF, TGF-β, FGF-2, VEGF, IFN-α, GM-CSF, TSLP, amphiregulin
Chemokines produced	CCL3, CCL4, CCL12, CXCL2	CCL1, CCL2, CCL3, CCL4, CCL5, CCL7, CCL8, CCL13, CCL17, CCL18, CCL19, CCL20, CCL22, CCL23, CCL25, CCL28, CXCL2, CXCL3, CXCL4, CXCL5, CXCL7, CXCL8, CXCL10, CXCL14, CXCL16, CXCL17, XCL1, CX3CL1
Surface Structures		
Ig receptors	FcεRI, FcγRII (CDw32), FcγRIIB, FcγRIIIA	FcεRI, FcγRI, FcγRIIA, FcγRIIB, FcγRIIIA
Cytokine/growth factor receptors	IL-1RIIb (CD121b), IL-2R (CD25), IL-3R, IL-4Rα, IL-5Rα, IL-18R, IL-33R, TSLPR, GM-CSFRα, TrkA	KIT (SCF receptor), IL-3R, IL-4Rα, IL5Rα, IL-6R, IL-18R, IL-33R, IFN-γRα, TGF-β type-I and type-II β receptors, TrkA, T1/ST2/IL-1R4
Chemokine receptors	CCR1, CCR2, CCR3, CCR5, CXCR1, CXCR2, CXCR4	CCR1, CCR3, CCR4, CCR5, CXCR1, CXCR2, CXCR3, CXCR4, CX3CR1
Other GPCRs	CRTH2, C3aR, C5aR	EP3, BLT1, BLT2, cysLT1, PAF receptor, C3aR, C5aR

LT, leukotriene; PG, prostaglandin; PAF, platelet-activating factor; TXA$_2$, thromboxane A$_2$; IL, interleukin; TSLP, thymic stromal lymphopoietin; SCF, stem cell factor; NGF, nerve growth factor; TGF-β, transforming growth factor-β; FGF-2, fibroblast growth factor-2; VEGF, vascular endothelial growth factor; IFN-α, interferon-α; GM-CSF, granulocyte macrophage–colony-stimulating factor; CCL, chemokine (C-C motif) ligand; CXCL, chemokine (C-X-C motif) ligand; XCL, chemokine (C motif) ligand; CX3CL, chemokine (C-X3-C motif) ligand; TrkA, tropomyosin receptor kinase A; CCR, C-C chemokine receptor; CXCR, C-X-C chemokine receptor; CX3CR, C-X3-C chemokine receptor; GPCRs, G protein–coupled receptors; CRTH2, chemoattractant receptor-homologous molecule expressed on Th2 cells; C3aR, complement component 3a receptor; C5aR, complement component 5a receptor.

hyperplasia of mast cells in multiple organs and tissues.[9] However, the profound reduction of mast cells in W/W^v, W^{sh}/W^{sh}, and *Sl/Sld* mice argue that none of these cytokines can substitute for the absence of SCF or CD117.

In contrast to mice, SCF is absolutely required to derive mast cells *in vitro* from human bone marrow, fetal liver, or cord blood progenitors. IL-3 cannot induce mast cell development from human hematopoietic progenitor cells, although it does can enhance survival of human cord blood mast cells (as do IL-4, IL-5, or IL-6).[10] Human intestinal mast cells proliferate in response to IL-4 when it is provided in combination with SCF. Notably, IL-4 primes human cord blood and/or intestinal mast cells for FcεRI-dependent degranulation, cytokine generation, and cysteinyl leukotriene (cysLT) generation,[11] the latter reflecting strong induction of leukotriene C$_4$ synthase (LTC$_4$S) expression. Thus cytokines other than SCF are likely to play context-specific roles in mast cell development and may help to account for the substantial heterogeneity of anatomically and functionally distinct mast cell subpopulations (see below). Tissue mast cells vary widely in their capacity for cysLT generation, which may reflect cytokine-induced modification of their effector phenotype *in vivo*.

Homing, Distribution, and Heterogeneity of Mast Cells

Mature mast cells are distributed throughout connective tissues and mucosal surfaces, often adjacent to blood or lymphatic vessels or peripheral nerves. Much of the current understanding of mast cell tissue homing comes from mouse models. MCPs home

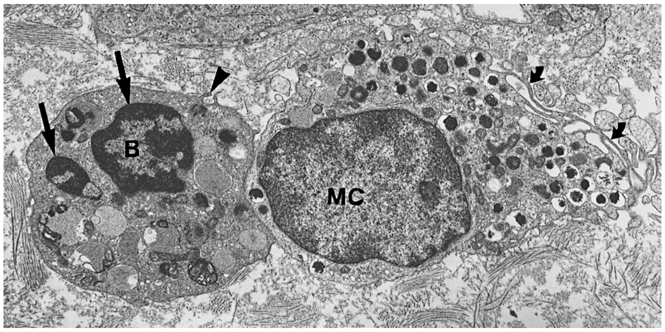

FIG 23.1 **Ultrastructures of Mast Cell and Basophil.** A basophil (B) adjacent to a mast cell (MC) in the ileal submucosa of a patient with Crohn disease. The basophil exhibits a bilobed nucleus (solid arrows) whose chromatin is strikingly condensed beneath the nuclear membrane. The basophil surface is relatively smooth with a few blunt processes (arrowhead). The mast cell nucleus is larger and its chromatin less condensed than that of the basophil. The mast cell's granules are smaller, more numerous, and more variable in shape and content than those of the basophil. The mast cell surface has numerous elongated, thin folds (curved arrows). (Original magnification ~ × 9000). (From Dvorak AM, Monahan RA, Osage JE, Dickersin GR. Crohn's disease: transmission electron microscopical studies. Hum Pathol 1980;11:606–619, with permission from Ann M. Dvorak.)

constitutively to the mouse small intestine, requiring both $\alpha_4\beta_7$ integrin, as well as the chemokine receptor CXCR2.[12] Although the lungs of naïve mice contain few mast cells, MCP recruitment can be experimentally induced in response to allergen sensitization and challenge. In this context, MCP recruitment to the lung is controlled by $\alpha_4\beta_7$ as well as $\alpha_4\beta_1$ and its counterligand, vascular cell adhesion molecule-1 (VCAM-1).[12] To date, no studies have addressed the requirements for homing or recruitment of MCPs to skin, the central nervous system, or other characteristic destinations. Cultured human mast cells express the chemokine receptors CCR3 and CXCR4[13] and respond chemotactically to their corresponding ligands. Mast cells localizing to asthmatic airway smooth muscle express CXCR3, and lung mast cell migration can be induced by airway smooth muscle cultures via activation of CXCR3.[14] However, definitive information regarding the homing requirements for human mast cells *in vivo* is lacking because of technical constraints.

Once in the tissues, MCPs give rise to anatomically and biochemically distinct subpopulations of mast cells. Rodent mast cell subsets are often referred to as *mucosal mast cells* (MMCs) and *connective tissue mast cells* (CTMCs), respectively, based on differences in anatomical distribution and staining characteristics. Early studies of Kanakura et al. used adoptive transfers to demonstrate that both MMCs and CTMCs arose in vivo from a single population of progenitor cells.[15] The differences between MMCs and CTMCs in staining characteristics relate to the relative content of heparin versus chondroitin sulfate glycosaminoglycans (GAGs) bound to the serglycin core of mast cell granules. These GAGs impart the basophilic staining characteristics of mast cell granules and are essential for the storage and stability of highly charged serine proteases and histamine that comprise the major preformed products of mast cells. The mouse genome encodes four mast cell–restricted tryptases and several chymases (at least five of which can be expressed by mast cells), as well as carboxypeptidase A3 (CPA3). Accordingly, the anatomically distinct mouse mast cell subpopulations express very different profiles of proteases (and correspondingly different GAG compositions), dependent on the microenvironment.[16]

In contrast to the mouse, human mast cells express only a single mast cell–specific chymase gene and thus exhibit less heterogeneity compared with their rodent counterparts. Human mast cells can express up to four tryptase genes (α, β, γ and δ), and CPA3. All human mast cells express tryptase β, and some also express chymase, CPA3, and cathepsin G. Human mast cells expressing tryptase in the absence (MC_T) or presence (MC_{TC}) of chymase, CPA3, and cathepsin G differ in anatomical distribution, with MC_T dominating in normal lung, intestinal mucosa, and bronchial and nasal epithelium and MC_{TC} dominating in skin, heart, uterus, and deep connective tissues.[16] These distributions can change with disease and inflammation. For example, the fraction of MC_{TC} among bronchial submucosal mast cells increases markedly with disease severity in asthma,[17] as do the numbers of MC_{TC} infiltrating the airway smooth muscle.[18] MC_{TC}s accumulate selectively in atherosclerotic plaques.[19] In allergic rhinitis and eosinophilic esophagitis, MC_T selectively accumulate in the inflamed mucosal surfaces. Thus while the extent and defining features of mast cell heterogeneity differ between human and rodent mast cells, there is considerable lineage plasticity in both species that reflect both tissue localization and context.

One of the most strongly conserved aspects of mast cell heterogeneity is the dependency, or lack thereof, on T cell–derived accessory growth factors. Athymic nude mice altogether lack MMCs in the intestinal mucosa despite the presence of wild-type levels of CTMCs in the same organ.[20] MC_T are lacking in the intestines of humans with T-cell immunodeficiencies, but MC_{TC} numbers are unaffected.[21] The differential requirement of mast cell subsets for T-cell help likely reflects the capacity of T cell–derived growth factors to synergize with SCF to promote mast cell proliferation and/or survival. This may be functionally important, since T cell–driven expansion of mast cells in the intestine is essential for the elimination of certain helminthic infections. Moreover, the capacity of IL-4 and IL-9 to alter expression of key mast cell effectors suggests that effector systems can be modulated by T cells to suit the needs of the host during immune responses.[9,11]

DEVELOPMENT AND DISTRIBUTION OF BASOPHILS

Basophils are the rarest of granulocytes in mammals (<1% of peripheral blood leukocytes) and take their name from the basophilic granules in their cytoplasm. The scarcity and short life span (~2.5 days in mice) of basophils hindered the study of their functions until recently, but there is now a growing appreciation for their roles in various immune processes that are distinct from the mast cell. These include FcεRI-dependent antigen capture and a potent and rapid capacity to generate and secrete IL-4 and IL-13.

Basophils are myeloid cells that originate and develop in bone marrow. Like mast cells, they develop from GMPs, which become BMCPs or BaPs, each of which has the capacity to develop into a mature basophil.[2,3] The basophil lineage commitment is regulated by the transcription factors GATA-2 and C/EBPα. Unlike mast cells, basophils exit bone marrow only after they have fully matured. Basophil development is promoted in the context of T-helper cell-2 (Th2) inflammatory responses. Cytokines, including IL-3 and the epithelial cell–derived cytokine TSLP, regulate basophil development as well.[3]

Ex vivo developmental studies with human progenitor cells have suggested a common origin for basophils and eosinophils. Denburg et al. showed that a fraction of clonal colonies arising from human peripheral blood progenitor cells contained both eosinophils and basophils, with some cells showing an intermediate phenotype with granules of both lineages.[22] Saito et al. showed that recombinant IL-3 stimulated the growth of both eosinophils and basophils from cord blood progenitors.[23] Human basophils express eosinophil cationic protein, major basic protein, Charcot-Leyden crystal protein, and eosinophil peroxidase, all of which are eosinophil granule markers,[24] consistent with a common origin of both cell types. A recent transcriptional profiling study confirmed that mouse blood basophils are more similar to eosinophils in their gene expression pattern than to any other cell type.[5] The shared lineage pathway for basophils and eosinophils explains why blood basophil counts are frequently elevated in conditions associated with increased blood eosinophil counts.

Basophil recruitment to the tissues is likely governed by a combination of protein and lipid chemoattractants. Human basophils express CCR1, CCR2, CCR3, CCR5, CXCR1, and CXCR2 and respond *ex vivo* to the corresponding ligands. Basophils strongly express chemoattractant receptor homologue expressed by Th2 cells (CRTH2), a specific receptor for prostaglandin D_2 (PGD_2). PGD_2 is an abundant product of activated mast cells, and CCR3 ligands (CCL11, CCL24, CCL26) are abundantly expressed by structural cells in allergic inflammation.[1] Thus all of these are good candidates to account for the accumulation of basophils that is frequently observed in rhinitis and asthma, and that is characteristic of allergen-induced late-phase responses.

BIOLOGICAL MEDIATORS PRODUCED BY MAST CELLS AND BASOPHILS

Mast cells and basophils can elaborate a broad array of potent biologically active mediators (see Table 23.1). Some of these products are stored preformed in cytoplasmic granules (*e.g.*, histamine, proteases, proteoglycans, certain cytokines), and others are synthesized *de novo* upon activation of the cell (*e.g.*, products of arachidonic acid oxidation via the cyclooxygenase [COX] or lipoxygenase pathways, platelet-activating factor [PAF], cytokines, chemokines, growth factors).[19] These mediators enable mast cells and basophils to orchestrate various functions in inflammation and host defense. Some, such as histamine and cysLT, are targets of the best-established drugs for the treatment of allergic diseases, validating the pathogenetic importance of mast cells, basophils, and their associated effector systems.

Preformed Mediators

Mediators that are stored in secretory granules can be rapidly (seconds to minutes) released into the extracellular environment upon stimulation. These mediators include histamine, proteoglycans, and (in the case of mast cells) proteases.[19]

Histamine is stored in the granules of mast cells and, to a lesser extent, basophils. Histamine is released within minutes of cell activation and mediates increased vascular permeability, smooth muscle contraction, mucus production, and increased heart rate and cardiac output, gastric acid secretion, itching, and sneezing. These actions are mediated via four types of histamine receptors (H1–4) on target cells.[1,3,16] H1 receptor antagonists are among the oldest antiallergy medications, and their efficacy supports the role of histamine in mediating the clinical signs and symptoms of rhinitis, allergic conjunctivitis, and urticaria.

KEY CONCEPTS

Mast Cell and Basophil Mediators

- Mast cells and basophils produce distinct but overlapping panels of mediators with diverse biological effects.
- Some mast cell and basophil mediators are preformed and stored in cytoplasmic granules (*e.g.*, histamine, proteoglycans, proteases). These can be released rapidly (seconds to minutes) upon cellular activation and degranulation.
- Mast cells and basophils produce lipid mediators (*e.g.*, PGD_2, LTC_4), which are derived from arachidonic acid and are newly synthesized upon cell activation.
- Mast cells and basophils can transcribe and secrete many cytokines, chemokines, and growth factors (see Table 23.1).

Proteases, including tryptases, chymase, and CPA3, comprise the major protein component of mast cell secretory granules. Tryptases are the most abundant proteases in the human mast cell and are found in basophils as well. Human tryptases are encoded by several different alleles, including α, β, γ, and δ. As noted previously, only a single mast cell–specific chymase gene exists in humans. CPA3 is expressed strongly by mast cells and weakly by basophils.[1,16] Tryptase β can activate protease-activated receptors, inducing fibroblast proliferation and collagen secretion. Both human tryptase β and its murine orthologue, mouse mast cell protease 6, can induce neutrophil recruitment in models of bacterial sepsis, suggesting prominent functions in innate immunity. Human mast cell chymase converts angiotensin 1 to angiotensin 2, suggesting a potential role in the control of blood pressure and cardiovascular homeostasis. CPA3 can neutralize endothelin 1 and the snake venom protein sarafotoxin.[25] These vasoprotective and antivenom functions are consistent with a role for resident cutaneous and perivascular mast cells vascular homeostasis and host defense. The functions of the mast cell proteases are reviewed comprehensively elsewhere.[16,26]

Newly Synthesized Mediators

Both mast cells and basophils utilize membrane phospholipid-derived arachidonic acid to synthesize eicosanoid mediators and can use the resultant lysophospholipids to generate PAF. These mediators are released within 15 minutes of activation. Both mast cells and basophils express 5-LO and LTC_4S, permitting them to generate LTC_4, the parent cysLT, from endogenous arachidonic acid. Mast cells, but not basophils, can generate smaller quantities of the dihydroxy leukotriene, LTB_4, which is a potent neutrophil chemoattractant. LTC_4 is converted extracellularly to LTD_4 (the most potent known bronchoconstrictor) and then to the stable metabolite LTE_4.[3,19] CysLTs are abundant in allergic inflammation, increasing microvascular permeability and causing bronchoconstriction. Mouse models suggest they play important roles in amplifying Th2 responses through several cellular targets. There are three cysLT receptors, respectively termed $CysLT_1R$, $CysLT_2R$, and GPR99.[27] Both $CysLT_1R$ antagonists and 5-LO inhibitors show efficacy in asthma, supporting the pathogenic role of the cysLT in this disease.

In contrast to basophils, mast cells generate substantial quantities of PGD_2, a product of successive metabolism of arachidonic acid by COX-1 or COX-2 and hematopoietic PGD_2 synthase, an enzyme that is expressed more strongly by mast cells than any other cell type. PGD$_2$ binds to two specific receptors, termed DP$_1$ and CRTH2 (also known as DP$_2$). Once released, PGD$_2$ elicits vasodilation (via DP$_1$) and bronchoconstriction (via the actions of a putative metabolite at the T prostanoid receptor). Additionally, PGD$_2$ is potently chemotactic for basophils, eosinophils, Th2 cells, and group 2 innate lymphoid cells (ILC2), each of which express CRTH2.[19] PGD$_2$ induces cytokine generation (IL-4, IL-5, IL-13) from both human Th2 cells and ILC2 and could, therefore, amplify type 2 inflammation in a polyclonal fashion. There are several CRTH2-selective antagonists in clinical development for the treatment of asthma and other allergic diseases.

Cytokines, Chemokines, and Growth Factors

Basophils and mast cells produce a wide variety of cytokines and chemokines that recruit and activate other cells (see Table 23.1). Mast cells generate tumor necrosis factor-α (TNF-α), IL-6, and IL-1β, which is consistent with their sentinel role in innate antimicrobial immunity (Chapter 3). Mast cells can generate the Th2 cytokines IL-5 and IL-13, a functional property that is induced when the cells are exposed to IL-4. TNF-α can be stored in granules constitutively as well as produced *de novo* in response to activation.[19] Activated mouse and human mast cells express a large range of both CC and CXC chemokines, likely reflecting their role in facilitating the recruitment of bloodborne effector cells. A recent study demonstrated that mast cell progenitors in the intestinal mucosa are an important source of IL-9 and IL-13 in a model of food allergy.[28] Basophils can secrete large quantities of IL-4 (and IL-13) rapidly, contributing to Th2 immune responses in a variety of settings. These observations suggest that basophils are more specialized than mast cells for a role in type 2 immunity.

MECHANISMS OF ACTIVATION OF MAST CELLS AND BASOPHILS

KEY CONCEPTS

Mechanisms of Mast Cell and Basophil Activation

- Mast cells and basophils have cell-surface high-affinity immunoglobulin E (IgE) receptors (FcεRI) that are tetrameric and thus fully functional, unlike the trimeric FcεRI found on other cells (*e.g.,* dendritic cells [DCs] and eosinophils).
- IgE-mediated activation of mast cells and basophils occurs when multivalent antigen cross-links IgE antibodies bound to adjacent FcεRI receptors, resulting in degranulation and *de novo* mediator production and release.
- Mast cells and basophils can be activated by non–IgE-mediated mechanisms (anaphylatoxins, Toll-like receptor [TLR] ligands, certain cytokines, drugs, venoms, etc.).
- Some types of non–IgE-mediated activation cause a more compartmentalized activation (*e.g.,* cytokine production without degranulation caused by activation of mast cells or basophils by interleukin-33 [IL-33] and thymic stromal lymphopoietin [TSLP]).

FcεRI-Mediated Activation (and Inhibition of IgE-Dependent Activation)

Both mast cells and basophils express the high-affinity IgE receptor, FcεRI. The FcεRI expressed on these cells is unique in that it has a tetrameric structure consisting of a single IgE-binding αα chain, a single β chain, and two identical disulfide-linked γ chains. Human hematopoietic cells other than mast cells and basophils (*e.g.,* eosinophils and dendritic cells [DCs]) express FcεRI in the absence of the β chain. The β chain amplifies signaling through the receptor, and the tetrameric form on mast cells and basophils is thus fully functional.[29] Activation occurs when adjacent FcεRI receptors, occupied by receptor-bound IgE, are cross-linked by multivalent antigen, stimulating degranulation and release of preformed mediators as well as *de novo* production and release of additional mediators described above.[1,3,19,29] The signaling cascades that are initiated by FcεRI cross-linking are reviewed in detail elsewhere.[30]

At the ultrastructural level, stimulation of sensitized human basophils with specific antigen provokes fusion of the membranes enveloping individual cytoplasmic granules with the plasma membrane (Fig. 23.2). This results in the release of the granules' contents via multiple narrow communications between single granules and the cell surface. IgE-dependent degranulation of human lung mast cells results in the fusion of granule membranes with the plasma membrane (Fig. 23.3). However, in this cell type the first ultrastructural changes detectable in the stimulated cells are granule swelling, followed by fusion of individual granule membranes forming interconnecting chains of swollen granules; histamine release is initiated by the opening of these channels to the exterior through multiple narrow points of fusion with the plasma membrane.[31]

Non–IgE-Mediated Activation

Mast cells and basophils can be activated through a variety of non–IgE-mediated mechanisms. Both mast cells and basophils express receptors for complement fragments C3a and C5a and release histamine in response to these complement components. The C5a receptor (CD88), in particular, is expressed in human lung on MC$_{TC}$s, and elevated C5a concentrations have been measured in induced sputum from subjects with asthma.[2,19] Mast cells and basophils can be activated by microbial constituents via Toll-like receptors (TLRs), many of which are expressed on their surface and internal membranes.[19,29] Both cell types respond to the barrier-derived cytokines IL-33 and TSLP, both of which drive Th2-type immune responses. Each cytokine can directly activate mast cells and, in some cases, amplify IgE-mediated responses.[29] In contrast to the complement fragment-dependent activation, IL-33 and TSLP fail to induce degranulation but are powerful inducers of cytokine production, particularly when they are provided together. Thus non–IgE-dependent activation mechanisms tend to elicit a response from mast cells that is more compartmentalized than FcεRI-mediated activation.

A variety of drugs, such as opiates and muscle relaxants, can directly activate mast cells.[19,29] Recently, the murine counterpart of the human G protein-coupled receptor, MAS-related G protein-coupled receptor X2 [MRGPRX2], was found to be necessary to trigger mast cell degranulation *in vivo* response to a range of basically charged drugs, as well as compound 48/80, a classic secretagogue for mast cells.[32] The potential that certain drugs possess in their ability to mimic components of innate immunity to trigger mast cells represents a major conceptual step forward toward understanding drug-induced pseudoallergic reactions that do not involve specific IgE.

Basophil activation is promoted by IL-3, and other cytokines, including IL-18 and IL-33, can activate basophils and enhance their effector functions.[3] Basophils can be directly activated by protease allergens, including the house dust mite protease Derp1.[3] Finally, both mast cells and basophils respond to PAF with

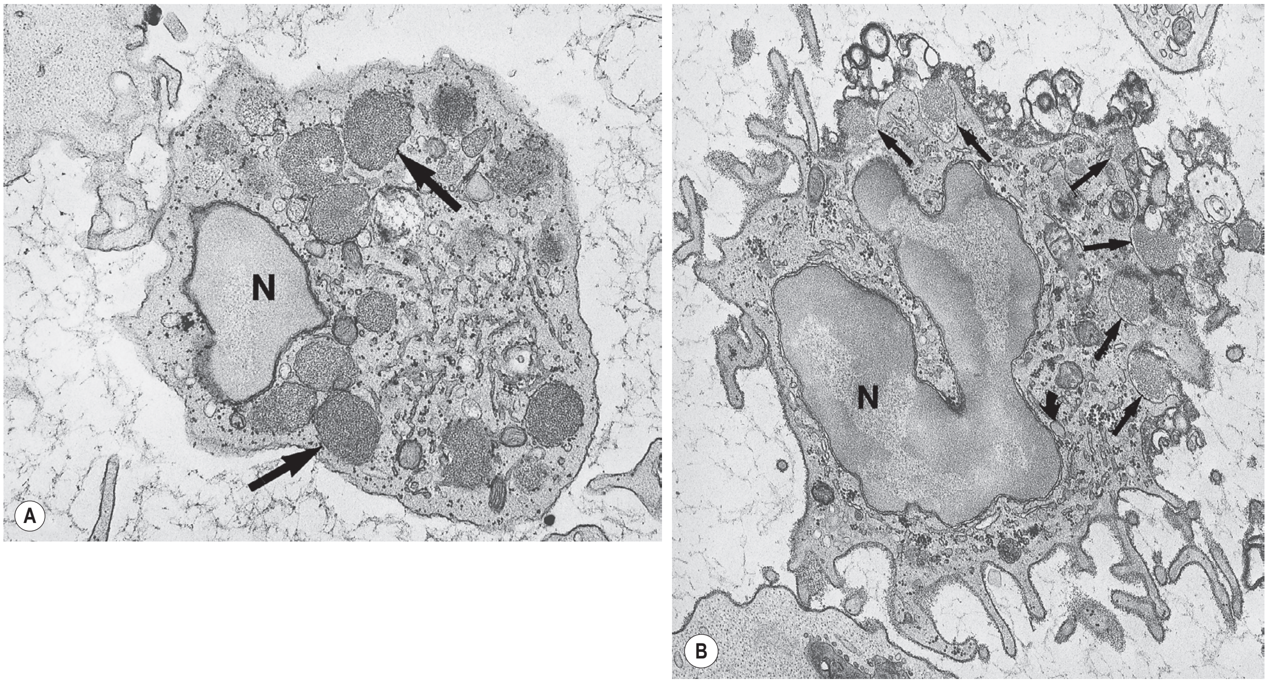

FIG 23.2 (A) Transmission electron micrograph of a human basophil in a preparation of peripheral blood leukocytes obtained by separation over Ficoll-Hypaque. All of the cytoplasmic granules (some indicated by solid arrows) contain particulate electron-dense material. N, nucleus. (Original magnification ~ × 19800). (B) A human basophil 2 minutes after exposure to antigen *in vitro.* The cell exhibits extrusion of granules from six separate sites on the plasma membrane (small arrows). At this time after cell stimulation, particle-filled granules retain their shape and characteristic structure even after exposure to extracellular milieu. Cationized ferritin coats the cell surface and enters culs-de-sac that contain exteriorized granules. The cell exhibits no fully intracytoplasmic typical basophilic granules, but one of the smaller kind of granules (curved arrow) can be observed in the perinuclear region. N, nucleus. (Original magnification ~ × 19200). (From Dvorak AM, Newball HH, Dvorak HF, Lichtenstein LM. Antigen-induced IgE-mediated degranulation of human basophils. Lab Invest 1980;43:126–139, with permission from Nature Publishing Group Ltd.)

activation and histamine release, and PAF concentrations are elevated in the plasma after anaphylactic reactions.[33] These findings suggest a mechanism by which endogenous lipid metabolism can magnify the physiological effects of mast cell activation in anaphylaxis.

MAST CELLS AND BASOPHILS IN DISEASE AND HOST DEFENSE

CLINICAL RELEVANCE

Mast Cells and Basophils in Health and Disease

- Mast cells and basophils are primary effector cells in atopic disorders (anaphylaxis, asthma, allergic rhinitis, atopic dermatitis).
- Antigen-specific, immunoglobulin E (IgE)-mediated mast cell activation results in an immediate clinical reaction and, in some cases, contributes to a late-phase reaction.
- Medications that block mast cell and basophil mediators are mainstays of treatment for atopic diseases.
- Mast cells and basophils contribute to host defense against parasites and bacterial pathogens.
- Mast cells may play a role in other human diseases, including atherosclerosis, autoimmune diseases, and burns and in responses to venom toxins.

Allergic Disease

Anaphylaxis

Anaphylaxis is an acute, life-threatening, multisystem reaction that results from the precipitous release of mast cell and basophil mediators into the circulation (Chapter 42). These mediators cause the cardinal manifestations of hypotension, bronchoconstriction, intestinal colic, urticaria, and, in some instances, disseminated intravascular coagulation. Anaphylactic reactions can be triggered by foods, insect stings, and medications, among other factors. Anaphylaxis, like mast cell and/or basophil activation, can be immunological or nonimmunological.

The classic mechanism of anaphylaxis in human disease is IgE mediated, with an interaction between antigen and antigen-specific IgE bound to FcεR1 on mast cells and/or basophils. In this instance, anaphylaxis can be considered a severe form of type I hypersensitivity. Production of histamine and leukotrienes in response to IgE-mediated activation of both mast cells and basophils induces smooth muscle contraction and contributes to the symptoms and physiology of systemic anaphylaxis.[3] Besides the classically described IgE-mediated type of anaphylaxis, IgG-driven, PAF-mediated anaphylaxis has also been described in mouse models. Mast cells are dispensable for this type of anaphylaxis, whereas basophils (among other lineages) have been reported as PAF-producing effector cells.[3] PAF levels are elevated

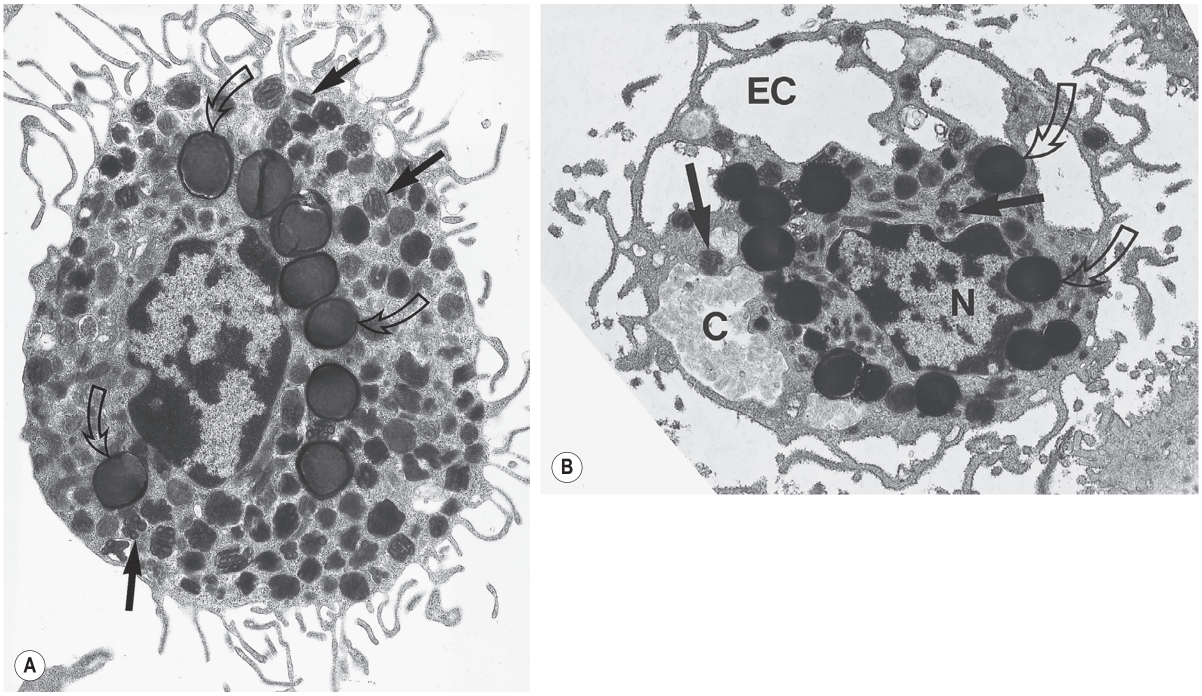

FIG 23.3 (A) Mast cell purified from human lung. The cell contains many cytoplasmic granules with scroll-like substructural elements (solid arrows) and eight large non–membrane-bound lipid bodies (open arrows). The plasma membrane has prominent folds. N, nucleus. (Original magnification ~ × 12 900). (B) An isolated human lung mast cell 10 minutes after exposure to anti-IgE *in vitro.* Some degranulation channels (C), formed by fusion of membranes surrounding individual cytoplasmic granules, contain altered granule matrix; others (EC) are empty. Cationized ferritin stains the plasma membrane and the membranes of some empty degranulation channels (EC). The membranes lining other channels (C) are unstained. A few unaltered scroll-containing granules (solid arrows) remain. Numerous lipid bodies are also present (open arrows). The cytoplasm contains prominent filaments. N, nucleus. (Original magnification ~ × 9 100). (From Galli SJ, Dvorak AM, Dvorak HF. Prog Allergy 1984;34:1, with permission from Ann M. Dvorak.)

in the serum of patients with severe peanut anaphylaxis, suggesting that PAF may serve to amplify the physiological manifestations of IgE-dependent anaphylaxis. Immune complex–mediated complement activation has been proposed as a mechanism for some anaphylactic reactions to drugs. Nonimmunological anaphylaxis can be caused by complement activation in the absence of immune complexes or by direct activation of mast cells, often by drugs, such as opiates or vancomycin.[34] As noted above, some of these (particularly muscle relaxants) may result from drugs that activate MRGPRX2 or related receptors.[32]

Asthma

Asthma is a chronic inflammatory disease of the airways characterized by variable airflow obstruction and airway hyperresponsiveness (AHR) (Chapter 41). The most direct evidence for a mechanistic contribution of mast cells to allergic asthma comes from allergen challenge studies. In sensitized individuals, allergen challenge causes an increase in mast cell granule contents in bronchoalveolar lavage (BAL) fluid, including histamine, tryptase, and cysLTs. About 60% of patients having an immediate, early-phase asthmatic response will have a late-phase reaction beginning 3–5 hours later, peaking around 8 hours, and resolving in about 24 hours. Mast cells contribute to both the early-phase and the late-phase asthmatic response, via the release of histamine and production of proinflammatory cytokines, leukotrienes, and prostanoids.[19] The involvement of mast cells in early- and late-phase responses is supported by earlier studies using mast cell stabilizing cromone drugs, as well as anti-IgE.

Immunohistological studies provide additional support for the role of mast cells in asthma. Bronchial biopsies from subjects with asthma exhibit mast cells localizing to the airway smooth muscle bundles, a region generally lacking mast cells in biopsies from healthy controls and from subjects with nonasthmatic eosinophilic bronchitis.[19] Smooth muscle mast cell density correlated strongly with disease severity and with hyperresponsiveness to methacholine,[35] a cardinal feature of asthma. Notably, these increases were observed irrespectively of atopic status of the study subjects. In biopsy samples from subjects with severe asthma, mast cells exhibit substantially higher proportions with positive immunostaining for chymase than in specimens from those with mild asthma. Thus both the distribution and phenotype of mast cells is altered in the airways of patients with severe asthma. The mechanisms responsible for these alterations, and the factors responsible for driving mast cell activation in severe disease, particularly in individuals without atopy remain to be determined.

Mast cells may play an especially important role in aspirin-exacerbated respiratory disease (AERD), a distinctive disorder in which asthma, severe rhinosinusitis, and nasal polyposis are associated with idiosyncratic respiratory reactions to aspirin and other drugs that inhibit COX-1. Although tissue mast cell burden in AERD does not exceed that seen in aspirin-tolerant control patients with asthma, baseline levels of serum tryptase and urinary PGD_2 metabolites are higher, potentially reflecting a loss of homeostatic PGE_2 from the surrounding tissue. These values increase markedly with aspirin challenges, and treatment with cromolyn or nedocromil blocks the characteristic reactions, supporting their mast cell dependency.[36] Notably, a mouse model suggests that mast cell activation in response to aspirin challenge depends on IL-33 rather than the allergen.[36] It is tempting to speculate than innate cytokines could account for mast cell activation in other nonatopic disorders.

There is growing evidence that basophils play a role in the pathogenesis of asthma as well. Basophils are enriched in postmortem human lung tissue from patients who have died as a result of asthma as well as in bronchial biopsy specimens of patients with asthma.[1,3] In mouse models of allergic airway inflammation, basophils have been shown to promote Th2 cytokine responses and pathological airway inflammation.[3] The specific functions of basophils relative to asthma are not yet known, though it seems likely that they could contribute Th2 cytokines and cysLTs.

Allergic Rhinitis

Allergic rhinitis is an inflammatory disease of the nasal mucosa that occurs as a reaction to airborne allergens (Chapter 41). Increased numbers of activated MC_T mast cells are found in the nasal epithelium of patients with allergic rhinitis, and these numbers increase further with allergy provocation challenge or during seasonal disease exacerbations.[34] Basophils are present in nasal washes from patients with allergic rhinitis.[3] In addition, nasal challenges with allergens lead to the release of histamine and cysLTs, which are preformed mediators of both mast cells and basophils.[34]

Atopic Dermatitis

Atopic dermatitis (AD) is a chronic, relapsing inflammatory skin condition that is commonly diagnosed in young children and often precedes the development of allergic rhinitis and asthma (Chapter 44). The pathogenesis of AD remains incompletely understood but is likely multifactorial with contributions from skin barrier dysfunction, innate and adaptive immune dysregulation, and environmental and genetic factors. Increased numbers of mast cells can be seen in skin lesions from human AD and mouse AD models, but their role in the pathophysiology of the disease is not known.[34]

Basophils have been identified in lesional skin of patients with AD, but their precise role in human disease remains unclear. In murine models of AD-like skin disease, significant TSLP-dependent basophilia has been noted in lesional skin. TSLP is also associated with human AD, so it is possible that TSLP-induced basophil populations could play a role in human disease as well.[1,3]

Mast Cells and Basophils in Immunity

Although mast cells are found throughout most tissues, they are notably located at interfaces with the environment, such as skin and the mucosal surfaces. This suggests a potential role in pathogen recognition and host defense. Additionally, mast cells have the capacity to increase in numbers during mucosal inflammatory responses, suggesting that their effector capabilities can be magnified to suit the context. The first associations of mast cells with host defense included observations of mast cells clustering around sites of parasitical infestation. Subsequent studies have demonstrated a role for mast cells in mouse models of helminth infection in the gut as well as in parasitical skin infections.[37]

Production of IL-4 and IL-13 by mast cells and basophils may play an important role in early parasitical infections, leading to IgE production, secretion of effector molecules, activation of smooth muscle cells, and increased mucus production, among other effects.[1] Furthermore, although expulsion of hookworm during primary infection in mice depends on mast cells, basophils are necessary to expel hookworms during secondary infection, possibly because of activation by helminth-specific antibodies.[1] Intestinal helminth infections typically elicit a T cell-dependent expansion of mast cells and basophils in the involved mucosal site.[8] In that regard, mast cells and basophils can be viewed as components of the effector arm of adaptive immunity.

Mast cells are important in the generation of immune responses to bacterial pathogens. For example, mast cell deficient mice have increased mortality in a model of *Escherichia coli*–induced peritonitis. Mast cells have shown protective roles in *K. pneumoniae* lung infections and *Pseudomonas* skin infections in mice.[37] Mice lacking mast cells as a result of loss-of-function *Kit* and *SCF* mutations are significantly more susceptible to lethal gram-negative sepsis than are congenic mast cell–sufficient controls. Reconstitution of the tissues with wild-type mast cells restores protective immunity. Both proteases and TNF-α are linked to the protection from bacterial infections conveyed by mast cells.

Mast Cells in Other Diseases

Mast cells may play a role in other disease processes as well. Increased numbers of mast cells have long been noted in human atherosclerotic lesions compared with healthy control tissue. Mast cell functions within these plaques are not completely understood, although mouse models suggest that atherosclerotic changes are promoted by release of proinflammatory cytokines by mast cells.[38] Mouse models of autoimmunity, including autoantibody-mediated arthritis[39] and multiple sclerosis,[40] have demonstrated a pathological role for mast cells. Skin mast cells are activated rapidly following thermal trauma, and the release of mast cell proteases is crucial for development of the inflammatory response in burn lesions.[41]

Recent work in mice has shown that mast cells protect from the detrimental effects of arthropod or reptile venoms via the degradation of venom toxins by mast cell proteases. Furthermore, acquired Th2 immune responses associated with IgE production can protect mice from challenge with potentially lethal doses of venoms from honeybee or the Russell viper.[42]

Mast Cell Roles in Normal Physiology

In addition to their immune functions, mast cells are thought to have normal physiological functions as well. Data from mouse studies suggest a role for mast cells in intestinal barrier function and homeostatic intestinal epithelial migration.[43] Human uterine tissue has increased density of mast cells during pregnancy, where they may mediate contractility,[44] in addition to contributing to local immunity.

MASTOCYTOSIS AND OTHER MAST CELL DISORDERS

A variety of human disorders are associated with excessive numbers of mast cells, increased activation of mast cells, or both.

Mastocytosis can be limited to skin or have widespread systemic effects. Mast cell disorders cause a broad range of symptoms that can mimic a variety of other conditions, often making diagnosis a challenge.

Epidemiology

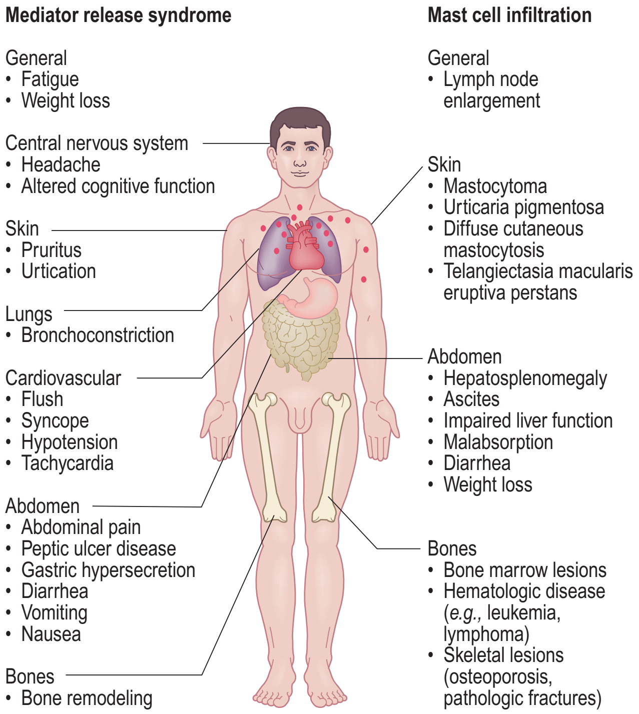
Mastocytosis can occur at any age, although it tends to have a more benign and transient course in children and often is limited to cutaneous manifestations. In a Polish case series of 100 children with cutaneous mastocytosis (CM), 73% had onset of the disease by age 6 months and 94% within the first year of life.[45] Most cases of systemic mastocytosis (SM) are diagnosed in middle age. The exact prevalence of mastocytosis is unknown, but an estimate from a recent Danish population-based study is approximately 1:10 000.[46] With rare exceptions, mastocytosis does not appear to be inherited.

Pathogenesis

The manifestations of mastocytosis can result from mast cell mediator release (both chronic and episodic) and from excessive accumulation of mast cells in one or more tissues. Although the molecular pathogenesis is incompletely understood, mastocytosis is frequently associated with somatic gain-of-function mutations in KIT (CD117). The most common of these mutations is Asp816Val, or D816V.[47] KIT-activating mutations lead to SCF-independent activation. Mast cells are thought to accumulate in tissues because of clonal expansion and apoptotic defects of KIT-mutated mast cells in mastocytosis.[6]

Clinical Features

The clinical signs and symptoms of mastocytosis are varied and can affect many different organ systems (Fig. 23.4). Clinical features can be broadly categorized as cutaneous, related to mast cell mediator release, or resulting from organ infiltration by mast cells.



Mediator release syndrome
General
• Fatigue
• Weight loss
Central nervous system
• Headache
• Altered cognitive function
Skin
• Pruritus
• Urtication
Lungs
• Bronchoconstriction
Cardiovascular

FIG 23.4 Clinical manifestations of mastocytosis.

Skin findings may be seen in both CM and SM, and the most common skin-related symptom in patients with mastocytosis is pruritus. Accumulations of mast cells in skin can present as a variety of lesions. Urticaria pigmentosa (UP), also called *maculopapular cutaneous mastocytosis* (MPCM), is the most common skin manifestation of mastocytosis in both adults and children. Lesions of UP appear as small, tan to reddish-brown macules or slightly elevated papules (Fig. 23.5A–C). UP is present more commonly in the less aggressive forms of SM.

Diffuse cutaneous mastocytosis (DCM) is characterized by edema and increased skin thickness, with or without a yellowish-brown coloration. DCM is rare, accounting for 1–3% of CM. Cutaneous mastocytomas are well-demarcated flat or slightly elevated lesions that may have a yellow or red-brown coloration. Mastocytomas can be solitary or multiple and are typically 2–5 cm in size. The least frequent form of CM (<1% of cases) is telangiectasia macularis eruptive perstans (TMEP). TMEP typically presents in adulthood and consists of tan/brown macules with telangiectasias.

Lesions of UP, DCM, and cutaneous mastocytomas display the Darier sign: localized urtication and redness of lesions following rubbing, scratching, or stroking of skin. Mastocytomas can also precipitate severe systemic symptoms when rubbed. In both CM and SM, mast cell mediator release can occur either chronically or episodically, resulting in a variety of symptoms, including flushing, pruritus, shortness of breath, nausea, vomiting, abdominal pain, diarrhea, hypotension, syncope, fatigue, and headache. Anaphylaxis can be seen in both CM and SM. Interestingly, urticaria and angioedema are uncommon in mastocytosis.

Gastrointestinal (GI) symptoms are particularly common in SM, with diarrhea and abdominal pain reported in up to 80% of patients with SM.[48] Neuropsychiatric symptoms, including depression, irritability, increased somnolence, and problems with memory and concentration, are often observed in mastocytosis, although the mechanisms are not well-understood.[49] Osteopenia and osteoporosis are observed in a subset of patients with SM. This may be attributed to the effects of mast cell mediators, including histamine, tryptase, heparin, IL-6, TNF-α, and transforming growth factor-β (TGF-β), on bone turnover.[50]

Mast cell mediator release can be triggered by a variety of factors, including medications (including nonsteroidal antiinflammatory drugs [NSAIDs], opiates, muscle relaxants, and contrast media), alcohol, surgical or endoscopic procedures, infections (viral, bacterial, parasitical), physical factors (exercise, friction, extremes of temperature), and emotional stress. Patients with mastocytosis are particularly susceptible to anaphylaxis during allergic reactions to *Hymenoptera* stings. Severe allergic reactions to *Hymenoptera* stings should prompt an evaluation for mastocytosis, and patients with mastocytosis should be offered venom immunotherapy.[51]

Infiltration and/or proliferation of mast cells in organs other than the skin distinguish SM from CM. The organ systems most often affected in SM include bone marrow, GI tract, lymph nodes, liver, spleen, and cortical bone. The most frequent hematological abnormality in SM is anemia, and eosinophilia is also common.[52] The lymph nodes and spleen are commonly infiltrated in all subtypes of SM, manifesting as lymphadenopathy or splenomegaly in many patients.

Classification

The World Health Organization (WHO) has defined seven variants of mastocytosis (Table 23.2). CM is limited to the skin and more

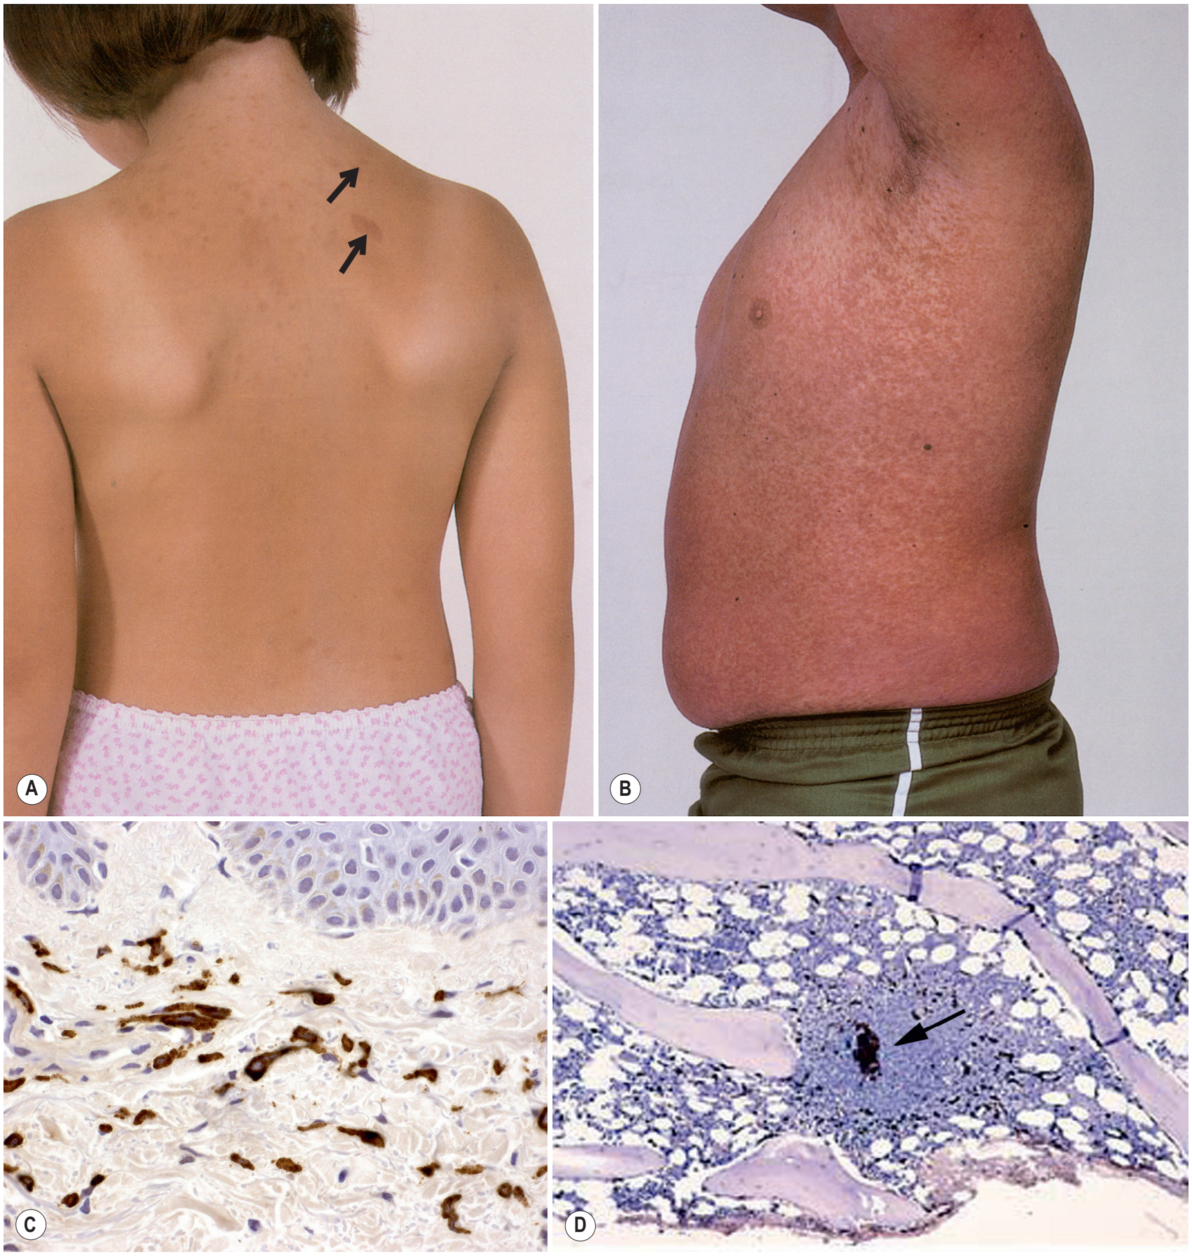

FIG 23.5 **Cutaneous Mastocytosis and Histopathology.** Urticaria pigmentosa is the most common form of cutaneous mastocytosis. In childhood, lesions are disseminated and consist of well-demarcated hyperpigmented macules (*e.g.,* arrows) (A). In adults, lesions may be numerous with less well-demarcated brownish-red macules and papules (B). Histopathology of cutaneous mastocytosis shows many mast cells containing abundant tryptase immunoreactive cytoplasmic granules in the papillary dermis (antitryptase, AA1 clone, Dako; original magnification ~ × 400) (C). Bone marrow pathology of indolent mastocytosis is characterized by paratrabecular lymphoid nodule containing small, well-differentiated lymphoid cells around substantial numbers of fusiform cells with prominent granules in the tryptase stain (arrow) (antitryptase, AA1 clone, Dako; original magnification ~ × 250) (D). (Courtesy of Cem Akin.)

commonly found in children. SM can include findings in a variety of organ systems, with or without skin involvement, and is defined by a set of major and minor diagnostic criteria[53] (Table 23.3). The different categories of SM are distinguished by clinical signs and symptoms and/or pathological findings, including mast cell burden and involvement of non–mast cell lineages,[52] and have different prognostic implications, as described below.

The term *monoclonal mast cell activation syndrome* (MMAS) refers to the condition in patients who have clinical symptoms consistent with mast cell activation and meet one or two of the minor criteria for SM but do not fully meet the diagnostic criteria. The term *mast cell activation syndrome* (MCAS) describes patients presenting with clinical symptoms of mast cell activation affecting at least two organ systems, but not fulfilling the criteria for

TABLE 23.2 World Health Organization (WHO) Classification of Mastocytosis

Cutaneous mastocytosis
Indolent systemic mastocytosis
Systemic mastocytosis with an associated clonal hematologic non–mast cell lineage disease
Aggressive systemic mastocytosis
Mast cell leukemia
Mast cell sarcoma
Extracutaneous mastocytoma

TABLE 23.3 Diagnosis of Systemic Mastocytosis Based on World Health Organization (WHO) Criteria[a]

Major Criterion

Multifocal, dense infiltrates of mast cells (≥ 15 mast cells in aggregates) detected in sections of bone marrow and/or other extracutaneous organ(s)

Minor Criteria

1. More than 25% of mast cells in biopsy sections of bone marrow or other extracutaneous organs are spindle shaped or display atypical morphology, or, of all mast cells in bone marrow aspirate smears, > 25 % are immature or atypical
2. Detection of an activating point mutation at codon 816 of c-*KIT* in blood, bone marrow, or another extracutaneous organ
3. Mast cells in the bone marrow, blood, or other extracutaneous organs express CD2 and/or CD25 in addition to normal mast cell markers
4. Serum total tryptase persistently exceeds 20 ng/mL

[a] One major and one minor, or three minor, criteria are needed for the diagnosis of systemic mastocytosis.

Data from Horny HP, Metcalfe DD, Bennett JM, et al. Mastocytosis In: Swerdlow SH, Campo E, Harris NL, Jaffe ES, Pileri SA, Stein H, Thiele J, Vardiman JW, editors. WHO classification of tumors of hematopoietic and lymphoid tissues. Lyon, France: IARC Press; 2008: p. 54–63.

anaphylaxis or for MMAS.[54] Patients who have anaphylaxis of unknown etiology are more properly diagnosed with idiopathic anaphylaxis.

Diagnosis

For all patients with mastocytosis, the diagnostic process begins with a thorough history and physical examination. The diagnosis of CM is made based on the appearance of characteristic skin lesions and may be confirmed with skin biopsy showing mast cell infiltrates in the skin. In adults with cutaneous findings, systemic disease must be ruled out.

The diagnostic process for patients with suspected mast cell disease typically includes measurement of serum tryptase. If the tryptase is found to be elevated during an anaphylactic episode or other symptomatic event, the measurement should be repeated at least 24 hours after symptoms have resolved. If basal tryptase is elevated (>20 ng/mL), there is a high probability of SM.[52] Another blood test that may be useful, particularly in patients with borderline tryptase levels or an indeterminate clinical presentation, is a screening test for the D816V mutation in peripheral blood leukocytes. Both elevated tryptase and the D816V mutation are minor criteria for mastocytosis. Other blood tests that should be performed to evaluate for specific organ involvement include complete blood count and liver function tests.

Most of the diagnostic criteria for mastocytosis (see Table 23.3) depend on bone marrow histopathological findings. Bone marrow biopsy is therefore an essential part of the diagnostic process. It should be considered for adult patients with typical skin lesions and as a confirmatory test in patients with elevated tryptase levels. Typical findings on bone marrow biopsy in mastocytosis include multifocal dense mast cell aggregates (>15 mast cells per cluster) and abnormal morphological features of mast cells (Fig. 23.5D). Such features include spindle shapes, bi- or multilobed nuclei, and expression of CD2 or CD25.[52]

The differential diagnosis of SM includes a variety of disorders with similar clinical manifestations, such as MMAS and MCAS (described above), hereditary/acquired angioedema, carcinoid syndrome, and pheochromocytoma.

Treatment

THERAPEUTIC PRINCIPLES

Approach to Treatment of Mastocytosis

- Avoidance of symptomatic triggers
- Control of symptoms
  - Antihistamines (H_1 and H_2 receptor antagonists)
  - CysLT receptor antagonists
  - Aspirin
  - Disodium cromoglycate
  - Epinephrine
- Management of osteoporosis
- Cytoreductive therapy for aggressive disease
  - Imatinib
  - Other tyrosine kinase inhibitors
- Management of associated hematological disorders

There is no cure for mastocytosis, and treatment is focused on control of symptoms. All patients with mastocytosis should avoid exposures to symptomatic triggers. In addition, patients should have epinephrine autoinjectors available at all times to treat possible anaphylaxis. Pharmacological treatment of mastocytosis includes drugs that fall into three main categories: *(i)* those that block or interfere with mast cell mediators, *(ii)* those that prevent mast cell activation, and *(iii)* those that affect mast cell survival and proliferation.

Type 1 histamine (H_1)-receptor antagonists are not only particularly useful for the control of cutaneous symptoms, including pruritus and flushing, but may also aid in the management of headache and neuropsychiatric symptoms (headache, depression, cognitive impairment). Type 2 histamine (H_2)-receptor antagonists are used in the treatment of GI symptoms, such as abdominal pain, cramping, diarrhea, heartburn, nausea, and vomiting. CysLT receptor antagonists are used in conjunction with antihistamines as a second-line treatment for cutaneous symptoms. Aspirin may be helpful for some patients with flushing, particularly those with high levels of urinary prostaglandin D_2 or 11β-$PGF_{2\alpha}$ but must be used with caution, as NSAIDs may trigger anaphylaxis in some patients.[52]

Disodium cromoglycate (cromolyn) is a weak *in vivo* inhibitor of mast cell activation but is used orally to reduce GI and neuropsychiatric symptoms.[52] Certain H_1-receptor antagonists, including ketotifen and rupatadine, are reported to block mast cell activation.

Osteoporosis in patients with SM is typically treated in the same manner as in patients in the general population. Bisphosphonate drugs are the first line of treatment, along with appropriate intake of calcium and vitamin D. Interferon-α (IFN-α) has been reported to be helpful as a second-line agent in refractory disease.[52]

Cytoreductive therapy has a role in the treatment of aggressive systemic mastocytosis (ASM) and mast cell leukemia, although data from large clinical trials are lacking. Imatinib, a tyrosine kinase inhibitor, has been effective in reducing mast cell burden in only a small subset of patients who lack the D816V mutation in KIT. Although clinical responses to other tyrosine kinase inhibitors have been largely disappointing,[52] a very recent trial of midostaurin, which is active on D816V, showed substantial promise in patients with advanced SM.[55] More studies are needed to determine those patients most likely to benefit.

Additional treatment of patients with SM and associated clonal hematological non–mast cell lineage disease (AHNMD) depends on the associated hematological disorder. The general approach is to treat AHNMD as if SM were not present and to treat the SM as if the AHNMD were not present, while closely monitoring patients for mast cell activation symptoms during therapy.[56]

Prognosis

Each category of mastocytosis carries a different prognosis. Pediatric patients with CM have complete resolution by adulthood in the majority of cases. Patients with indolent systemic mastocytosis (ISM) generally have a normal life expectancy, and ISM rarely evolves into more aggressive categories. However, median survival in other forms of SM is diminished (24 months in SM-AHNMD, 48 months in ASM). Mast cell leukemia is the rarest and most severe form of mast cell disease, with median survival of only 2 months.[57]

SUMMARY AND FUTURE RESEARCH DIRECTIONS

ON THE HORIZON

- Newer mouse models of mast cell deficiency and of inducible basophil deficiency will help:
  - Clarify the role of mast cells in normal physiology
  - Improve understanding of the role of mast cells in atopic and nonatopic diseases
- Translational research will help:
  - Improve understanding of the mechanisms of mast cell- and basophil-mediated diseases
  - Identify additional mutations in *c-KIT* and other genes that are associated with mastocytosis
- Clinical research is needed:
  - To improve diagnostic tools for atopic diseases and mast cell disorders
  - To improve treatment of and eventually cure asthma and atopic diseases
  - To improve treatment of and eventually cure mastocytosis

The mouse models that have been classically used to study mast cell functions are based upon *Kit* mutations that result in other defects besides a lack of mast cells. Newer transgenic models of mast cell deficiency have been developed in recent years and will help clarify mast cell roles in both normal physiology and in disease processes by avoiding these confounding factors. Mouse models of inducible basophil deficiency have recently been developed and will be important in improving our understanding of basophil functions.[58]

There is a great need for better understanding of molecular mechanisms of mast cell–related human diseases for improved diagnosis and treatment in the long term. For most atopic diseases and for mastocytosis, the current standard of care consists of avoidance of triggers and symptomatic therapies aimed at mediator blockade.[59] Drugs that safely and selectively suppress the pathogenic functions of mast cells could substantially improve quality of life in patients suffering from common conditions, such as asthma, as well as rare ones, such as mastocytosis. At the same time, the critical functions for mast cells in innate immunity identified in mouse models require investigation in humans. Whether mast cell effector functions can be selectively exploited to enhance immune responses and vaccine efficacy is an area of active investigation.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following is TRUE of the development of mast cells and basophils?
   A. Mast cells and basophils both develop and mature fully in bone marrow.
   B. Mast cells originate in bone marrow but mature in peripheral tissues; basophils originate and mature fully in bone marrow.
   C. Mast cells originate and mature fully in bone marrow; basophils originate in bone marrow but mature in peripheral tissues.
   D. Mast cells and basophils both originate in bone marrow and mature in peripheral tissues.

2. Which of the following mast cell mediators is preformed and stored in granules?
   A. Interleukin (IL)-6
   B. LTC_4
   C. Tryptase
   D. IL-4

3. Mast cells and basophils can be activated by which of the following mechanisms?
   A. immunoglobulin (Ig)E cross-linking
   B. Platelet-activating factor
   C. Binding of complement components C3a or C5a
   D. All of the above

4. Which of the following is TRUE of the diagnosis of potential mastocytosis?
   A. A child with an isolated mastocytoma requires a bone marrow biopsy to rule out systemic mastocytosis.
   B. An adult with urticaria pigmentosa and an elevated serum tryptase level requires a bone marrow biopsy to rule out systemic mastocytosis.
   C. Elevated serum tryptase level during an anaphylactic reaction is a diagnostic criterion for systemic mastocytosis.
   D. Detection of a D816V mutation in *c-KIT* is not useful in making a diagnosis of systemic mastocytosis.

24

Eosinophils and Eosinophilia

Anna Kovalszki, Peter F. Weller

Eosinophils are terminally differentiated, bone marrow–derived granulocytes that normally circulate in blood in low numbers and tend to localize in those tissues with mucosal epithelial surfaces. Increased blood or tissue eosinophils occur in helminth parasite infections, as well as in allergic diseases and a variety of other, often idiopathic, conditions. Conventionally, the major focus on eosinophils has been delineating the "effector" functions of these end-stage granulocytes, including what roles these cells play as helminthotoxic effector cells and the contribution they make to the immunopathogenesis of allergic diseases. More recent findings have indicated that eosinophil functions are considerably more extensive.[1-4] Eosinophils contain stores of multiple, preformed cytokines; engage in cognate cell–cell interactions with other cell types, including lymphocytes; and have roles in varied host immune and inflammatory responses not conventionally marked by quantitatively extensive eosinophil infiltration.[4]

PRODUCTION AND DISTRIBUTION OF EOSINOPHILS

Eosinophilopoiesis

The development of eosinophils in bone marrow can be elicited by three cytokines. Granulocyte macrophage–colony-stimulating factor (GM-CSF), interleukin (IL)-3, and IL-5 all promote eosinophilopoiesis. In contrast to IL-3 and GM-CSF, which also promote the development of other lineages, IL-5 uniquely promotes the development and terminal differentiation of eosinophils. IL-5 is produced by type 2 innate lymphoid cells,[5] CD8 T cells, natural killer (NK) cells, and other leukocytes, including eosinophils themselves. IL-5 is a defining cytokine product of T-helper cell-2 (Th2) CD4 T cells. The production of IL-5 by Th2 lymphocytes accounts for the eosinophilia accompanying T-helper 2 (Th2) cell–mediated immune responses characteristic of helminth infections and allergic diseases.

Eosinophilopoiesis develops over about a week. Retained in bone marrow is a pool of mature eosinophils. IL-5, alone and in concert with the chemokine eotaxin-1 (CCL11), rapidly releases this pool of mature eosinophils into the circulation to acutely increase blood eosinophilia and facilitate recruitment of eosinophils to sites of inflammation.[1] Blood eosinophils circulate with a half-life of about 8–18 hours. Eosinophils leave the circulation and localize in tissues, especially those with mucosal interfaces with the outside world, such as the gastrointestinal (GI) and lower genitourinary tracts. Although the mechanisms governing this homing of eosinophils to mucosal tissues are not fully known, the chemokine eotaxin-1 is involved in the homing of eosinophils to the GI tract, but not to the respiratory tract.[2] Eosinophils live longer compared with neutrophils and probably persist in tissues for several weeks. They are principally tissue-dwelling cells: as demonstrated in rodents, for every eosinophil present in the circulation, there are 300–500 in tissues.

Eosinophil Adherence Mechanisms

The transit of eosinophils from bone marrow, through the circulation, and into tissues is governed, in part, by multiple adherence molecules expressed on eosinophils (Fig. 24.1). As for other leukocytes, recruitment of eosinophils into tissue sites of inflammation utilizes combinatorial interactions involving specific adhesion molecules (via their expression and altered affinity states) that mediate cellular interactions with the vascular endothelium and actions of chemoattractant molecules. Eosinophils express several adhesion molecules that they broadly share with other leukocytes. These adhesion molecules mediate their initial rolling and subsequent adherence to endothelial cells. Similar to neutrophils, eosinophils can adhere via CD11/CD18 heterodimeric β_2 integrins to the intercellular adhesion molecule-1 and -2 (ICAM-1 and ICAM-2). Likewise, specific sialoglycoproteins mediate adherence between eosinophils and endothelial E- and P-selectins. Unlike neutrophils, but similar to lymphocytes, eosinophils are able to bind to vascular cell adhesion molecule-1 (VCAM-1). Eosinophils express two α_4 integrins, very late activation antigen-4 (VLA-4, $\alpha_4\beta_1$) and $\alpha_4\beta_7$, which bind to VCAM-1. Moreover, $\alpha_4\beta_7$ binds to the mucosal addressin cell adhesion molecule (MAdCAM). The β_2 integrin $\alpha d\beta_2$, which binds ICAM-3 and is expressed on other leukocytes, is an additional integrin that mediates eosinophil adhesion to VCAM-1. Enhanced expression of VCAM-1 on the vascular endothelium, as elicitable by IL-4 or IL-13 stimulation, may contribute to the localization of eosinophils in some tissue sites of inflammation.

In addition to mediating interactions with the endothelium, eosinophil adherence molecules, by their interactions with extracellular matrix components, modulate the activity of eosinophils that have exited the bloodstream. Eosinophil VLA-6, $\alpha_6\beta_1$, binds laminin. Both $\alpha_4\beta_1$ and $\alpha_4\beta_7$ interact with specific domains of tissue fibronectin, and these interactions can enhance eosinophil functional responses. Eosinophils express CD44 (PGP-1), which binds hyaluronic acid. Siglec-8, a sialic acid–binding immunoglobulin-like lectin, is expressed on eosinophils and binds sialoglycoconjugates.[6]

KEY CONCEPTS

Actions of Eosinophilopoietic Cytokines Interleukin (IL)-3, Granulocyte Macrophage–Colony-Stimulating Factor (GM-CSF), IL-5

Promote eosinophil development and maturation in bone marrow (IL-5).
Release a pool of mature eosinophils from bone marrow (IL-5).
Sustain the viability and antagonize apoptosis of mature eosinophils, enhance multiple effector responses of mature eosinophils.

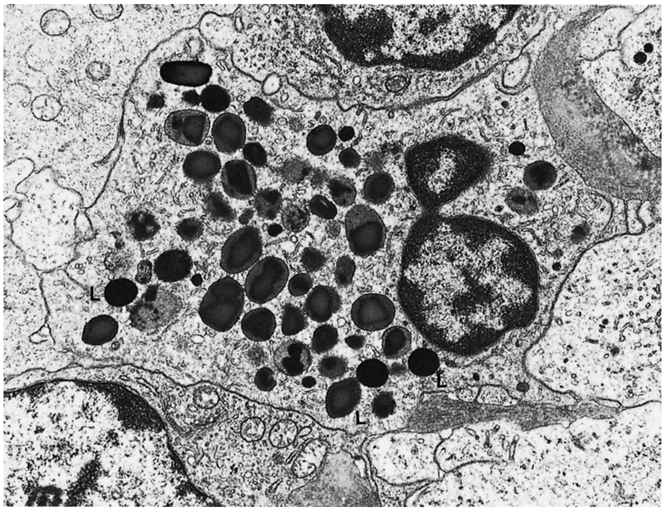

FIG 24.2 Transmission Electron Micrograph of a Human Eosinophil. The numerous cytoplasmic specific granules contain the electron-dense crystalline cores that are unique to eosinophils. In addition, lipid bodies are visible as globular, uniformly dark structures. (Original magnification × 11,180.) (Courtesy of Dr. Ann M. Dvorak, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston.)

Eosinophil Chemoattractants

Mobilization of eosinophils into tissues is governed by receptor-mediated chemoattractant stimuli. Chemoattractants promote the directed migration of eosinophils and may enhance the adhesion of eosinophils to vascular endothelium and their subsequent migration through the endothelium. Many compounds have been identified as eosinophil chemoattractants, including humoral immune mediators, such as platelet-activating factor (PAF) and the complement anaphylatoxins C5a and C3a; certain cytokines; and several chemokines, most notably the eotaxins. None of these is specific solely for eosinophils, but eotaxin-1, eotaxin-2, and eotaxin-3 exhibit the most restricted specificity.[1] Eotaxins signal through CCR3 chemokine receptors that are expressed on eosinophils as well as basophils, some Th2 cells, and some mast cells. Thus recruitment of eosinophils to sites of immunological reactions is governed by their response to chemoattractants that facilitate intravascular emigration and direct migration of extravascular eosinophils, as well as by the functional states of eosinophil adherence molecules and the differential expression of endothelial cell adherence ligands.

STRUCTURE OF EOSINOPHILS

Human eosinophils, unlike neutrophils, usually have a bilobed nucleus (Fig. 24.2). Defining attributes of eosinophils are their large, cytoplasmic "specific" granules that are morphologically distinct because of their unique content of crystalloid cores. Crystalloid cores are recognizable by transmission electron microscopy and usually appear electron dense (see Fig. 24.2). The cores and surrounding matrices of specific granules contain cationic proteins that account for the tinctorial staining of granules with eosin. Eosinophils at sites of inflammation can exhibit morphological changes in their specific granules, including loss of either matrix or core components from within intact granules, compatible with the extracellular release of granule constituents.

Lipid bodies, cytoplasmic structures distinct from granules (see Fig. 24.2), are roughly globular in shape and range in size from minute to the size of specific granules. Lipid bodies are dissolved by common alcohol-based hematological stains but are preserved and stain darkly with osmium fixation. Lipid bodies lack a delimiting membrane but contain internal membranes that are often obscured by overlying lipid. Lipid bodies are found in neutrophils and other cells, especially in association with inflammation; but eosinophils typically contain more lipid bodies compared with neutrophils. Lipid body formation in eosinophils is rapidly inducible within minutes. In eosinophils, key enzymes involved in eicosanoid formation, including prostaglandin H synthase, the 5- and 15-lipoxygenases, and leukotriene (LT) C_4 synthase, localize at lipid bodies; and lipid bodies are sites of eicosanoid synthesis.[7]

CELL-SURFACE RECEPTORS AND PROTEINS

Eosinophil receptors for immunoglobulins include those for immunoglobulin G (IgG), IgE, and IgA. The receptor for IgG on eosinophils is principally the low-affinity FcγγRII (CD32), whereas neutrophils have FcγRII and FcγRIII (CD16).

Eosinophil IgE receptors include the high-affinity IgE receptor FcεRI, typically found on basophils and mast cells, as well as FcεRII, the low-affinity IgE receptor, such as CD23, found on lymphocytes, monocytes, and antigen-presenting cells (APCs). Although FcεRI α-chain protein is present within eosinophils, its surface expression can be low or undetectable. Engagement of eosinophil FcεRI does not elicit exocytotic degranulation, as it does on basophils and mast cells. FcεRI may participate in IgE-mediated antigen uptake by antigen-presenting eosinophils. Eosinophil expression of IgE receptors is notable because IgE levels and eosinophil numbers frequently increase concomitantly in helminth infections as well as allergic diseases.

Eosinophils express FcαRI (CD89), which binds secretory IgA more potently than other forms of IgA. Engagement of FcαRI triggers eosinophil release of granule proteins. With the characteristic localization of eosinophils to mucosal surfaces of the respiratory, GI, and genitourinary tracts, this IgA receptor enables eosinophils to engage secretory IgA present at these mucosal sites.

Eosinophils have receptors for complement components, including C1q (CR1), C3b/C4b (CR1), iC3b (CR3), C3a, and C5a. Both C3a and C5a are eosinophil chemoattractants and stimulate the production of oxygen radicals by eosinophils. Eosinophils express several receptors for chemokines. CCR1 is a receptor for MIP-1α, MCP-3, and RANTES, whereas CCR3 is a receptor for eotaxin-1, eotaxin-2, eotaxin-3, MCP-3, and RANTES. Eosinophils express CXCR4 and respond to the ligand for this receptor, stromal cell–derived factor 1α.

Mature eosinophils, like their immature precursors, express receptors for the three cytokines, GM-CSF, IL-3, and IL-5, which promote eosinophilopoiesis and stimulate the functioning of mature eosinophils. In addition, eosinophils have receptors for a broad range of other cytokines, including IL-1α, IL-2, IL-4, interferon (IFN)-α and IFN-γ, tumor necrosis factor (TNF)-α, stem cell factor (c-KIT), and IL-16 (which signals via CD4 on eosinophils). Thus eosinophils are subject to stimulation by many cytokines, although little is understood about how many of them affect eosinophil functioning *in vivo*.

Of pertinence to interactions between eosinophils and B and T lymphocytes, eosinophils can express several relevant plasma membrane proteins. Class II major histocompatibility complex (MHC) proteins, generally absent on blood eosinophils, are induced for expression on eosinophils in sites of inflammation. In addition, eosinophils can express CD40, CD154 (CD40 ligand), CD153 (CD30 ligand), CD28 (B7–2), and CD86.[4]

Eosinophils express receptors for several lipid mediators, including PAF and leukotriene B_4 (LTB_4), which are chemoattractants for eosinophils and stimulate eosinophil degranulation and respiratory burst activity. Eosinophils also have receptors for prostaglandins D_2 and E_2 and for cysteinyl leukotrienes.

CONSTITUENTS OF EOSINOPHILS

Eosinophil-specific granules contain preformed proteins that include both specific cationic proteins and stores of diverse cytokines and chemokines.

Cationic Granule Proteins

Eosinophil granule cationic proteins have been extensively studied because of their abundance in the granules and their capacity to exert multiple effects on host cells and microbial targets. Major basic protein (MBP), named for its quantitative predominance within the granule and its markedly cationic (basic) isoelectric point of about 11, is a 13.8- to 14-kilodalton (kDa) protein. A homolog of MBP that is somewhat smaller (13.4 kDa) and less basic (pI 8.7) has been identified. MBP lacks enzymatic activity and probably exerts its varied effects via its markedly cationic nature. MBP was found to be toxic to both airway epithelium and helminths and to have antibacterial effects.[8]

A second granule protein is eosinophil peroxidase (EPO), an enzyme distinct from neutrophil myeloperoxidase. Cationic EPO (pI 10.8) uses hydrogen peroxide and halide ions to form hypohalous acids, which are toxic for parasites, bacteria, and tumor and host cells. EPO utilizes bromide in preference to chloride and is even more active with a pseudohalide, thiocyanate, to generate oxidant products, including hypobromous and hypothiocyanous acids.

Two additional granule proteins are eosinophil cationic protein (ECP) (18 kDa, pI 10.8) and eosinophil-derived neurotoxin (EDN) (18–19 kDa, pI 8.9). EDN, never demonstrated to be neurotoxic for humans, is so named only because, after it is injected intracerebrally into test rabbits, it elicits a characteristic neuropathological response. Both ECP and EDN are ribonucleases (RNases). EDN expresses 100 times more RNase activity compared with ECP, although their toxic effects on bacterial, parasitic, and mammalian target cells are not simply a result of their RNase catalytic activities.

Within the specific granule, MBP is localized to the crystalloid core and to tubulovesicular structures within and arising from the granules,[8] whereas ECP, EDN, and EPO are localized in the matrix of the granule around the core (see Fig. 24.2). MBP is also found in low amounts (~3% of eosinophil levels) in basophils, but whether this reflects endocytosis or endogenous synthesis is not known. Uptake of MBP and EPO into mast cells is known to occur via endocytosis. Small amounts of EDN and ECP are present in neutrophils, and as neutrophils contain messenger RNA (mRNA) transcripts for these, EDN and ECP are likely synthesized by neutrophils. Nevertheless, eosinophils are the dominant source of these four cationic proteins. The properties of these proteins and their numerous biological effects have been reviewed,[9] as these proteins have major effects not only in the potential role of eosinophils in host defense against helminth parasites but also in contributing to tissue dysfunction and damage in eosinophil-related allergic and other diseases.

Cytokines and Chemokines

Eosinophils are capable of elaborating at least four dozen diverse cytokines and chemokines, and studies continue to identify more cytokines released by eosinophils. The potential activities of eosinophil-derived cytokines are extensive. Eosinophil-derived cytokines include those with autocrine growth factor activities for eosinophils and those with potential roles in acute and chronic inflammatory responses. A notable feature of eosinophils as a source of cytokines is that they contain stores of these cytokines preformed within eosinophil granules and secretory vesicles.[10] Thus in contrast to most lymphocytes, which must be induced to synthesize *de novo* cytokines destined for release, eosinophils can immediately release preformed cytokine and chemokine proteins into the surrounding milieu. The local, rapid release of eosinophil-derived cytokines in tissues to effect adjacent cells could, and has been shown to, readily induce responses in varied cell types.

Eosinophils synthesize the three growth factor cytokines GM-CSF, IL-3 and IL-5, which promote eosinophil survival, antagonize eosinophil apoptosis, and enhance eosinophil effector responses. Other cytokines elaborated by human eosinophils that may have activities in acute and chronic inflammatory responses include IL-1α, IL-6, IL-8, IFN-γ, TNF-α, and MIP-1α. Human eosinophils can elaborate other various "growth" factors, including transforming growth factor (TGF)- α, TGF-β_1, vascular endothelial growth factor, platelet-derived growth factor (PDGF)-β, heparin-binding epidermal growth factor, and a proliferation-inducing ligand (APRIL). These cytokines have roles in contributing to epithelial hyperplasia and fibrosis, as well as other immune homeostatic activities. In addition, eosinophils are recognized as sources of specific cytokines and chemokines capable of stimulating or inhibiting lymphocyte responses, including IL-2, IL-4, IL-10, IL-12, IL-16, RANTES, and TGF-β_1. Of note, eosinophil cytokines include those associated with Th2 (IL-4, IL-5, IL-13), Th1 (IL-12, IFN-γ), and T-regulatory (IL-10, TGF-β) responses, emphasizing the diverse immunoregulatory potentials for eosinophil-secreted cytokines.[10]

ACTIVATED EOSINOPHILS

A well-recognized attribute of eosinophils is that, in conjunction with eosinophilic diseases, some blood and tissue eosinophils may exhibit various alterations, indicating that these cells have been "activated." These changes include increased metabolic activity, diminished density ("hypodense"), enhanced LTC_4 formation, and morphological alterations, including cytoplasmic vacuolization, alterations in granule numbers and size, and losses within specific granules of MBP-containing cores or matrices. Activated eosinophils may exhibit enhanced plasma membrane expression of some proteins, including CD69, human leukocyte antigen–D related (HLA-DR), and CD25.

Features associated with *in vivo* "activated" eosinophils can be elicited, in part, by exposing eosinophils to specific stimuli, including GM-CSF, IL-3, and IL-5. In addition, interactions with extracellular matrix components can further contribute to eosinophil activation. Eosinophil "activation," however, is not a singularly binary process, and some attributes of activation can be elicited without other attributes by mediators and mechanisms that remain to be delineated.

MECHANISMS OF EOSINOPHIL DEGRANULATION

As eosinophil granules contain four major cationic proteins and a multitude of preformed cytokines and chemokines, the processes by which eosinophils mobilize these granule constituents for their extracellular release are important in understanding the regulated functioning of eosinophils. Unlike mast cells or basophils that undergo acute exocytotic degranulation in response to cross-linking of their high-affinity Fcε receptors, an analogous mechanism to elicit comparable exocytotic degranulation of fluid-phase eosinophils has not been identified. Cross-linking of eosinophil IgG or IgA Fc receptors *in vitro* can stimulate release of eosinophil cationic proteins, but this rapid FcR-mediated acute "degranulation" process is cytolytic for eosinophils. In contrast, observations of eosinophils on the surfaces of large nonphagocytosable multicellular helminth parasites do provide evidence that eosinophils can degranulate by exocytosis to wholesale release granule contents on the surfaces of target parasites.

An alternative mechanism of mobilizing granule contents for secretion that eosinophils utilize is a process of vesicular transport-mediated "piecemeal" degranulation. Electron microscopic observations of lesional eosinophils provided evidence that eosinophil granule contents were mobilized *in vivo* by selective incorporation into small vesicles that traffic to the cell surface and release these granule contents. By this process, there may be agonist-elicited selective secretion of certain eosinophil-derived cytokines.[11] Ultrastructural studies have demonstrated that secretory vesicles arise from granules and transport cytokines, such as IL-4.[11] Insights into the selectivity and mechanisms of differential cytokine secretion have been gained by the finding, at least for IL-4, that a receptor for IL-4 mediates the transport of IL-4 from granules and within secretory vesicles.[12] How this process of vesicular transport is regulated and functions to selectively mobilize specific eosinophil granule–derived cytokines or cationic proteins remains under investigation.

In addition to regulated release of granule contents from viable eosinophils, a common, but often overlooked, occurrence is the lysis of eosinophils. Both cutaneous and pulmonary biopsy specimens of eosinophil-associated diseases contain free, extracellular, but still membrane-bound, eosinophil granules. These free extracellular granules express cytokine, chemokine, and cysteinyl leukotriene receptors and are secretion competent even outside of intact eosinophils.[13,14] Cytolytic stimuli elicit both the release of nuclear DNA to form extracellular DNA "traps" and the release of free secretion-competent eosinophil granules in humans.[15]

FUNCTIONS OF EOSINOPHILS

Conventional considerations of the roles that eosinophils may play have been guided by quantitative considerations so that those diseases characteristically marked by more prominent eosinophilia have occasioned the most interest. Thus studies have focused on the "effector" roles eosinophils play in host defense against helminth infections and in the immunopathogenesis of allergic and other eosinophilic diseases. Additional roles for eosinophils must be considered in immune or inflammatory responses not conventionally recognized to contain abundant eosinophils.[4]

ROLES IN HOST DEFENSE

Because the host response to infections with multicellular helminth parasites is characteristically associated with eosinophilia, it is often believed that eosinophils evolved to have a role in killing helminths, especially during their larval stages. Indeed, *in vitro* eosinophils can kill numerous helminths, organisms too large to be phagocytosed. Eosinophils adhere to the parasite and deposit eosinophil granule contents onto its surface. Cell products that can contribute to parasite death include MBP, ECP, EDN, and EPO.

As reviewed earlier,[16] the helminthotoxic roles of eosinophils *in vivo* are less certain in humans and rodents. In eosinophil-depleted mice, the intensities of primary and secondary infections with some helminths have not been greater than in eosinophilic mice, nor have IL-5 transgenic mice exhibited increased resistance to infection with some helminth species. Moreover, schistosome infections in two lines of eosinophil-ablated mice have shown no differences in measures of infection compared with normal mice.[17] Nevertheless, murine studies need to be interpreted with caution. Many experimental infections involve introducing helminth infections that are often host species–restricted into unnatural host mice, in which innate immune responses may be prominent. Natural human infections are usually a consequence of repeated exposures, during which acquired, rather than innate, immunity becomes prominent. Thus eosinophil functions as helminthotoxic cells *in vivo* remain unclear. Eosinophils might have alternative functions in host responses to helminths, including functioning as APCs and even favoring the survival of *Trichinella* larvae in muscles.[18,19]

ROLES IN DISEASE PATHOGENESIS

The abilities of eosinophils to release biologically active lipids as paracrine mediators of inflammation and to release preformed cationic and cytokine granule constituents enable eosinophils to contribute to the immunopathogenesis of various diseases, including asthma.[1] Eosinophils form several classes of biologically active lipids. Eosinophils may liberate PAF, whose diverse activities can be mediated either directly or by stimulating other cells to release leukotrienes, prostaglandins, and complement peptides. Stimulated eosinophils release LTC_4. LTD_4 and LTE_4 are formed from LTC_4 by the sequential enzymatic removal of glutamic acid and glycine from its tripeptide glutathione side chain. LTC_4 and especially LTD_4 have bronchoconstrictor activities, constrict terminal arterioles, dilate venules, and stimulate airway mucus secretion. Thus eosinophils are a potential source of two major types of mediator lipids, the sulfidopeptide leukotrienes and PAF.

Oxidants released by eosinophils, including superoxide anion, hydroxyl radical, and singlet oxygen, as well as EPO-catalyzed hypothiocyanous acid and other hypohalous acids, have the potential to damage host tissues.

Released eosinophil granule proteins are immunologically detectable in fluids, including blood, sputum, and synovial fluids, and in tissues, including the respiratory and GI tracts, skin, and heart, in association with various eosinophil-related diseases. The eosinophil cationic proteins, including MBP, ECP, and EPO, can damage various cell types. Thus extracellular release of eosinophil granule proteins, by degranulation or cytolysis of eosinophils, could contribute to local tissue damage by causing dysfunction and damage to adjacent cells.

OTHER EOSINOPHIL FUNCTIONS

Other potential functions for the eosinophil are not fully defined. In addition to the acute release of lipid, peptide, and cytokine mediators of inflammation, eosinophils probably contribute to chronic inflammation, including the development of fibrosis. Eosinophils can be a major source of the fibrosis-promoting cytokine TGF-β. Additional roles of eosinophils in modulating extracellular matrix deposition and remodeling are suggested by studies of normal wound healing. During dermal wound healing, eosinophils infiltrate into wound sites and sequentially express TGF-α early and TGF-β_1 later during wound healing. These findings suggest that eosinophils may contribute to the more chronic subepithelial airway fibrosis characteristic of chronic asthma.

Additional functions for eosinophils are indicated by the findings that they may be induced to express class II MHC proteins and can function as APCs.[20] Blood eosinophils lack HLA-DR expression, but eosinophils recovered from the airways 48 hours after segmental antigen challenge have been shown to express HLA-DR. Cytokines, including GM-CSF, IL-3, IL-4, and IFN-γ, induce eosinophil HLA-DR expression. Both murine and human eosinophils can function as HLA-DR–dependent MHC-restricted APCs in stimulating the proliferation of T cells. *In vivo,* murine eosinophils can process exogenous antigens in the airways, traffic to regional lymph nodes, and function as antigen-specific APCs to stimulate responses of CD4 T cells.[21]

Eosinophils, that normally become resident in submucosal and less prominently in other tissues, undoubtedly participate in ongoing homeostatic immune responses at these sites. Some of these responses are mediated by cytokines secreted by eosinophils, including IL-6 and APRIL to stimulate plasma cells development[22] and IL-4 to activate macrophages in fat tissue and effect glucose metabolism.[23] Further investigations will help delineate eosinophil's functional roles and interactions with other cells, so that the scope of eosinophil functions will probably extend beyond its currently more defined role as an effector cell contributing to allergic inflammation.

EOSINOPHILIA AND EOSINOPHILIC DISORDERS

Diverse infectious, allergic, neoplastic and idiopathic disease processes can be associated with increased blood and/or tissue eosinophil numbers. Blood eosinophilia, present when eosinophil numbers are in excess of their usual level of <450/μL of blood, may be intermittently, modestly, or (less frequently) markedly increased. Blood eosinophil numbers are not necessarily indicative of the extent of eosinophil involvement in affected tissues.

Some patients with sustained blood eosinophilia can develop organ damage, especially cardiac damage. This cardiac involvement can include the formation of intraventricular thrombi and endomyocardial fibrosis with secondary mitral or tricuspid regurgitation (Fig. 24.3). Such damage can complicate the sustained eosinophilia of hypereosinophilic syndromes and has been noted with eosinophilias accompanying other diseases, including eosinophilia with carcinomas, lymphomas, GM-CSF, or IL-2 administration, drug reactions, and parasitic infections. Most patients with eosinophilia, however, develop no evidence of endomyocardial damage. Conversely, cardiac disease can rarely present in patients without known eosinophilia. The pathogenesis of eosinophil-mediated cardiac damage involves both usually

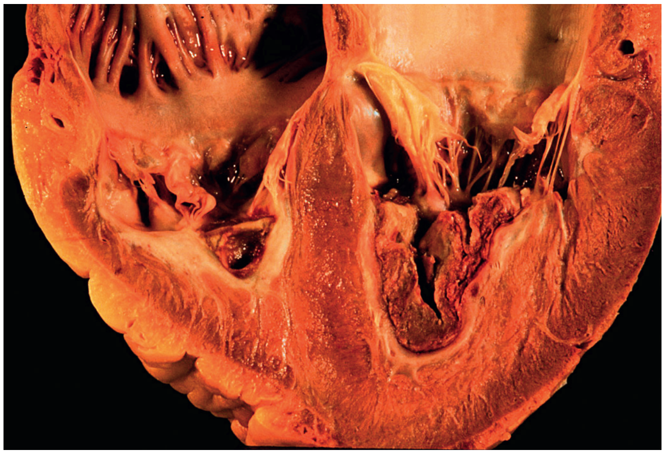

FIG 24.3 **Eosinophil Endomyocardial Disease.** A large thrombus is present in the apex of the left ventricle and the chordae tendineae are entrapped, leading to severe mitral valve regurgitation.

heightened numbers of eosinophils and some activating events, as yet ill-defined, that promote eosinophil-mediated tissue damage.

Cardiac damage progresses through three stages. In the first stage, there is damage to the endocardium and infiltration of the myocardium with eosinophils and lymphocytes, with eosinophil degranulation and myocardial necrosis. Elevated plasma levels of troponin can be a sensitive assay of early eosinophil-mediated cardiac damage. A similar acute eosinophilic myocarditis can develop with drug hypersensitivity reactions and may be more fulminant. The first stage is frequently clinically occult, although subungual splinter hemorrhages may be prominent. Elevations of serum troponins as a measure of myocardial injury should be evaluated. Echocardiography usually detects no abnormalities at this stage, although cardiac magnetic resonance imaging (MRI) is evolving as a technique to potentially detect cardiac involvement at an earlier stage. Uncommonly, death due to acute progressive cardiac disease can occur. Corticosteroid therapy during the acute stage may help control and prevent the evolution of myocardial fibrosis.

The second stage of heart disease, the formation of thrombi along the damaged endocardium, affects either or both ventricles and occasionally the atrium. Outflow tracts near the aortic and pulmonic valves are usually spared. These thrombi can embolize to the brain and elsewhere. Finally, in the fibrotic stage, progressive scarring leads to entrapment of chordae tendineae with the development of mitral and/or tricuspid valve regurgitation and to endomyocardial fibrosis, producing a restrictive cardiomyopathy. Echocardiography and MRI are valuable in detecting intracardiac thrombi and the manifestations of fibrosis. Patients with sustained eosinophilia should be monitored by using echocardiography and serum troponin assays for evidence of cardiac disease. In an older series of patients referred to the National Institutes of Health (NIH), much of the mortality among these patients with hypereosinophilia was attributable to end-stage congestive heart failure. In contemporary times, earlier recognition of cardiac involvement, mitral valve replacement with bioprostheses and additional therapeutic options for hypereosinophilic syndromes (see below) have largely minimized the morbidity and mortality attributable to end-stage eosinophilic endomyocardial disease.

INFECTIOUS DISEASES ASSOCIATED WITH EOSINOPHILIA

Eosinophilia is encountered only with specific infectious diseases. With active bacterial or viral infections, eosinopenia is characteristic. This suppression of blood eosinophils is, in part, caused by heightened endogenous corticosteroid production as well as by inflammatory mediators released during these infections. This suppression of eosinophilia, with either serious bacterial infections or marked inflammation, accounts for the absence of otherwise expected eosinophilia in some patients with helminth infections, including those with hyperinfection strongyloidiasis.[24] As a general clinical guideline, patients with a febrile illness and an increased or even normal blood eosinophilia are not likely to have common bacterial or viral infections, unless they have adrenal insufficiency or a confounding medication-elicited eosinophilia.

Helminth Parasites

Helminth parasites are multicellular metazoan organisms—the "worm" parasites. Infections with diverse helminths elicit eosinophilia (Chapter 31).[24] Although eosinophilia may provide a hematological clue to the presence of helminth infection, the absence of blood eosinophilia does not exclude such infections. The eosinophilic response to helminths is determined both by the host's immune response and by the parasite, including its distribution, migration, and development within the infected host. The level of eosinophilia tends to parallel the magnitude and extent of tissue invasion by helminth larvae or adults. In several helminth infections, the migration of infecting larvae or subsequent developmental stages through tissues is greatest early in infection, and hence the magnitude of the elicited eosinophilia will be the greatest in these early phases. In established infections, local eosinophil infiltration will often be present around helminths within tissues, without significant blood eosinophilia. Eosinophilia may be absent in those helminth infections that are well contained within tissues (*e.g.,* intact echinococcal cysts) or are solely intraluminal within the intestinal tract (*e.g., Ascaris,* tapeworms). In some established infections, increases in blood eosinophilia may be episodic. Intermittent leakage of cyst fluids from echinococcal cysts can transiently stimulate increases in blood eosinophilia and also cause symptoms attributable to allergic or anaphylactic reactions (urticaria, bronchospasm). For tissue-dwelling helminths, increases in eosinophilia may occur principally in association with migration of adult parasites, as in loiasis and gnathostomiasis.

Helminth infections more likely to elicit prolonged hypereosinophilia in adults include filarial and hookworm infections and strongyloidiasis (Table 24.1).[24] Trichinellosis can elicit an acute hypereosinophilia. *Strongyloides stercoralis* infection, difficult to diagnose solely by stool examinations, is especially important to exclude, not only because it elicits modest to even marked eosinophilia but also because, unlike other helminths, it can develop into a disseminated, often fatal, disease (hyperinfection syndrome) in patients given immunosuppressive corticosteroids.[24] Enzyme-linked immunosorbent assay (ELISA) serology has proved valuable in detecting strongyloidiasis and should be obtained for patients with eosinophilia likely to receive corticosteroids. Some tissue- or blood-dwelling helminths that are not diagnosable by stool examinations but that can cause marked eosinophilia require diagnostic examination of blood or biopsied tissues or specific serological tests.[24] Infections with these organisms include filarial infections, trichinellosis, and visceral larva migrans. In

TABLE 24.1 Parasitical Diseases Capable of Causing Marked (>3000/µL) or Long-Standing Eosinophilia

Helminth Infection	Hypereosinophilia	Chronic Eosinophilia
Angiostrongyliasis costaricensis		
Ascariasis	+ During early lung migration	
Hookworm infection	+ During early lung migration	+ Common cause of low-grade eosinophilia
Strongyloidiasis	Uncommonly	+ Self-perpetuating, may last > 50 years
Trichinellosis	+ With heavy infections	
Visceral larva migrans	+ Principally in children	
Gnathostomiasis		
Cysticercosis		
Echinococcosis		+ May be episodic with cyst fluid leakage
Filariases:		
Tropical pulmonary eosinophilia	+	+
Loiasis	+ Especially in expatriates	+
Onchocerciasis	+	+
Flukes:		
Schistosomiasis	+ During early infection in nonimmune patients	+
Fascioliasis	+ During early infection	+
Clonorchiasis	+ During early infection	+
Paragonimiasis	+ During early infection	+
Fasciolopsiasis	+ During early infection	+

children, owing to their propensity for geophagous pica and ingestion of dirt contaminated by dog ascarid eggs, visceral larva migrans caused by *Toxocara canis* is a potential etiology for sustained eosinophilia. ELISA serological testing can evaluate this possibility.

Other Infections: Protozoa and Fungi

Infections with single-celled protozoan parasites do not characteristically elicit eosinophilia. This is true of all intestinal, blood-, and tissue-infecting protozoa, with three exceptions. Two intestinal protozoans, *Dientamoeba fragilis* and *Isospora belli,* can at times be associated with low-grade eosinophilia. Hence, in patients with symptoms of enteric infection and eosinophilia, diagnostic trophozoites of *D. fragilis* or oocysts of *I. belli* should be sought in stool examinations. Fecal examinations for *I. belli* oocysts must be specifically requested, as they are not usually detected in routine stool ova and parasite examinations. Other enteric protozoa do not elicit eosinophilia and, if detected in stool examinations, should not be accepted as causes of eosinophilia. *Sarcocystis,* a myositis producing protozoan, can elicit modest eosinophilia.

Three fungal diseases can be associated with eosinophilia. (i) Aspergillosis is accompanied by eosinophilia only in the form of allergic bronchopulmonary aspergillosis, not when it is an invasive pathogen. (ii) Coccidioidomycosis, following primary infection, especially in conjunction with erythema nodosum, and at times with progressive disseminated disease, can elicit blood eosinophilia and may cause an eosinophilic meningitis. (iii) Basidiobolomycosis infection can also be associated with eosinophilia.[24]

Human Immunodeficiency Virus and Retroviral Infections

Eosinophilia can uncommonly accompany human immunodeficiency virus (HIV) infections for several reasons. First, leukopenia may increase eosinophil percentages without reflecting true eosinophilia. Second, adverse reactions to medications may elicit eosinophilia. Third, patients with acquired immunodeficiency syndrome (AIDS) who develop adrenal insufficiency as a result of cytomegalovirus and other infections may exhibit eosinophilia as a consequence. In addition, modest, and uncommonly marked, eosinophilia and eosinophilic pustular folliculitis can be observed in some patients with HIV infection.[24] Eosinophilia more commonly develops with HTLV-1 infections.[24]

ALLERGIC DISEASES ASSOCIATED WITH EOSINOPHILIA

Among the noninfectious diseases associated with eosinophilia (Table 24.2) are allergic diseases, notably those mediated by IgE-dependent mechanisms. In these diseases, including allergic rhinitis, conjunctivitis, and asthma, eosinophils are present in involved tissues as well as often being increased in blood.

MYELOPROLIFERATIVE AND NEOPLASTIC DISEASE

Eosinophilia can occur with specific neoplastic diseases, as well as in some disorders of uncertain etiology, including some hypereosinophilic syndromes.

Hypereosinophilic Syndromes

A syndrome previously termed *idiopathic hypereosinophilic syndrome* is not a single entity but rather a constellation of leukoproliferative disorders characterized by sustained overproduction of eosinophils. The three original diagnostic criteria for this syndrome were eosinophilia in excess of 1500/µL of blood persisting for longer than 6 months; lack of an identifiable parasitic, allergic, or other etiology for eosinophilia; and signs and symptoms of organ involvement. In contemporary practice, if eosinophilia is sustained over a month and the other criteria are reliably met before the 6-month time frame, a diagnosis can be made and treatment promptly initiated. Moreover, in recent years there has been increasing recognition that hypereosinophilic syndromes (HES), even at times without evident organ damage, encompass a spectrum of disorders, and progress has been made in identifying the underlying defects in some of these (Fig. 24.4).[25]

KEY CONCEPTS

Hypereosinophilic Syndromes

Eosinophilia sustained in excess of 1500/µL.
Absence of allergic, parasitic, or other etiologies for eosinophilia.
Usually evidence of organ involvement.

TABLE 24.2 Eosinophil-Associated Diseases and Disorders

Allergic or Atopic Diseases
Asthma
Allergic rhinitis
Eosinophilic esophagitis
Atopic dermatitis
Allergic urticaria
Nasal polyps

Myeloproliferative and Neoplastic Disorders
Hypereosinophilic syndromes: myeloproliferative, lymphoproliferative, and others
Leukemia
Lymphoma- and tumor-associated
Mastocytosis

Pulmonary Syndromes
Parasite-induced eosinophilic lung diseases:
Loeffler syndrome: patchy migratory infiltrates, resolving over weeks, seen with transpulmonary migration of helminth parasites, especially *Ascaris*
Tropical pulmonary eosinophilia: miliary lesions and fibrosis; heightened immune response causing one form of lymphatic filariasis; increased immunoglobulin E (IgE) and antifilarial antibodies
Pulmonary parenchymal invasion: paragonimiasis
Heavy hematogenous seeding with helminths: trichinellosis, schistosomiasis, larva migrans
Allergic bronchopulmonary aspergillosis
Chronic eosinophilic pneumonia: dense peripheral infiltrates, fever; progressive, blood eosinophilia may be absent; steroid responsive
Acute eosinophilic pneumonia: acute presentation diagnosed by bronchoalveolar lavage or biopsy
Eosinophilic granulomatosis with polyangiitis (Churg–Strauss syndrome) vasculitis: small- and medium-sized arteries; granulomas, necrosis; asthma often antecedent; extrapulmonary (*e.g.,* neurological, cutaneous, cardiac, or gastrointestinal) involvement likely
Drug- and toxin-induced eosinophilic lung diseases
Other: hypereosinophilic syndromes, neoplasia, bronchocentric granulomatosis

Skin and Subcutaneous Diseases
Skin diseases: atopic dermatitis, blistering diseases, including bullous pemphigoid, urticarias, drug reactions
Diseases of pregnancy: pruritic urticarial papules and plaques syndrome, herpes gestationis
Eosinophilic pustular folliculitis
Eosinophilic cellulitis (Wells syndrome)
Kimura disease and angiolymphoid hyperplasia with eosinophilia
Shulman syndrome (eosinophilic fasciitis)
Episodic angioedema with eosinophilia: recurrent periodic episodes with fever, angioedema, and secondary weight gain; may be long-standing without untoward cardiac dysfunction

Gastrointestinal Disorders
Eosinophilic gastroenteritides
Inflammatory bowel disease: eosinophils in lesions; occasionally blood eosinophilia with ulcerative colitis

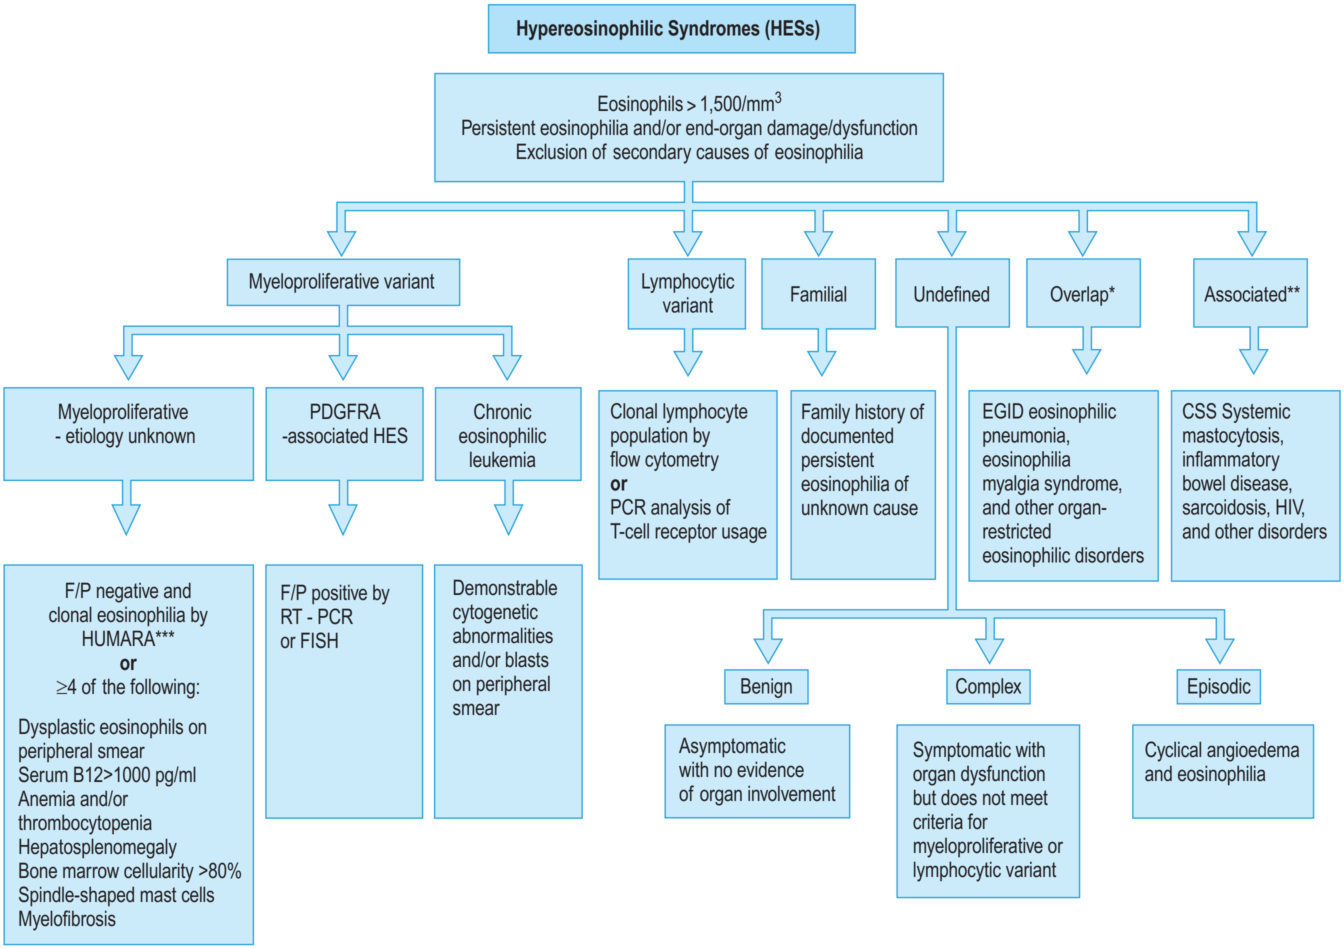
Rheumatologic Diseases
Vasculitis: Eosinophilic granulomatosis with polyangiitis (Churg–Strauss) and cutaneous necrotizing eosinophilic vasculitis

Immunological Reactions
Medication-related eosinophilias
Immunodeficiency diseases: Job's syndrome and Omenn syndrome
Transplant rejections

Endocrine
Hypoadrenalism: Addison disease, adrenal hemorrhage, hypopituitarism

Other Causes of Eosinophilia
Atheromatous cholesterol embolization
Hereditary
Serosal surface irritation, including peritoneal dialysis and pleural eosinophilia

Adapted from Weller PF. Eosinophilia and eosinophil-related disorders. In: Adkinson NF, Jr., Yunginger JW, Busse WW, et al., eds. Allergy: Principles and Practice, 6th ed. Philadelphia, Penn.: Mosby; 2003:1105.



Hypereosinophilic Syndromes (HESs)
Eosinophils > 1,500/mm3
Persistent eosinophilia and/or end-organ damage/dysfunction
Exclusion of secondary causes of eosinophilia
Myeloproliferative variant
Lymphocytic variant
Familial
Undefined
Overlap*
Associated**
Myeloproliferative - etiology unknown
PDGFRA -associated HES
Chronic eosinophilic leukemia
Clonal lymphocyte population by flow cytometry or PCR analysis of T-cell receptor usage
Family history of documented persistent eosinophilia of unknown cause
EGID eosinophilic pneumonia, eosinophilia myalgia syndrome, and other organ-restricted eosinophilic disorders
CSS Systemic mastocytosis, inflammatory bowel disease, sarcoidosis, HIV, and other disorders
F/P negative and clonal eosinophilia by HUMARA*** or ≥4 of the following:
Dysplastic eosinophils on peripheral smear
Serum B12>1000 pg/ml
Anemia and/or thrombocytopenia
Hepatosplenomegaly
Bone marrow cellularity >80%
Spindle-shaped mast cells
Myelofibrosis
F/P positive by RT - PCR or FISH
Demonstrable cytogenetic abnormalities and/or blasts on peripheral smear
Benign
Complex
Episodic
Asymptomatic with no evidence of organ involvement
Symptomatic with organ dysfunction but does not meet criteria for myeloproliferative or lymphocytic variant
Cyclical angioedema and eosinophilia

FIG 24.4 **Classification of Hypereosinophilic Syndromes Based on a Workshop Summary Report.** Specific syndromes discussed at the workshop are indicated in bold. *Incomplete criteria, apparent restriction to specific tissues/organs. †Peripheral eosinophilia, >1500/mm^3 in association with a defined diagnosis. ‡ Presence of the FLPL1/PDGFRA (F/P) mutation. § Clonality analysis based on the digestion of genomic DNA with methylation-sensitive restriction enzymes followed by polymerase chain reaction (PCR) amplification of the CAG repeat at the human androgen receptor gene (HUMARA) locus at the X chromosome. CSS, Churg-Strauss syndrome (now called eosinophilic granulomatosis with polyangiitis); EGID, eosinophil gastrointestinal diseases; FISH, fluorescence *in situ* hybridization. (From Klion AD, Bochner BS, Gleich GJ, et al. Approaches to the treatment of hypereosinophilic syndromes: a workshop summary report. J Allergy Clin Immunol 2006; 117:1294, with permission from the American Academy of Allergy, Asthma and Immunology.)

Some patients with HES, termed *myeloproliferative variants of HES,* exhibit features common to myeloproliferative disorders, including elevated vitamin B_{12} and lactate dehydrogenase (LDH) levels, splenomegaly, cytogenetic abnormalities, myelofibrosis, anemia, myeloid dysplasia, and often elevated serum level of mast cell tryptase. In many patients with myeloproliferative HES, the molecular defect has been identified as a chromosome 4 deletion that yields a fusion gene encoding a FIP1LI/PDGFRA (PDGF-α receptor) (F/P) protein that constitutively expresses receptor kinase activity. This fusion gene can be diagnostically evaluated by reverse transcription–polymerase chain reaction (RT-PCR) or fluorescence *in situ* hybridization (FISH) (Chapter 96). Importantly, the majority of patients with this fusion mutation, which constitutes a form of chronic eosinophilic leukemia (CEL), respond to therapy with imatinib, which is considered the first line of therapy for FIP1LI/PDGFRA-positive HES.[26] For patients with any evidence of cardiac involvement, including elevated troponin levels, it is recommended that glucocorticoids be administered along with initiation of imatinib therapy. Other patients with eosinophilia without F/P mutations have also responded to imatinib, indicating that other receptor tyrosine kinase mutations can underlie some of these CEL/myeloproliferative forms of HES.[27] The presence of more than four myeloproliferative features commonly seen in mutation-positive disease, predicted response in those without known mutations. Some of these features included dysplastic eosinophils, vitamin B_{12} level >1000 picograms per milliliter (pg/mL), tryptase level ≥12 nanograms per milliliter (ng/mL), anemia/thrombocytopenia, hypercellular marrow, and spindled mast cells, reticulin fibrosis, and dysplastic megakaryocytes on bone marrow biopsy.[28] In addition, clonal abnormalities in the eosinophil lineage have been reported in a few patients (see Fig. 24.4).

Another variant form of HES is a lymphoproliferative form resulting from clonal expansions of lymphocytes, often $CD4^{+}CD3^{-}$ Th2-like lymphocytes, which elaborate IL-5.[29] These aberrant T cells can be sought by flow cytometry or T-cell receptor (TCR) analysis. These patients, who may have elevated IgE levels, usually do not develop eosinophilic endomyocardial disease but are at risk for developing T-cell lymphomas.[29]

In addition to these recognized variants, there are a substantial number of patients with HES for whom the etiologies of the eosinophilia remain unknown.[26] Some such patients develop no signs or symptoms of disease and can be monitored without therapy.[30] For those who require therapy, including those with lymphoproliferative variants,[29] glucocorticosteroids are the mainstay of treatment.[26] With glucocorticoid therapy, partial or complete remission of eosinophilia within 1 month has been reported to occur in 85% of patients.[26] Second-line agents include hydroxyurea and IFN-α.[26] The neutralizing anti-IL-5 monoclonal antibody (mAb), mepolizumab, has beneficial and steroid-sparing effects in those with FIP1L1-PDGFRA negative hypereosinophilic syndromes,[31] but it is approved by the US Food and Drug Administration (FDA) for treating severe eosinophilic phenotype asthma but not yet approved for hypereosinophilic syndromes. Anti-CD52 mAb (alemtuzumab) and allogeneic hematopoietic cell transplantation have been used for particularly severe and refractory HES.

In contrast to older reports, with earlier diagnosis and therapy and with more varied and targeted therapeutic options, morbidity and, particularly, mortality in HES syndromes have been reduced.

Eosinophilia With Tumors or Leukemias

The F/P-positive and related chromosomal fusion gene mediated myeloproliferative variants of HES are forms of CEL.[27] Eosinophilia is a characteristic of the M4Eo subtype of acute myeloid leukemia, having the common M4 characteristic of chromosomal 16 abnormalities. Other forms of eosinophilic leukemia, often with specific cytogenetic and molecular genetic abnormalities, have been recognized.[27] Eosinophilia may accompany chronic myelogenous leukemia (often with basophilia) but is uncommon with acute lymphoblastic leukemia. Eosinophilia may be observed in some patients with lymphoma, including Hodgkin disease, especially the nodular sclerosing form, T-cell lymphoblastic lymphoma, and adult T-cell leukemia/lymphoma. A small proportion of patients with carcinomas, especially of mucin-producing epithelial cell origin, have associated blood and tissue eosinophilia. Eosinophilia may accompany angioimmunoblastic lymphadenopathy, mycosis fungoides, Sézary syndrome, and lymphomatoid papulosis. Eosinophilia occurs in about 20% of patients with systemic mastocytosis and may be the presenting finding in the absence of cutaneous manifestations.

ORGAN SYSTEM INVOLVEMENT AND EOSINOPHILIA

Eosinophilic syndromes limited to specific organs, such as eosinophilic pneumonias or eosinophilic GI disorders (EGIDs; Chapter 46), characteristically do not extend beyond their own target organ, and hence lack the multiplicity of organ involvement often found with non–organ-specific hypereosinophilic syndromes. They also do not have the predilection to develop secondary eosinophil-mediated cardiac damage, for reasons that are not known.

Pulmonary Eosinophilias

Blood eosinophilia can infrequently accompany pleural fluid eosinophilia, a nonspecific response seen with various disorders, including trauma and repeated thoracenteses. In addition, several pulmonary parenchymal disorders can be associated with eosinophilia (see Table 24.2).[32]

Helminth parasites are responsible for four forms of eosinophilic lung disease.[24,32] The first form, Loeffler syndrome, is marked by blood eosinophilia, eosinophilic patchy pulmonary infiltrates that appear and resolve over weeks, and, at times, bronchospasm, and is typically caused by those helminth parasites (*Ascaris lumbricoides/Ascaris suum),* and less commonly hookworm and *Strongyloides* that migrate through the lungs early in their developmental lifecycle.[24] Stool examinations are not helpful, as the pulmonary response is elicited by infecting larval forms months before productive egg-laying from later adult stages begins in the intestines. Diagnosis is made on epidemiological grounds.[24]

The second form of helminth-induced lung disease is the syndrome of tropical pulmonary eosinophilia, which develops in a minority of patients infected with lymphatic-dwelling filarial species.[23] This syndrome is characterized by marked blood eosinophilia, a paroxysmal nonproductive cough, wheezing, occasional weight loss, lymphadenopathy, and low-grade fevers. On chest X-rays, increased bronchovesicular markings, diffuse interstitial lesions 1–3 mm in diameter or mottled opacities, usually more prominent in lower lung fields, are common. Patients have markedly increased numbers of blood and alveolar eosinophils, and elevations in both total serum IgE and antifilarial antibodies.

A third form of helminth-induced lung disease is caused by helminths that invade the pulmonary parenchyma, notably lung flukes that cause paragonimiasis.

The fourth form of lung disease is caused by larger than usual numbers of helminth organisms that are carried hematogenously into the lungs. Examples include schistosomiasis, trichinellosis, and larva migrans.

Bronchopulmonary aspergillosis constitutes another type of eosinophil-associated pulmonary disease. Two forms of idiopathic eosinophilic pneumonia are recognized.[32] In *chronic eosinophilic pneumonia,* patients may exhibit peripheral pulmonary infiltrates that can extend across lobar fissures. Chronic eosinophilic pneumonia is of unknown etiology and is responsive to corticosteroids but is prone to relapse. An *acute form of eosinophilic pneumonia,* which manifests as fever, pulmonary infiltrates, and respiratory insufficiency, is diagnosable by finding eosinophils in bronchoalveolar lavage (BAL) fluids or on lung biopsy. Acute eosinophilic pneumonia, which often follows new exposures to cigarette or other smoke or dusts, responds to corticosteroid treatment and does not relapse.

The major vasculitis associated with eosinophilia is eosinophilic granulomatosis with polyangiitis (EGPA, formerly called *Churg-Strauss syndrome*) (Chapter 58).[33] Late-onset asthma, eosinophilia, and at times transient pulmonary infiltrates antedate the development of systemic vasculitis in about half the cases. Pulmonary involvement is seen in almost all patients, and pulmonary infiltrates occur in three-quarters of them. Nasal and sinus involvement is common. Corticosteroids, anti-IgE mAb, or anticysteinyl leukotriene agent therapies for asthma may mask the evolution of EGPA. Neurological, cutaneous, cardiac, and GI organ involvement is common.[33] Cardiac involvement includes pericarditis and small vessel cardiac vasculitis, and, much less commonly, endomyocardial thrombosis and fibrosis.

Diverse drugs are capable of eliciting pulmonary eosinophilia. More commonly implicated medications include nonsteroidal antiinflammatory drugs (NSAIDs) and antimicrobial medications. Likewise, toxic agents, including those from occupational exposure, can be responsible for pulmonary eosinophilia. Each of these reactions has a defined etiological stimulus and hence differs from idiopathic and other eosinophilic diseases, but the clinical presentation of drug- and toxin-elicited pulmonary eosinophilias can resemble other forms of pulmonary eosinophilia, including acute or chronic eosinophilic pneumonia.

Skin and Subcutaneous Diseases

A number of cutaneous diseases can be associated with heightened blood eosinophils,[34] including atopic dermatitis, blistering disorders including bullous pemphigoid, drug reactions, and two diseases associated with pregnancy: (i) herpes gestationis and (ii) the syndrome of pruritic urticarial papules and plaques of pregnancy. Eosinophilic pustular folliculitis is seen mostly in patients with HIV infections and in those treated for hematological malignancies or after bone marrow transplantation. In patients with cutaneous involvement and eosinophilia, angiolymphoid hyperplasia with eosinophilia and Kimura disease, eosinophilic cellulitis (Wells syndrome), eosinophilic fasciitis, and eosinophilic pustular folliculitis can be differentiated on the basis of histopathology of biopsied lesions. Another syndrome, episodic angioedema with eosinophilia, is characterized by recurring episodes of angioedema, urticaria, fever, and marked blood eosinophilia. This syndrome responds to glucocorticosteroid therapy.

Gastrointestinal Diseases

EGIDs (Chapter 46), including eosinophilic esophagitis, eosinophilic gastroenteritis, and eosinophilic colitis, represent a heterogeneous collection of disorders in which there may be eosinophilic infiltration of the mucosa, the muscle layer or the serosa, the last of which can lead to eosinophilic ascites. Peripheral blood eosinophilia may occur in EGIDs, although with eosinophilic esophagitis, peripheral blood eosinophil counts are often normal. Eosinophils are present in the lesions of collagenous colitis and ulcerative colitis, but blood eosinophilia is usually absent. GI eosinophilia elicited by intestinal helminths and eosinophilic enterocolitis as a result of hypersensitivity reactions to medications must be excluded in patients with these diseases who have tissue eosinophilia.

Rheumatological Disorders

Of the various forms of vasculitis, only two are commonly associated with eosinophilia. The principal eosinophil-related vasculitis is EGPA, formerly called Churg-Strauss syndrome (as discussed above; and in Chapter 58). Cutaneous necrotizing eosinophilic vasculitis with hypocomplementemia and eosinophilia is a distinct vasculitis of small dermal vessels that are extensively infiltrated with eosinophils. This form of vasculitis may occur in patients with connective tissue diseases. In addition, eosinophilia may uncommonly accompany rheumatoid arthritis itself but more commonly results from adverse reactions to treatment medications (including NSAIDs, gold, and tetracyclines) or concomitant vasculitis.

Immunological Disorders

CLINICAL PEARLS

Eosinophilia and Drug Reactions

Drug Reactions	Examples
Interstitial nephritis	Semisynthetic penicillins, cephalosporins
Pulmonary infiltrates	Nitrofurantoin, sulfas, nonsteroidal antiinflammatory drugs (NSAIDs)
Pleuropulmonary	Dantrolene
Hepatitis	Semisynthetic penicillins, tetracyclines
Hypersensitivity vasculitis	Allopurinol, phenytoin
Asthma, nasal polyps	Aspirin
Eosinophilia–myalgia	L-Tryptophan contaminant syndrome
Asymptomatic	Ampicillin, penicillins, cephalosporins
Cytokine-mediated	Granulocyte macrophage–colony-stimulating factor (GM-CSF), interleukin (IL)-2
DRESS (drug reaction with eosinophilia and systemic symptoms)	Minocycline, allopurinol, anticonvulsants

Adapted from Weller PF. Eosinophilia and eosinophil-related disorders. In: Adkinson NF, Jr., Yunginger JW, Busse WW, et al., eds. Allergy: Principles and Practice, 6th ed. Philadelphia, Penn.: Mosby; 2003:1105.

Adverse reactions to medications are a common cause of eosinophilia. Although often considered as hypersensitivity reactions, in most instances of drug-associated eosinophilia, the mechanism leading to eosinophilia is not understood. Eosinophilia may develop without other manifestations of adverse drug reactions, such as rashes or drug fevers. In addition, drug-induced eosinophilia may be associated with distinct clinicopathological patterns in which eosinophilia accompanies drug-induced diseases that are characteristically limited to specific organs with or without associated blood eosinophilia. When organ dysfunction develops, cessation of drug administration is necessary. Drug-induced interstitial nephritis may be accompanied by blood eosinophilia, and eosinophils may be detectable in urine. Unlike granulocyte–colony-stimulating factor (G-CSF) therapy, therapy with GM-CSF can lead to prominent blood and tissue eosinophilia. Administration of IL-2 or of IL-2-stimulated lymphocytes can be followed by the development of eosinophilia, most likely as a result of stimulated production of IL-5. Reactions to medications, often anticonvulsants, minocycline, and allopurinol, can elicit DRESS (*d*rug *r*eaction with *e*osinophilia and *s*ystemic *s*ymptoms).[34] In addition to cutaneous eruptions, fever, lymphadenopathy, hepatitis, nephritis, atypical lymphocytosis, GI tract involvement, and eosinophilia are common but variable elements of this drug-induced syndrome, which can be fatal. The triggering medication must be stopped, and corticosteroids are often administered.

Some primary immunodeficiency syndromes are associated with eosinophilia.[35] Hyper-IgE syndrome is characterized by recurrent staphylococcal abscesses of the skin, lungs, and other sites; pruritic dermatitis; hyperimmunoglobulinemia E; and eosinophilia of blood, sputum, and tissues. Eosinophilia is characteristic of Omenn syndrome, combined immunodeficiency with hypereosinophilia (Chapter 35).

Infiltration of eosinophils accompanies rejection of lung, kidney, and liver allografts. Tissue and blood eosinophilia occur early in the rejection process, and eosinophil counts and eosinophil granule protein levels (in urine, BAL fluids, and involved allograft tissues) have correlated with prognosis, severity, and response to rejection therapy.

Endocrine Diseases

The loss of endogenous adrenoglucocorticosteroid production in Addison disease, adrenal hemorrhage, or hypopituitarism can cause increased blood eosinophilia, although usually not more than mild to moderate.

Other Causes of Eosinophilia

The syndrome of atheromatous cholesterol embolization is at times associated with hypocomplementemia, eosinophilia, and eosinophiluria. Rarely, cases of hereditary eosinophilia among family members have been recognized. Irritation of serosal surfaces can be associated with eosinophilia, and related diseases can include Dressler syndrome; eosinophilic pleural effusions; peritoneal and, at times, blood eosinophilia developing during chronic peritoneal dialysis; and perhaps the eosinophilia that follows abdominal irradiation.

THERAPEUTIC PRINCIPLES

Therapy of Specific Eosinophilic Diseases

Eosinophil-Associated Diseases With Identifiable Etiologies	
Parasitic infections	Treat causative parasite
Drug-reaction related eosinophilias	Terminate eliciting medication
Adrenal insufficiency	Corticosteroid replacement therapy
Allergic/atopic diseases	Varied, may include topical or inhaled corticosteroids
Distinct Eosinophilic Syndromes Involving Specific Organs	
Eosinophilic pulmonary diseases:	
Acute eosinophilic pneumonia	Corticosteroids
Chronic eosinophilic pneumonia	Corticosteroids, interferon-α
Eosinophilic granulomatosis with polyangiitis	Corticosteroids, interferon-α
Hypereosinophilic Syndromes	
F/P-positive myeloproliferative	Imatinib
Lymphoproliferative and other	Corticosteroids, interferon-α, hydroxyurea, anti–interleukin (IL)-5 monoclonal antibody (mAb), other

EVALUATION OF EOSINOPHILIA

Because a diversity of disorders can be accompanied by eosinophilia, evaluation of the patient with eosinophilia requires a consideration of features based on the patient's history, physical examination, and other laboratory, radiographic, or diagnostic tests.[26,36,37] An initial approach can focus on identifying eosinophilic diseases that have a defined treatable etiology. These include infections with helminth parasites, and for these, the approach should be guided by information obtained from patient history about potential exposures; results of the history and physical examinations with regard to signs and symptoms of any clinically apparent associated illness; results of standard biochemical and radiographic tests for evidence of organ involvement; and results of specific parasitological tests, including potentially stool, urine, blood, sputum, or tissue examinations, as well as results of serological tests.[24] The duration and magnitude of the eosinophilia may suggest some entities, especially if it is prolonged or markedly elevated (see Table 24.1). Other causes of eosinophilia that are amenable to treatment include eosinophilia secondary to medications, for which cessation of the offending drug may be indicated if the eosinophilia is accompanied by organ damage. Likewise, if eosinophilia is secondary to glucocorticosteroid deficiency, diagnostic testing can corroborate this deficiency and lead to the administration of replacement corticosteroids and consequent resolution of the eosinophilia.

Because allergic diseases usually are associated with at least some degree of eosinophilia, clinical and laboratory evidence of such disease should be sought. If the eosinophilia is not attributable to allergic diseases, parasitic infections, medications, or steroid deficiency, further evaluation will be guided by whether the patient has evidence of organ disease and, if so, which organs are involved (see Table 24.2). This is germane, for instance, in defining whether the patient has a distinct eosinophilic pulmonary, GI, or cutaneous syndrome. Bone marrow examinations in most patients with eosinophilia are not usually informative, revealing only evidence of enhanced eosinophilopoiesis; but bone marrow should be examined if there is suspicion of a hematological malignancy or myeloproliferative disorder. For patients with sustained eosinophilia who meet the criteria for HES, diagnostic testing should aim to identify which variant form of HES the patient may have, in which case, bone marrow examination is often needed (see Fig. 24.4).

ON THE HORIZON

- Identify the causes of those hypereosinophilic syndromes for which etiologies currently remain unknown.
- Delineation of the signaling mechanisms that govern the agonist-specific, differential secretion of cytokines that are preformed and stored within eosinophil granules and secretory vesicles.
- Continue to evaluate the therapeutic efficacies of anticytokine therapeutics, including anti–interleukin (IL)-5 neutralizing antibodies, in the treatment of the varied forms of eosinophilic diseases.
- Identify biomarkers that are predictive of eosinophil-mediated tissue damage and that can be used for clinical diagnostic and therapeutic monitoring tools.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following may NOT contribute to or elicit eosinophilia?
   A. $CD3^-$, $CD4^+$ aberrant lymphocyte subsets
   B. FIP1L1-PDGFRα chromosomal gene rearrangement
   C. *Giardia lamblia* infection
   D. *Strongyloides stercoralis* infection

2. A 45-year-old male who has had eosinophilia of between 2500 and 5000/ mm^3 documented for the past 6 months has been referred to you. Your evaluation could include:
   A. Flow cytometry for lymphocyte phenotyping
   B. Serum immunoglobulin E (IgE)
   C. Serum troponin
   D. *Strongyloides* enzyme-linked immunosorbent assay (ELISA) serology
   E. All of the above

3. Which three cytokines promote eosinophil development in bone marrow and sustain eosinophil viability?
   A. Transforming growth factor (TGF)-β, interleukin (IL)-2, IL-4
   B. IL-7, IL-2, IL-13
   C. Granulocyte macrophage–colony-stimulating factor (GM-CSF), IL-3, IL-5
   D. Interferon (INF)-γ, IL-8, IL-10

Host Defenses to Viruses

Barry T. Rouse, Scott N. Mueller

Viruses as obligate intracellular parasites require their host to replicate them and to facilitate their spread to others. In humans, most clinically relevant infections were derived from other animals, and this process continues. Recent examples include human immunodeficiency virus (HIV), Ebola virus, severe acute respiratory syndrome (SARS) virus, and Zika virus. Viral infections are rarely lethal, even if they are highly cytolytic to individual cells. Mortality commonly occurs when viruses jump species, when the virus undergoes a major antigenic change (*i.e.*, influenza viruses), or when host immunity is compromised. HIV (Chapter 39) represents one of the most dramatic human examples of an exotic virus that kills its host. However, HIV kills slowly, providing ample time to spread to new hosts and an effective strategy for persistence in the species. Death or dire consequences following virus infection in mammals with inadequate immunity are well illustrated by observations that fetuses or neonates, especially if deprived of passive immunity, succumb to many agents well tolerated by healthy adults. The science of viral immunology seeks to understand mechanisms of virus–host interactions with a view to applying this knowledge to the design of effective vaccines and immunomodulators that control virus infections. These objectives are facilitated by an increasing wealth of immunological techniques, an expanding array of genetically manipulated animal models, and an abundance of high throughput technologies, which generate data that can be subjected to complex computational analysis. Such analyses can yield signatures indicative of optimal immunogenicity and vaccine efficacy or failure and can explain the variable outcome of infections in individual hosts. In most situations, defense against viruses involves multiple immune components, and the impact of a single mechanism varies greatly according to the method by which individual viruses enter, replicate, and spread within the host. In this chapter, we highlight the principal means by which the host achieves immunity after infection by viruses. Table 25.1 presents an overview.

VIRAL ENTRY AND INFECTION

Access to target tissues presents numerous obstacles for entry and infection by most human viruses. Most effective of these are the mechanical barriers provided by skin and the mucosal surfaces, as well as the chemically hostile environment of the gut (Fig. 25.1). A number of common human viral pathogens enter through the gastrointestinal tract, including rotavirus, enteric adenoviruses, and hepatitis A virus (HAV). These are usually spread via person-to-person contact or contaminated food and water. Respiratory infections caused by influenza viruses, rhinoviruses, coronaviruses, measles virus, varicella-zoster virus (VZV), and respiratory syncytial virus (RSV) are often spread by aerosol transmission, as well as person-to-person contact. Many of the herpes viruses target the skin or the mucosae, such as herpes simplex virus (HSV) and VZV. HSV, in particular, can infect the oral and genital mucosae, the eye, and skin through small cuts and abrasions. Other herpes viruses, such as Epstein-Barr virus (EBV) and cytomegalovirus (CMV), target mucosae. CMV can also spread vertically from mother to baby or rarely via blood transfusions. Human papillomavirus (HPV) targets skin and mucosae and causes warts and may transform cells, inducing cancers, such as cervical cancer. Some viruses, such as West Nile virus, Dengue virus, Semliki forest virus, and Zika virus, can enter through skin via insect vectors. HIV and hepatitis B virus (HBV) are commonly spread via sexual contact. HIV, HBV, and hepatitis C virus (HCV) can also infect humans by direct entry into the bloodstream via transfusions or contaminated needles.

Most human viruses replicate only in certain target tissues, this being mainly the consequence of viral receptor distribution. Many viruses use two receptors, such as the use of the CD4 coreceptor and the chemokine receptor CCR5 on T cells by HIV. After attachment to a cellular receptor, viruses may fuse with the cell membrane or be endocytosed and then gain entry into the cytoplasm or nucleus by fusing with the vesicular membrane (enveloped viruses, such as HSV and HIV), or translocate across the cell membrane or induce lysis of the endocytic vesicle once in the cytoplasm (nonenveloped viruses, such as Norwalk virus and poliovirus).[1] Viruses then utilize host cell machinery and specialized virally encoded proteins to replicate rapidly within the cell. Once they have multiplied within the cell, many viruses induce cytolysis to facilitate release of new infectious virions (*e.g.*, poxviruses, poliovirus, and herpes viruses). Other viruses are released from infected cells by budding through the cell membrane in the absence of cell death (*e.g.*, HIV and influenza virus). Having entered the body, however, viruses encounter numerous innate defenses and activate the components of adaptive immunity. The latter usually assures that clinical disease, if not infection, will not become evident. Successful exploitation of these defenses through the use of vaccines (Chapter 90) remains a central challenge for many human viruses, particularly those that cause chronic infections, such as HIV and HCV.[2]

INNATE IMMUNITY TO VIRUSES

Viral infection induces an extensive array of defense mechanisms in the host. Innate defenses come into play to block or inhibit

TABLE 25.1 Viral Infections and Immunity

Viral Event	Obstacles	Time Course
Transmission	Mechanical and chemical barriers	0
Infection and replication	Innate immunity	0 →
Infection stopped or spreads	Viral antigens transported to lymphoid tissues	Within 24 hours
Infection controlled	Specific antibodies and cell-mediated immunity	4–10 days
Sterile immunity	Immune memory	14 days to years
Viral persistence if infection not controlled	Immune disruption or evasion	Weeks to years

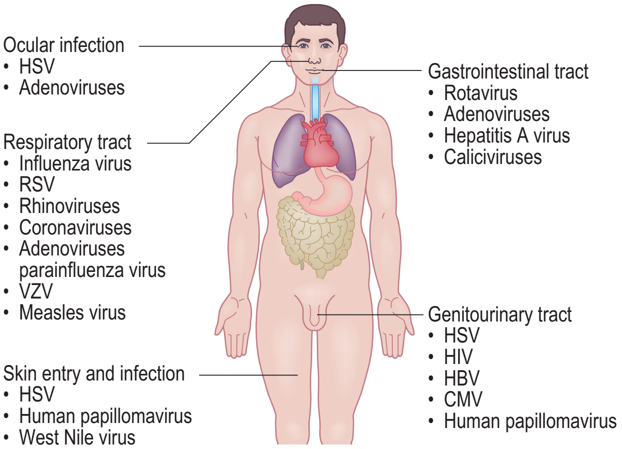

FIG 25.1 Common Routes of Entry and Infection for Human Viral Pathogens. CMV, cytomegalovirus; HBV, hepatitis B virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

TABLE 25.2 Sensors of Viral Infection

Toll-Like Receptors (TLRs)	
TLR3	dsRNA, MCMV, VSV, LCMV, HSV, EBV
TLR7 and TLR8	ssRNA, Influenza virus, HIV, VSV
TLR9	dsDNA, HSV, MCMV
TLR2	MV hemagglutinin protein, HSV, HCMV
TLR4	MMTV envelope protein, RSV
RIG-I-Like Helicases (RLHs)	
RIG-I	Influenza virus, VSV, HCV, JEV, MV, RSV, Sendai virus, EBV
MDA-5	Poly(I:C), MV, Sendai virus, VSV, MCMV, Picornaviruses
NOD-Like Receptors (NLRs)	
NLRP3	Influenza virus, Sendai virus, Adenovirus, Vaccinia virus
NOD2	Influenza virus, VSV, RSV
Other sensors	
AIM2	Vaccinia virus, MCMV
ZBP1 (DAI)	Cytosolic dsDNA, HSV
IFI16	Cytosolic dsDNA, HSV
cGAS	Cytosolic dsDNA, HSV

AIM2, absent in melanoma-2; IFI16, Gamma-interferon-inducible protein Ifi-16; cGAS, cyclic GMP-AMP Synthase; ZBP1, Z-DNA-binding protein 1; DAI, DNA-dependent activator of IFN; dsRNA, double-strand RNA; EBV, Epstein-Barr virus; HCMV, human cytomegalovirus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HSV, herpes simplex virus 1/2; JEV, Japanese encephalitis virus; LCMV, lymphocytic choriomeningitis virus; MCMV, murine cytomegalovirus; MDA-5, melanoma differentiation-associated gene; MMTV, mouse mammary tumor virus; MV, measles virus; NLR, NOD-like receptor; RLH, RIG-I-like helicase; RSV, respiratory syncytial virus; ssRNA, single-strand RNA; TLR, Toll-like receptor; VSV, vesicular stomatitis virus.

initial infection, to protect cells from infection, or to eliminate virus-infected cells. Innate mechanisms occur well before the effectors of adaptive immunity become active, but they are critical for the initiation of adaptive immunity via the elicitation of inflammation that promotes immune cell activation. The innate immune defenses are initiated via pattern recognition receptors (PRRs), which recognize pathogen-associated molecular patterns (PAMPs)[3] (Chapter 3). These include transmembrane receptors of the Toll-like receptor (TLR) family, two families of intracellular receptors including the NOD-like receptors (NLRs) and the RIG-I–like helicases (RLHs), as well as the sensor molecule absent in melanoma-2 (AIM2). Additionally, the molecules cyclic guanosine monophosphate–adenosine monophosphate (GMP-AMP) synthase (cGAS), DDX41, IFI16, and Z-DNA–binding protein 1 (ZBP1) can sense cytosolic DNA (Table 25.2). These cellular sensors promote the expression of interleukin-1 (IL-1) and IL-18, type I (α/β) interferon (IFN-I), and a variety of IFN-stimulated genes and inflammatory cytokines, and chemokines. TLRs are cell surface or endosomal membrane–bound proteins expressed by numerous cells, including dendritic cells (DCs), macrophages, lymphocytes, and parenchymal cells. Expression of TLRs is largely inducible in most cell types, although some (TLR7/8/9) are constitutively expressed at high levels by specialized plasmacytoid DCs for rapid IFN production. Different TLR molecules recognize specific viral products, such as single- and double-stranded RNA (TLR 3 and TLR7/8, respectively) or double-stranded DNA (TLR9).

The RLHs retinoic acid-inducible gene I (*RIG-I*) and melanoma differentiation-associated gene (*MDA-5*) mediate cytoplasmic recognition of viral nucleic acids. These activate mitochondrial antiviral signaling (MAVS) proteins to stimulate IFN-I production and activate inflammasomes, which are molecular complexes that facilitate the activation of caspases and induce the production of proinflammatory IL-1β and IL-18.[4] NLRs are a second class of cytosolic sensors of PAMPs that activate inflammasomes via the adapter protein ASC. These include the NLRP (or NALP), NOD, and IPAF/NAIP receptors. Three major inflammasomes have been shown to be involved in antiviral immunity: the NLRP3 inflammasome, the RIG-I inflammasome, and the AIM2 inflammasome.[3]

The innate defense system consists of multiple cellular components and many specialized proteins. The longest known and best-studied antiviral proteins are the α/β IFNs, which act by binding to the type I IFN receptor and result in the transcription of more than 100 IFN-stimulated genes. One consequence of this "antiviral state" is the inhibition of cell protein synthesis and the prevention of viral replication.[5] Multiple leukocyte subsets are involved in innate defense, including macrophages, DCs, neutrophils, natural killer (NK) cells, natural killer T cells (NKT cells), and γδT cells. Furthermore, tissue cells, including fibroblasts, epithelial cells, and endothelial cells, express PRRs and respond to viral infection via the production of innate cytokines, including IFN-I and IL-1. IFN-I is a critical link between the innate and adaptive immune system, via activation of DCs and T cells, as well as protecting T cells from NK cell-mediated attack.[6] IFN-Is can also activate NK cells and induce other cytokines that promote

KEY CONCEPTS

Major Antiviral Innate Defense Mechanisms

- Acting to block infection:
  - Natural antibodies
  - Complement components
  - Some cytokines and chemokines
- Acting to protect cells from infection:
  - Interferon-α/β
  - Interferon-γ (IL-γ)
  - IL-1, IL-18
- Acting to destroy or inhibit virus-infected cells:
  - Natural killer (NK) cells
  - Natural killer T cells (NKT cells)
  - Macrophages
  - Neutrophils
  - γδ T cells
  - Nitric oxide
- Involved in regulating antiviral inflammatory response:
  - ILs-1, 6, 10, 12, 18, 23, 33
  - Transforming growth factor (TGF)-β
  - Chemokines (CCL2, 3, 4, 5)

NK responses, such as IFN-γ and IL-12. NK cells produce proinflammatory cytokines; they can kill infected cells and interact with DCs, and are an important component of innate defense against viruses. NK cells can protect against some herpes viruses, which downregulate major histocompatibility complex (MHC) expression in the cells they infect. NK cells are also important in resistance to mouse and human CMV and possibly to HIV, influenza virus, and Ebola virus.[7] NK cells have also recently been shown to possess traits of adaptive immunity and, like T and B cells, can form populations of memory cells.[8] NK cells are regulated by an array of activating and inhibitory receptors, whose expression and function are just beginning to be understood. Uninfected cells are usually protected from NK cell cytolysis as they deliver negative signals, such as high expression of MHC molecules. In contrast, virus-infected cells are killed either because they deliver positive signals or because they lack adequate MHC-negative signals. NK cells may also control excessive immune responses to viruses by killing CD4$^+$ T cells and indirectly regulating cytotoxic T lymphocyte (CTL) responses. NKT cells may provide some antigen-specific innate immune protection against certain viruses, such as influenza virus.[9]
